The continuum limit of three-dimensional SU(2) lattice Yang–Mills theory on a torus

P. M. Aronow

Patrick Lopatto

AUTHORS' NOTE

With the exception of this note, the entire document is machine-written. We have taken care to supervise this writing to ensure that the proofs meet a minimum standard of readability and that previous literature is appropriately cited.

The manuscript began as an attempt to pursue the program of Magnen, Rivasseau, and Sénéor [132] using large language models. Our hope was that understanding the problem on the torus might offer some insight into the general case. The construction that resulted from this starting point is three-dimensional and lattice-based, and draws extensively on Bałaban's renormalization group methods.

As we were verifying these results, we learned that Sussman and Alpöge announced that YM4 has been done, following Bałaban's program (`https://github.com/ethanwsussman/Yang--Mills-LLM-experiment`). We are thrilled and look forward to learning more about these exciting developments. We hope that this manuscript nonetheless contributes to understanding constructive approaches to three-dimensional Yang–Mills theory. We did not inspect and, to the best of our knowledge, the LLMs we used did not access the ongoing work of Sussman and Alpöge.

Although we have done extensive machine auditing of these proofs, including adversarial passes with multiple models, the proof is too complex for either (i) Lean autoformalization given the authors' resources or (ii) our own understanding of the results. Thus we are less confident in correctness than we are in our other work. We welcome suggestions concerning mathematical corrections, omitted citations, and attribution of ideas.

ABSTRACT

We consider the Wilson lattice gauge measure for SU(2) on a periodic three-dimensional torus of fixed size, with bare coupling $g^2 = g_3^2 a$ proportional to the lattice spacing a, as dictated by the superrenormalizability of three-dimensional Yang–Mills theory. Observables are Wilson loops of the lattice configuration evolved by the Wilson flow, the lattice gradient flow of the Wilson action, at positive flow time. We prove that, at every fixed value of the coupling, the joint laws of finitely many flowed Wilson loops converge as the lattice spacing tends to zero along the sequences of lattice sides nM^k, for fixed odd $M \geq 3$ and fixed positive n divisible by four. For each such refinement class, the limits are realized by a unique probability measure on the space of gauge orbits of Yang–Mills heat-flow trajectories at positive times, a version of the state space introduced by Cao and Chatterjee. Under this measure the energy at positive times is tight, and the measure is invariant under the lattice symmetries and the center symmetries. We also show that, at short distances, the rescaled deficits $(1 - W)/(g_3^2 \varepsilon)$ of the normalized fundamental Wilson loops W of loops $x + \varepsilon \ell$, flowed for time $\sigma \varepsilon^2$ with fixed $\sigma > 0$, converge to explicit quadratic functions of the heat-smoothed Gaussian free field. As the coupling tends to zero, the measure concentrates on flat connections, with Gaussian fluctuations of explicit covariance near regular commuting holonomies and fluctuations governed by the constant-mode quartic form near the central holonomies. The proof is a multiscale renormalization group analysis in the tradition of Bałaban, carried out on a small-field event whose complement we show to have small probability, uniformly in the lattice spacing, using reflection positivity and chessboard estimates. It is combined with stochastic estimates for the lattice heat flow and a deterministic analysis of the Wilson flow for rough initial data.

PART I

Introduction

SECTION 1

Introduction

1.1 Yang–Mills theory and its lattice formulation

Yang and Mills introduced non-Abelian gauge theories in 1954 [156]. In the Euclidean formulation of the quantum theory, one would like to define a probability measure on connections A on a three- or four-dimensional manifold, formally given by

$$d\mu(A) = Z^{-1} \exp\Big(-\frac{1}{2g^2} \int |F_A|^2 \, dx\Big) \, \mathcal{D}A. \tag{1.1}$$

Here F_A is the curvature of A, g is the coupling constant, and $\mathcal{D}A$ stands for a Lebesgue measure on the infinite-dimensional space of connections, which does not exist. The measure should be invariant under gauge transformations, so it is really a measure on gauge orbits. The natural observables are gauge-invariant functions, such as traces of holonomies around closed loops, which are called Wilson loops.

Wilson's lattice regularization [153] replaces the connection by variables U_e in the gauge group, one for each link e of a lattice with mesh a. The action becomes the sum of $1 - \operatorname{tr} U_p/2$ over the plaquettes p of the lattice, where U_p is the product of the link variables around p. For every $a > 0$ this defines a probability measure that is exactly invariant under lattice gauge transformations. Osterwalder and Seiler established reflection positivity and other basic properties of these measures [134]; see also Seiler's monograph [141]. The central problem is to remove the regularization: one must show that suitable observables have limits as $a \to 0$, with the bare coupling tuned appropriately, and describe the limit. In four dimensions this is part of the problem described by Jaffe and Witten [114]; see [77] for a recent review by Douglas.

In this paper we consider the gauge group $\mathrm{SU}(2)$ in three dimensions, on a periodic torus $\mathbb{T}^3_L = (\mathbb{R}/L\mathbb{Z})^3$ of fixed side L. In three dimensions the coupling g_3^2 in (1.1) has the dimension of inverse length. The dimensionless strength of the interaction at length scale ε is $g_3^2\varepsilon$. In the sense of power counting, the theory becomes weakly coupled at short distances; it is superrenormalizable. The bare lattice coupling at mesh a is $g^2 = g_3^2 a$. With $N = L/a$ lattice sites along each side, this means that

$$g_N^2 = \frac{\gamma}{N}, \qquad \gamma = g_3^2 L, \tag{1.2}$$

where the dimensionless number γ is the coupling measured in units of the size of the torus.

Three-dimensional Yang–Mills theory is of independent physical interest. It describes the magnetic sector of four-dimensional gauge theory at high temperature and long distances; see Ginsparg [98] and Appelquist and Pisarski [5], and also Linde [126] and Jackiw and Templeton [113] on the infrared problems of its perturbative treatment. It is also expected to have a mass gap and to confine. Feynman gave qualitative arguments for both [88]. Karabali, Kim, and Nair developed a gauge-invariant Hamiltonian analysis of the gap and an approximate prediction of the string tension [115, 116], and Teper computed the spectrum and string tensions numerically, with continuum extrapolations [150]. Our results concern only the ultraviolet problem in a fixed finite volume.

Even in three dimensions, the ultraviolet problem is not only a question of bounds. In the Gaussian (Maxwell) approximation to (1.1), after gauge fixing and with the constant modes treated separately, a connection in three dimensions is a random distribution of Hölder–Besov regularity α for every $\alpha < -1/2$, and no better. Holonomies along general fixed loops then require an additional regularization [42, 43]. A convenient way to obtain gauge-invariant observables with limits is to smooth the field first. The gradient flow of the Yang–Mills action, $\partial_t A = -D_A^* F_A$, smooths connections at length scale $\sqrt{t}$ and commutes with gauge transformations. Its lattice version is the gradient flow of the Wilson action. Narayanan and Neuberger studied continuum limits of smeared Wilson loops numerically [133], and Lüscher developed this lattice flow systematically under the name Wilson flow [128, 129]. In [131], Lüscher and Weisz showed that in four dimensions the correlation functions of the flowed field are finite to all orders in renormalized perturbation theory. Wilson loops of the flowed field at positive flow time are bounded gauge-invariant functions of the lattice configuration, and we use them as our observables.

The geometric study of Yang–Mills connections and their flow has a long history, including work of Atiyah and Bott [6] and Donaldson [75, 76]. In three dimensions, global existence and regularity for smooth initial data are due to Råde [139]. Charalambous and Gross developed the flow for rough initial data and proposed it as a way to define gauge fields [47–49, 105]. In [43], Cao and Chatterjee made this proposal precise. They defined a state space for three-dimensional Yang–Mills theory, consisting of gauge orbits of trajectories of the Yang–Mills heat flow at positive times. They showed that it carries a natural topology in which Wilson loops of the flowed field are continuous, and they gave a tightness criterion for measures on it. Their arguments rest on Uhlenbeck's compactness theorem [151] and on Sengupta's result that holonomies separate gauge orbits [144]. In [42] they also proved local existence of the flow in the DeTurck gauge for a class of random distributional initial data that includes the Gaussian free field. Their decomposition into a rough linear part and a smoother nonlinear part follows the random-data method of Bourgain [32] and of Da Prato and Debussche [63]. The construction of a Yang–Mills measure on this state space from the lattice theory was left open. Our main result is such

a construction.

1.2 Previous rigorous results

We summarize the rigorous results most closely related to ours. The literature is large, and Chatterjee's survey [51] gives an overview from the point of view of probability.

Abelian theories, Higgs models, and two dimensions. In [104], Gross proved that three-dimensional pure $U(1)$ lattice gauge theory converges to the free electromagnetic field, for the Villain action and, in the electric sector, for the Wilson action. Brydges, Fröhlich, and Seiler constructed the Abelian Higgs model in two dimensions [36, 37, 40, 41]. King constructed the Abelian Higgs model in two and three dimensions by proving convergence of effective actions [117, 118]. Chatterjee constructed a Gaussian scaling limit of $\mathrm{SU}(2)$ lattice Yang–Mills theory coupled to a fixed-length Higgs field in the fundamental representation, in every dimension $d \geq 2$ [53]. The result uses unitary gauge, sends the Higgs length to infinity and the gauge coupling to zero rapidly, and yields independent massive Proca fields; it concerns a different scaling regime from the pure gauge theory considered here. In two dimensions, Yang–Mills theory is exactly solvable. Gross, King, and Sengupta [106] and Driver [78] gave probabilistic constructions in the plane, and Driver proved that the lattice Wilson loop expectations converge. Sengupta [142, 143, 145] and Lévy [124, 125] treated compact surfaces, and Fine gave a different geometric approach [89, 90]. In [154], Witten related the weak-coupling limit on surfaces to volumes of moduli spaces of flat connections. In [55], Chevyrev realized the two-dimensional measure on the torus as a random distributional connection.

The renormalization group for lattice gauge theories. Bałaban developed a renormalization group method for lattice gauge theories in a long series of papers. He proved estimates for lattice Green's functions and propagators [9–11, 13], introduced a gauge-covariant averaging operation for group-valued fields [12], and analyzed regular configurations and the variational problem that defines the background field [14, 16]. The culmination is ultraviolet stability on a fixed torus: bounds on renormalized effective densities and suitably normalized partition functions that are uniform in the lattice spacing. He proved it in three dimensions in [15], and the later papers on effective actions and large fields developed the four-dimensional program [17, 19–21]. His treatment of the complete effective densities also gave convergent renormalization expansions for superrenormalizable gauge models [18]. Bałaban, Imbrie, and Jaffe explained the exact renormalization group for gauge theories and treated Higgs models [22–25]. Federbush developed a different phase-cell approach to the stability problem [81–86]. Ultraviolet stability is a statement about bounds, and it does not by itself give convergence of observables or a limiting measure.

In [132], Magnen, Rivasseau, and Sénéor developed a constructive analysis of the Schwinger functions of four-dimensional pure $\mathrm{SU}(2)$ Yang–Mills theory with a fixed infrared cutoff, in the trivial topological sector. They work in a regularized axial gauge, with counterterms that restore gauge invariance, and they prove large-field estimates and nonperturbative Slavnov identities. Dimock gave a detailed exposition of Bałaban's method for the scalar ϕ^4_3 model [67–69], and applied related ideas to gauge fixing and to quantum electrodynamics in three dimensions [70–73]. More broadly, our methods descend from the block-spin renormalization group of Gawędzki and Kupiainen [94, 95, 97]. They also use the cluster expansion methods described by Glimm and Jaffe [99], Brydges [38, 39], and Rivasseau [140]. More specifically, we use the convergence criterion of Kotecký and Preiss [120] and the tree estimates going back to Penrose, as explained by Fernández and Procacci [87] and recorded in the graph estimate of Dimock [68].

Stochastic quantization. A different approach constructs the Yang–Mills measure as the invariant measure of a Langevin dynamics. This idea goes back to Parisi and Wu [135], with the gauge-fixing term introduced by Zwanziger [157]. Using regularity structures [107], Chandra, Chevyrev, Hairer, and Shen constructed a gauge-covariant Langevin dynamics and a state space of gauge orbits in two dimensions [45]. They also constructed local-in-time dynamics for the Yang–Mills–Higgs model in three dimensions [46]. Chevyrev and Shen proved that the Yang–Mills measure on the trivial bundle over the two-dimensional torus is invariant for this dynamics [57]. They also proved that the mass renormalization of the Yang–Mills field that yields gauge-covariant solutions of the stochastic three-dimensional Yang–Mills–Higgs equations is unique [58]. Bringmann and Cao gave a paracontrolled approach in two dimensions [35]. For the non-Abelian theory in three dimensions, these results give local dynamics, and they do not yet construct an invariant measure. For the Abelian theory, Chevyrev, Qu, and Shen proved convergence of gauge-fixed three-dimensional lattice Langevin dynamics to the one-form stochastic heat equation for a class of plaquette actions including Wilson, Manton, and Villain actions, under assumptions on the initial data [59]. We refer to Chevyrev's survey [56] for more on this approach.

Lattice estimates. Many recent results concern lattice gauge theories at a fixed lattice spacing, for instance at strong coupling or large rank [2, 26, 44, 52, 54, 146]. Closer to the present work are results on the free energy and on bounds that are uniform in the lattice spacing. In [50], Chatterjee identified the leading term of the $U(N)$ lattice Yang–Mills free energy, and in [34], Brennecke computed its Maxwell constant. Faria da Veiga and O'Carroll proved stability bounds and bounds for generating functions of scaled plaquette fields [64, 65]. These results control the normalization and local plaquette observables. They do not identify the continuum laws of macroscopic flowed Wilson loops, and asymptotics of the free energy that are extensive in the volume do not

by themselves control normalized observables.

1.3 Main results

We now describe our results informally; the precise statements are in Section 2. Let $\mu_{N,\gamma}$ denote the Wilson measure for $\mathrm{SU}(2)$ on the periodic lattice in $\mathbb{T}_L^3$ with N^3 sites and mesh $a_N = L/N$, with the coupling (1.2). For a configuration U and a physical time $t > 0$, we write $U(t)$ for the Wilson flow of U run for the lattice time $4t/a_N^2$; with this normalization, $U(t)$ approximates the continuum Yang–Mills heat flow at time t. Let ℓ be a piecewise C^1 closed loop in $\mathbb{T}_L^3$, and let ℓ_N be a lattice approximation of ℓ of bounded length, in the sense of Definition 2.1. The flowed Wilson loop is $\operatorname{tr} \mathrm{Hol}_{\ell_N} U(t)/2$, the normalized trace of the product of the flowed link variables along ℓ_N.

We fix an odd integer $M \geq 3$ and an integer n divisible by four, and consider the lattice sides $N_k = nM^k$ for $k \geq 0$. The restriction to such sequences comes from the renormalization group, which divides the lattice into blocks of side M.

- *Existence of the continuum limit* (Theorem 2.3). Fix $L > 0$ and $\gamma > 0$. Consider finitely many flowed Wilson loops, for arbitrary piecewise C^1 loops, characters of $\mathrm{SU}(2)$, and positive flow times. As $k \to \infty$, their joint laws under $\mu_{N_k,\gamma}$ converge, for every choice of admissible lattice approximations, and the limits do not depend on this choice. All these limits are realized by a single probability measure λ on the space $\mathcal{X}_L$ of gauge orbits of Yang–Mills heat-flow trajectories at positive times. That is, the limiting law of each finite family of flowed Wilson loops is the law of the corresponding continuum holonomies under λ. The energy at each positive flow time is tight. The measure λ depends only on L, γ, and the class of n under multiplication by powers of M, and it is invariant under translations, rotations, and reflections of the lattice, and under the center symmetries.
- *A bound on large fields that is uniform in the coupling* (Theorem 2.7). We carry out the renormalization group analysis on a small-field event, an explicit set of configurations that are close to a gauge transform of the identity at every scale of a multiscale decomposition. Let u be the side of the coarsest lattice in the decomposition. We prove that the complement of the event has probability at most $Cu^3 \exp(-cu/\gamma)$, plus a term of order $u^3 \exp(-c \log^2(u/\gamma))$. The bound is uniform in the number of renormalization group steps and in γ below any fixed ceiling.
- *Short distances* (Theorem 2.8). Fix a smooth loop ℓ in $\mathbb{R}^3$ and $\sigma > 0$, and let W be the flowed Wilson loop of the loop $x + \varepsilon\ell$ at flow time $\sigma\varepsilon^2$. As $\varepsilon \to 0$, the normalized deficit $(1 - W)/(g_3^2 \varepsilon)$ converges in law to $|C|^2/8$, where C is an explicit Gaussian vector given by the free field. This holds at every fixed coupling and uniformly in the position of the loop. Jointly for finitely many fixed loop shapes, the limit is a quadratic function of a Gaussian vector, and it is asymptotically independent of every fixed

bounded measurable function on $\mathcal{X}_L$. This makes precise, for flowed Wilson loops, the statement that the theory is weakly coupled at short distances. In three dimensions this is a consequence of superrenormalizability, rather than of the logarithmic running of the coupling found in four dimensions by Gross and Wilczek [102] and Politzer [137].

- *Weak coupling* (Theorems 2.9 to 2.11). As $\gamma \to 0$, every subsequential limit of the measures λ_γ is supported on stationary flat connections. In particular, the holonomies (H_1, H_2, H_3) around the three coordinate cycles concentrate on commuting triples. On compact regular patches near the identity, the four normal components of the logarithms of the flowed holonomies have asymptotically Gaussian fluctuations of size $\sqrt{\gamma}$, with an explicit covariance, in a sense made precise in Theorem 2.10. At the central triples the flat connections are singular, and the logarithms of the holonomies live on the scale $\gamma^{1/4}$. Ratios of expectations of compactly supported invariant functions of the rescaled logarithms converge to the corresponding ratios of integrals against $e^{-Q(Y)}\,dY$, where $Q(Y) = \sum_{i<j} |y_i \times y_j|^2/2$ is the constant-mode quartic form. The error is $O(\gamma^{1/4})$ for Lipschitz test functions. The measure $e^{-Q(Y)}\,dY$ has infinite total mass, so this is not a statement about a limiting probability measure. In both regimes we obtain explicit statistics that distinguish λ_γ from specific Gaussian and Abelian reference measures; the leading coefficient in the regular regime is itself the coefficient of the Gaussian approximation around a regular flat connection.

Section 2 also contains further results, including continuity of λ in γ, with convergence that is uniform on compact sets of couplings, and exact scaling in L. We also prove convergence of the energy and loop processes on compact intervals of positive times, and convergence in the Sobolev topology of Cao and Chatterjee. Finally, for $0 < \gamma \le 1$ and along the subsequences of Remark 2.4, the limit does not change when the Wilson flow is replaced by the gradient flow of $\sum_p [q(U_p) + c\, q(U_p)^2]$, uniformly for c in a fixed bounded interval of nonnegative numbers.

We emphasize that the main theorem holds at every fixed coupling $\gamma > 0$, not only at small coupling. This reflects superrenormalizability: at lattice side u the effective coupling is γ/u, so we can run the renormalization group from the finest lattice down to a coarse lattice whose side u is large compared to γ, where the field is still weakly coupled. By the large-field bound, the probability discarded by this procedure tends to zero as $u \to \infty$, uniformly in the lattice spacing. The results on weak coupling concern the opposite limit, $\gamma \to 0$ at fixed u, taken after the continuum limit.

1.4 Relation to previous work

Compared to Bałaban's three-dimensional theorem [15], which bounds renormalized effective densities and suitably normalized partition functions uniformly in the cutoff, our

main theorem identifies the limits of normalized observables and constructs a limiting measure. Our proof follows Bałaban's general strategy. We use several of his constructions: the averaging operation, the background field obtained by minimizing the action subject to block constraints, and estimates for the associated propagators. However, we organize the analysis differently. Bałaban decomposes the configurations into small-field and large-field regions at every scale. Instead, we condition on a single small-field event. We bound the probability of its complement directly under the Wilson measure, using the reflection positivity of Osterwalder and Seiler [134] and the chessboard estimates of Fröhlich, Israel, Lieb, and Simon [92, 93], in the form given by Biskup [29]. Large fields enter only in this probability estimate, whose proof uses a localized version of the renormalization group. Beyond stability, we also need convergence of the conditioned measures at every fixed number of renormalization group steps. Further, we need estimates for the reconstruction of the fine field from the coarse fields, which control the flowed observables. The localization and fluctuation estimates adapt Combes–Thomas localization [61], the Brascamp–Lieb inequality [33], the Bakry–Émery criterion [8], the Helffer–Sjöstrand representation of covariances [110], and the Herbst argument as described by Ledoux [123]. The quadratic fluctuation bounds are of Hanson–Wright type [108], in the form of Adamczak [1], and the maximal estimates use chaining [74, 79].

Compared to the work of Magnen, Rivasseau, and Sénéor [132], our setting is three-dimensional and superrenormalizable. They work in four dimensions, with gauge-fixed Schwinger functions, a fixed infrared cutoff, the trivial topological sector, and counterterms that restore gauge invariance. We work with the Wilson lattice measure without counterterms, and our observables are gauge-invariant flowed Wilson loops. Cao and Chatterjee [43] constructed the state space and proved conditional tightness results; we construct a measure on a version of their state space from the lattice theory. We use their deterministic results on the flow and on the topology of the state space, but not their results for random initial data. The stochastic quantization approach gives local dynamics in three dimensions for the Yang–Mills–Higgs model, including the pure gauge case [46, 58]. We construct an equilibrium measure for the pure gauge theory and prove nothing about dynamics. Gross's three-dimensional Abelian result [104] and King's construction of the Abelian Higgs model [117, 118] are earlier continuum limits of three-dimensional lattice gauge theories; our result concerns a non-Abelian theory.

Our weak-coupling theorems are related to the analysis of Yang–Mills theory on a small torus. The center symmetries fit into the framework of electric and magnetic flux of 't Hooft [149]; we divide out strictly periodic gauge transformations, treat the center operations as symmetries, and include no twist. In the Hamiltonian formulation of the four-dimensional theory on a small spatial torus, Lüscher [127], Lüscher and Münster [130], and Koller and van Baal [119] showed that the constant modes must be treated nonperturbatively. The leading classical interaction of the constant modes is quartic at

the trivial flat connection, and integrating out the other modes adds further terms to the effective Hamiltonian; see van Baal's review [152]. Near regular flat connections our analysis is a version of Laplace's method around a nondegenerate critical manifold, in the sense of Bott [31]. González-Arroyo, Jurkiewicz, and Korthals Altes [101], and Coste and these authors [62], studied the zero-momentum modes of the Euclidean lattice theory in a finite box. In this literature the periodic flat connections are often called torons [100]. Fodor and collaborators combined an exact treatment of the constant modes with perturbation theory for gradient-flow observables on the four-dimensional torus [91]. The integral of e^{-Q} over the constant modes is the bosonic Yang–Mills integral of three matrices, studied by Krauth, Nicolai, and Staudacher [122], by Krauth and Staudacher [121], and by Austing and Wheater [7]. For $\mathrm{SU}(2)$ and three matrices it diverges, and for this reason our theorem at the central triples is stated for compactly supported test functions. Our weak-coupling theorems give rigorous versions of these pictures for the measure we construct, at positive flow time and in the order of limits described above.

1.5 Scope

We record what we do not prove. The limit is taken along the sequences $N_k = nM^k$. We do not compare the limits for different classes of n or different M; we expect, but do not prove, that λ does not depend on these choices. The torus is fixed: we do not take the infinite-volume limit, and we prove nothing about a mass gap or confinement. The observables are flowed Wilson loops at positive flow time. We do not construct a random distributional connection at time zero, and we do not prove reflection positivity of the limit or the Osterwalder–Schrader axioms. We do not give a rate of convergence in the lattice spacing. The large-field bound and the weak-coupling results are uniform in γ below fixed ceilings. The convergence in the main theorem, however, is not shown to be uniform as $\gamma \to 0$ or as $\gamma \to \infty$.

1.6 Organization

Section 2 states our results precisely, and Section 3 gives a detailed outline of the proof. Section 4 collects notation and conventions. The proof occupies the remaining sections, grouped into parts. Part II contains finite-dimensional tools: integration over $\mathrm{SU}(2)$, the block averaging map, reflection positivity, gauge fixing, and the linearized theory. Part III constructs the background fields. Part IV constructs the renormalization group transformation on the small-field event, and proves convergence at each fixed resolution. Part V estimates the reconstruction of the fine field. Part VI proves the bound on large fields. Part VII studies the lattice and continuum gradient flows, and Part VIII proves the stochastic estimates for the flowed field. Part IX constructs the limiting measure and

proves the main theorem. Parts X and XI prove the results on short distances and on weak coupling.

SECTION 2

Statement of results

This section states our results precisely. Section 2.1 defines the lattice model, the Wilson flow, and the lattice approximations of loops, and Section 2.2 defines the space on which the limiting measure lives. The main theorem is stated in Section 2.3, and further properties of the limit in Section 2.4. Section 2.5 states the bound on large fields that underlies the proof. The results on short distances and on weak coupling are in Sections 2.6 and 2.7.

2.1 The lattice model

Fix a side length $L > 0$ and an integer $N \geq 4$, and let $a_N = L/N$. Let $\Lambda_N = a_N\mathbb{Z}^3/L\mathbb{Z}^3$ be the periodic cubic lattice of mesh a_N in the torus $\mathbb{T}^3_L = \mathbb{R}^3/L\mathbb{Z}^3$. A positive link is a pair $(x, x + a_N e_i)$ with $x \in \Lambda_N$ and $i \in \{1,2,3\}$, and a positive plaquette is the positively oriented boundary of the square spanned by $a_N e_i$ and $a_N e_j$ at x, with $i < j$. Let $\mathcal{E}_N$ and $\mathcal{P}_N$ denote the sets of positive links and positive plaquettes; each has $3N^3$ elements. A configuration is an element $U = (U_e)_{e\in\mathcal{E}_N}$ of $\mathcal{U}_N = \mathrm{SU}(2)^{\mathcal{E}_N}$. For the reversed link we set $U_{\bar{e}} = U_e^{-1}$, and for a path $e_1 \cdots e_m$ in the lattice we write $U_{e_1} \cdots U_{e_m}$ for the transport along it. For a plaquette p, U_p is the transport around its boundary.

Let H be the Haar probability measure on $\mathrm{SU}(2)$, and let H_N be the product of copies of H over $\mathcal{E}_N$. Set

$$q(U) = 1 - \tfrac{1}{2}\operatorname{tr} U, \qquad U \in \mathrm{SU}(2).$$

For $\gamma > 0$ we define the Wilson measure

$$d\mu_{N,\gamma}(U) = \frac{1}{Z_{N,\gamma}} \exp\Big(-\frac{4N}{\gamma} \sum_{p\in\mathcal{P}_N} q(U_p)\Big)\, dH_N(U), \tag{2.1}$$

where $Z_{N,\gamma}$ is the normalizing constant. In the usual notation the inverse coupling is $\beta = 4/g_N^2$ with $g_N^2 = \gamma/N$, as in (1.2). A lattice gauge transformation $k \in \mathrm{SU}(2)^{\Lambda_N}$ acts by $(U^k)_{(x,y)} = k_x U_{(x,y)} k_y^{-1}$, and $\mu_{N,\gamma}$ is invariant under this action.

We write $\mathfrak{su}(2)$ for the Lie algebra of $\mathrm{SU}(2)$, with the inner product $\langle X, Y\rangle = -2\operatorname{tr}(XY)$ and norm $|X| = \langle X, X\rangle^{1/2}$. With this normalization $q(e^X) = |X|^2/8 + O(|X|^4)$. On $\mathcal{U}_N$ we use the product of the corresponding bi-invariant Riemannian metrics.

The Wilson flow. Let Φ^{W}_s be the flow on $\mathcal{U}_N$ of the vector field $-\nabla \sum_{p\in\mathcal{P}_N} q(U_p)$, the negative gradient of the Wilson action. It is defined for all $s \geq 0$ and commutes with lattice gauge transformations. For a physical time $t \geq 0$ we write

$$\Psi^{(N)}_t = \Phi^{\mathrm{W}}_{4t/a_N^2},$$

and call $\Psi^{(N)}_t U$ the flowed configuration at time t. We choose the factor $4t/a_N^2$ so that $\Psi^{(N)}_t U$ approximates the Yang–Mills heat flow at time t: if $U_e = \exp(a_N A(x)\cdot e_i)$ for a smooth connection A, then $\Psi^{(N)}_t U$ approximates the heat flow of A; see Section 24. This is the flow introduced by Lüscher [128], with time measured in physical units. We also use the lattice energy

$$\mathsf{E}_{a_N}(U) = \frac{8}{a_N} \sum_{p\in\mathcal{P}_N} q(U_p), \tag{2.2}$$

which is nonincreasing along the flow and approximates the continuum energy (2.3) below.

Lattice approximations of loops. A loop is a piecewise C^1 map $\ell : [0,1] \to \mathbb{T}^3_L$ with $\ell(0) = \ell(1)$. We approximate loops by closed paths in the lattice in the following sense.

Definition 2.1. Let ℓ be a loop, and let $(N_k)_{k\geq 0}$ be an increasing sequence of lattice sides. A sequence $(\ell_k)_{k\geq 0}$ of closed lattice paths, with ℓ_k in Λ_{N_k}, is an *admissible approximation* of ℓ if the physical lengths of the ℓ_k are bounded, and if for all sufficiently large k there exists a piecewise C^1 based homotopy between ℓ_k and ℓ (together with a path joining their base points, if these differ) whose swept area, counted with absolute value, tends to zero as $k \to \infty$.

Every loop has an admissible approximation (Lemma 29.10), and a sequence of lattice paths of bounded length that converges uniformly to ℓ, after reparametrization, is an admissible approximation of ℓ (Theorem 29.23). For a closed lattice path ℓ_k with base point x we write $\mathrm{Hol}_{\ell_k} U \in \mathrm{SU}(2)$ for the transport along ℓ_k; it changes by conjugation under gauge transformations, so $\chi(\mathrm{Hol}_{\ell_k} U)$ is gauge invariant for every character χ of a finite-dimensional representation of $\mathrm{SU}(2)$. The basic observables of this paper are the flowed Wilson loops

$$\chi\big(\mathrm{Hol}_{\ell_k} \Psi^{(N_k)}_t U\big), \qquad t > 0.$$

2.2 The trajectory space

Let $\mathcal{A}_L = C^\infty(\mathbb{T}^3_L; \mathfrak{su}(2)^3)$ be the space of smooth connections on the trivial bundle over $\mathbb{T}^3_L$, and let $\mathcal{G}_L = C^\infty(\mathbb{T}^3_L; \mathrm{SU}(2))$ act by $A^k = kAk^{-1} - (dk)k^{-1}$. For $A \in \mathcal{A}_L$ we write

$F_{ij} = \partial_i A_j - \partial_j A_i + [A_i, A_j]$ and

$$E_L(A) = \sum_{i<j} \int_{\mathbb{T}^3_L} |F_{ij}(x)|^2 \, dx \tag{2.3}$$

for the Yang–Mills energy; with this normalization the exponent in (2.1) approaches $E_L/(2g_3^2)$ for smooth configurations. The Yang–Mills heat flow $\partial_t A_i = \sum_j D_j F_{ji}$, with $D_j = \partial_j + [A_j, \cdot]$, has a global smooth solution for every smooth initial datum on $\mathbb{T}^3_L$, and it induces a semigroup $(\Phi_t)_{t\geq 0}$ on the orbit space $\mathcal{A}_L/\mathcal{G}_L$ (Råde [139]; see Section 24). Following Charalambous and Gross [47] and Cao and Chatterjee [43], we consider trajectories of this flow at positive times.

Definition 2.2. The trajectory space is

$$\mathcal{X}_L = \big\{ X : (0,\infty) \to \mathcal{A}_L/\mathcal{G}_L : \ X(t) = \Phi_{t-s} X(s) \text{ for all } 0 < s < t \big\}.$$

For a loop ℓ, a character χ, and $t > 0$, let $W_{\ell,\chi,t}(X) = \chi(\mathrm{Hol}_\ell\, X(t))$, where Hol_ℓ is the holonomy of any representative of $X(t)$ along ℓ. The Wilson topology $\mathcal{T}_W$ on $\mathcal{X}_L$ is the weakest topology for which all the functions $W_{\ell,\chi,t}$ are continuous.

The space $\mathcal{X}_L$ is a version of the state space of Cao and Chatterjee [43]. In Theorem 29.3 we choose a countable family $(\ell_j, t_j)_{j\geq 1}$ of loops and positive times and set $w_j(X) = \mathrm{tr}\,\mathrm{Hol}_{\ell_j} X(t_j)/2$. We show that

$$d_c(X,Y) = \sum_{j\geq 1} 2^{-j} |w_j(X) - w_j(Y)|$$

is a metric on $\mathcal{X}_L$ whose topology is coarser than $\mathcal{T}_W$, that both topologies are separable and have the same Borel σ-algebra, and that a Borel probability measure on $\mathcal{X}_L$ is determined by the joint laws of finitely many of the w_j. For this reason we call the w_j determining coordinates. The energy $X \mapsto E_L(X(t))$ is a Borel function for every $t > 0$. For every sequence $(R_j)_{j\geq 1}$ of finite nonnegative numbers, the set $\{X : E_L(X(L^2 2^{-j})) \leq R_j \text{ for all } j \geq 1\}$ is compact for both topologies (Theorem 29.6).

2.3 The main theorem

Fix an odd integer $M \geq 3$. For integers $n, n' \geq 1$ we write $n \sim_M n'$ if $nM^a = n'M^b$ for some integers $a, b \geq 0$, and $[n]_M$ for the equivalence class of n.

Theorem 2.3. *Fix $L > 0$, $\gamma > 0$, an odd integer $M \geq 3$, and a positive integer n divisible by four. Set $N_k = nM^k$ and $\mu_k = \mu_{N_k,\gamma}$. Then the following statements hold.*

1. *Let $\ell_1, \dots, \ell_m$ be loops, $\chi_1, \dots, \chi_m$ characters of finite-dimensional representations of $\mathrm{SU}(2)$, and $t_1, \dots, t_m > 0$, and for each i let $(\ell_{i,k})_{k\geq 0}$ be an admissible approximation of ℓ_i. Then the law under μ_k of the random vector*

$$\Big(\chi_i\big(\mathrm{Hol}_{\ell_{i,k}} \Psi_{t_i}^{(N_k)} U\big)\Big)_{i=1}^{m} \tag{2.4}$$

   converges as $k \to \infty$, and the limit does not depend on the choice of admissible approximations. For every $R > 0$, the expectations of $\exp\big(\sum_i z_i \chi_i(\mathrm{Hol}_{\ell_{i,k}} \Psi_{t_i}^{(N_k)} U)\big)$ converge uniformly in $z \in \mathbb{C}^m$ with $\sum_i |z_i| \leq R$.
2. *There exists a unique Borel probability measure $\lambda = \lambda_{L,\gamma,[n]_M}$ on $\mathcal{X}_L$ such that, for every choice of data as in (1), the limit law of (2.4) is the law of $(W_{\ell_i,\chi_i,t_i})_{i=1}^m$ under λ.*
3. *There exist Borel maps $\pi_k : \mathcal{U}_{N_k} \to \mathcal{X}_L$, invariant under all lattice gauge transformations, such that the measures $(\pi_k)_\# \mu_k$ converge to λ against every bounded $\mathcal{T}_W$-continuous function and weakly with respect to d_c, and such that*

$$\lim_{k\to\infty} \mathbb{E}_{\mu_k} \big| w_j(\pi_k U) - \tfrac{1}{2} \operatorname{tr} \mathrm{Hol}_{\ell_{j,k}} \Psi_{t_j}^{(N_k)} U \big| = 0$$

   for every $j \geq 1$, where $(\ell_{j,k})_k$ is a fixed admissible approximation of ℓ_j.
4. *The energies are tight at positive times: for every $t > 0$,*

$$\lim_{R\to\infty} \sup_{k\geq 0} \mu_k\big(E_L((\pi_k U)(t)) > R\big) = 0.$$

5. *The measure λ depends only on L, γ, and the class $[n]_M$; in particular it does not depend on the auxiliary parameters used in its construction.*

The proof is completed in Theorem 29.28. The maps π_k do not preserve holonomies exactly: they are measurable selections of smooth trajectories whose Wilson loops approximate the flowed lattice Wilson loops, and we construct them in Theorem 29.19. Their role is to realize all limits on one probability space. Part (2) and the determining property of the coordinates w_j show that λ is characterized by the limits in part (1).

Remark 2.4. The proof first establishes the theorem along the subsequences $N_K = n_* B^K$ with $B = M^J$, for a fixed integer J chosen at the start, and for n_* larger than a threshold depending on γ; see Theorem 29.24. For every finite Γ, the parameters of the construction, including J and the threshold, can be chosen before $\gamma \in (0, \Gamma]$ is fixed. This uniformity is used in the results on weak coupling. The extension to the full sequence nM^k and to every n uses two consecutive values of J and the fact that the corresponding sequences of lattice sides share infinitely many terms.

2.4 Further properties of the limit

The following theorem collects further properties of the limit. For $0 < \tau < T$ we consider the lattice energy (2.2) and the flowed Wilson loops as continuous functions of the flow time.

Theorem 2.5. *Assume the hypotheses of Theorem 2.3, and let $\lambda = \lambda_{L,\gamma,[n]_M}$.*

1. *(Energy and loop processes.) Let $0 < \tau < T < \infty$, and let ℓ_i, χ_i, and $(\ell_{i,k})_k$, $1 \le i \le m$, be as in Theorem 2.3. Under μ_k, the processes*

$$t \mapsto \Big(\mathsf{E}_{a_{N_k}}(\Psi_t^{(N_k)} U),\ (\chi_i(\mathrm{Hol}_{\ell_{i,k}} \Psi_t^{(N_k)} U))_{i=1}^m \Big), \qquad t \in [\tau, T],$$

   converge in distribution in $C([\tau,T]; \mathbb{R} \times \mathbb{C}^m)$ to $t \mapsto (E_L(X(t)), (W_{\ell_i,\chi_i,t}(X))_i)$ with X distributed according to λ. For two admissible approximations of the same loops, the expected supremum over $[\tau, T]$ of the difference of the corresponding loop processes tends to zero.
2. *(Sobolev topology.) The image measures of $(\pi_k)_\# \mu_k$ and λ in the space of trajectories of Sobolev connections in H^1 modulo gauge transformations in $W^{2,2}$, with the topology of Cao and Chatterjee described in Definition 29.1, converge against every bounded continuous function.*
3. *(Symmetries.) The measure λ is invariant under the maps induced by the isometries $x \mapsto Qx + y$ of $\mathbb{T}_L^3$ with $Q \in O(3,\mathbb{Z})$ and $y \in \mathbb{T}_L^3$. It is also invariant under the three center symmetries: for $z \in \{\pm I\}^3$, the map $[A] \mapsto [A^h]$, where $h : \mathbb{R}^3 \to \mathrm{SU}(2)$ is smooth with $h(x + Le_i) = z_i h(x)$. In particular, if $\ell_1, \dots, \ell_m$ are loops with winding vectors $\nu(\ell_j) \in \mathbb{Z}^3$, $t_1, \dots, t_m > 0$, and $b_1, \dots, b_m \ge 0$ are integers with $\sum_j b_j \nu(\ell_j) \neq 0$ in $(\mathbb{Z}/2\mathbb{Z})^3$, then $\mathbb{E}_\lambda \prod_j \big(\mathrm{tr}\, \mathrm{Hol}_{\ell_j} X(t_j)/2\big)^{b_j} = 0$.*
4. *(Scaling.) Let D_L map a trajectory X on the unit torus to the trajectory $(D_L X)(t) = L^{-1} X(t/L^2)(\cdot/L)$ on $\mathbb{T}_L^3$. Then $\lambda_{L,\gamma,[n]_M} = (D_L)_\# \lambda_{1,\gamma,[n]_M}$.*
5. *(Continuity in the coupling.) On every compact interval $I \subset (0,\infty)$ of couplings, the convergence in Theorem 2.3(1) holds uniformly in $\gamma \in I$ in the bounded-Lipschitz distance, and the maps π_k can be chosen independently of $\gamma \in I$ so that the convergence in Theorem 2.3(3) and the tightness in Theorem 2.3(4) hold uniformly in $\gamma \in I$. The map $\gamma \mapsto \lambda_{L,\gamma,[n]_M}$ is weakly continuous on $(0,\infty)$ for both topologies on $\mathcal{X}_L$.*

Part (1) is Theorem 30.4, part (2) is Theorem 30.5, part (3) is Theorem 30.6, part (4) is Theorem 30.1, and part (5) is Theorem 30.10. By parts (4) and (5), at fixed physical coupling $g_3^2 = \gamma/L$ the measures on different tori, transported to the unit torus, depend continuously on L. Since $\gamma = g_3^2 L$, part (4) is not an infinite-volume statement.

Other smoothing flows. The limit does not depend on the details of the smoothing within the following family of flows. For $c \ge 0$, let $\Psi_t^{(N,c)}$ be the flow of the vector field

$-\nabla \sum_p [q(U_p) + c\, q(U_p)^2]$ run for the lattice time $4t/a_N^2$; for $c = 0$ this is the Wilson flow. The measure $\mu_{N,\gamma}$ is unchanged.

Theorem 2.6. *Fix $L > 0$ and $0 < \gamma \le 1$, and let $N_K = n_* B^K$ be as in Remark 2.4. Let $C_0 \ge 0$, let ℓ_i, χ_i, t_i, and $(\ell_{i,K})_K$ be as in Theorem 2.3, and write $W^c_{K,i} = \chi_i(\mathrm{Hol}_{\ell_{i,K}} \Psi^{(N_K,c)}_{t_i} U)$. Then*

$$\lim_{K\to\infty} \mathbb{E}_{\mu_{N_K,\gamma}} \sup_{0\le c\le C_0} \max_i |W^c_{K,i} - W^0_{K,i}| = 0.$$

Further, for $0 < \tau < T$, the joint fields of lattice energies and Wilson loops along the modified flows converge in distribution in $C([0,C_0]\times[\tau,T];\mathbb{R}\times\mathbb{C}^m)$ to the field $(c,t) \mapsto (E_L(X(t)), (W_{\ell_i,\chi_i,t}(X))_i)$, $X \sim \lambda$, which does not depend on c.

This is Theorems 30.13 and 30.15.

2.5 The bound on large fields

The proof of Theorem 2.3 rests on a renormalization group analysis of $\mu_{N,\gamma}$ restricted to a small-field event. We describe the event briefly; the precise definition is Definition 4.4. Fix an odd integer $M \ge 3$ and an integer $J \ge 1$, and set $B = M^J$. For $N = uB^K$, let T_M be the block averaging map of Definition 4.3, which maps configurations on $\Lambda_{N'}$ to configurations on $\Lambda_{N'/M}$; it is a version of Bałaban's averaging operation [12]. Let $V^j = T_M^j U$ be the averaged configurations. A renormalization group step consists of J consecutive averaging steps. At the step from V^{kJ} to $V^{(k+1)J}$, the fine configuration is described by the coarse configuration and by normalized fluctuation variables w_i, one for each of the J intermediate scales. In free logarithmic coordinates z_i on the fiber of the averaging map, in a fixed gauge-fixed chart, they are defined by $z_i = z_i^* + g_i K_i^{-1/2} w_i$. Here z_i^* is the conditional constrained minimizer of the effective classical action, K_i is its constrained Hessian, and g_i is the coupling at that scale; see Section 3.2. The small-field event $S_{N,u,\gamma}$ is the set of configurations U such that U and each $V^{(k+1)J}$, $0 \le k < K$, are gauge equivalent to configurations all of whose link variables are close to the identity, such that each renormalization group step is defined at U, and such that every normalized fluctuation variable of the k-th step has size at most $A_{\mathrm{w}} \log(1/t_k)$, where $t_k^2 = \gamma/(M n_{(k+1)J})$ is the largest effective coupling of that step and $n_j = N/M^j$.

Theorem 2.7. *Fix $L > 0$, an odd integer $M \ge 3$, and $0 < \Gamma < \infty$. There exist an integer $J \ge 1$, a choice of the remaining parameters in the definition of $S_{N,u,\gamma}$, and an integer n_Γ such that the following holds with $B = M^J$. There exist constants $C, C_{\mathrm{w}}, c_*, a_{\mathrm{w}} > 0$ and $H_0, H_2 \ge 0$ such that, for every $\gamma \in (0,\Gamma]$, every $u \ge n_\Gamma$ divisible by four, and every $K \ge 0$,*

$$\mu_{uB^K,\gamma}(S^c_{uB^K,u,\gamma}) \le C u^3 \exp\Big(H_0 + H_2 \log\frac{\Gamma}{\gamma} - \frac{c_* u}{\gamma}\Big) + C_{\mathrm{w}} u^3 \exp\Big(-a_{\mathrm{w}} \log^2 \sqrt{\frac{Mu}{\gamma}}\Big). \quad (2.5)$$

The constants depend only on L, M, Γ, and the chosen parameters. In particular, for every fixed $u \geq n_\Gamma$ and every $q > 0$ there exists $C_{u,q}$ with $\sup_{K\geq 0} \mu_{uB^K,\gamma}(S^c_{uB^K,u,\gamma}) \leq C_{u,q}\gamma^q$ for all $\gamma \in (0,\Gamma]$, and the right side of (2.5) tends to zero as $u \to \infty$, uniformly in $\gamma \in (0,\Gamma]$. Further, for each such u there exist $c_u, C_u > 0$ and $\gamma_u > 0$ such that

$$e^{-C_u(1+\log(1/\gamma))^2} \leq \sup_{K\geq 0} \mu_{uB^K,\gamma}\big(S^c_{uB^K,u,\gamma}\big) \leq e^{-c_u \log^2(1/\gamma)} \qquad (0 < \gamma \leq \gamma_u).$$

This is proved in Theorems 23.5 and 23.10 and Corollary 23.13. By the last display, at fixed u the supremum over K of the discarded probability lies between $\exp(-C_u(1+\log(1/\gamma))^2)$ and $\exp(-c_u \log^2(1/\gamma))$; in particular it is much larger than $\exp(-c/\gamma)$. The lower bound comes from configurations that violate the cutoff on the normalized fluctuation variables, and it already holds for $K = 1$. The first term in (2.5) bounds the probability that some averaged configuration has a plaquette with large curvature. We prove it using reflection positivity and chessboard estimates under the unconditioned Wilson measure. The second term bounds the probability that some normalized fluctuation variable exceeds its cutoff.

2.6 Short distances

For a loop ℓ in $\mathbb{R}^3$, a point $x \in \mathbb{T}^3_L$, and $\varepsilon > 0$ small, let $x + \varepsilon\ell$ be the scaled and translated loop in $\mathbb{T}^3_L$, and let

$$W_{x+\varepsilon\ell,s}(X) = \tfrac{1}{2} \operatorname{tr} \operatorname{Hol}_{x+\varepsilon\ell} X(s)$$

be the normalized fundamental Wilson loop under the measure λ of Theorem 2.3.

Theorem 2.8. *Fix $L > 0$, $\gamma > 0$, an odd integer $M \geq 3$, and n divisible by four, let $\lambda = \lambda_{L,\gamma,[n]_M}$, and set $g_3^2 = \gamma/L$. Let $\ell_1, \dots, \ell_m$ be smooth loops in $\mathbb{R}^3$ and $\sigma > 0$. For $x \in \mathbb{T}^3_L$ and $\varepsilon > 0$ set*

$$Z_\varepsilon(x) = \Big(\frac{1 - W_{x+\varepsilon\ell_i,\sigma\varepsilon^2}}{g_3^2\varepsilon}\Big)_{i=1}^m.$$

Let $C^a = (C^a_i)_{i=1}^m$, $a = 1,2,3$, be independent centered Gaussian vectors with covariance

$$\Sigma_{ij} = (2\pi)^{-3} \int_{\mathbb{R}^3} \frac{e^{-2\sigma|k|^2}}{|k|^2} \overline{\widehat{J}_i(k)} \cdot \widehat{J}_j(k)\, dk, \qquad \widehat{J}_i(k) = \int_0^1 e^{-ik\cdot\ell_i(s)} \dot{\ell}_i(s)\, ds, \tag{2.6}$$

and set $Z_G = (|C_i|^2/8)_{i=1}^m$, where $C_i = (C^1_i, C^2_i, C^3_i)$. Then the following statements hold.

1. *As $\varepsilon \to 0$, the law of $Z_\varepsilon(x)$ under λ converges to the law of Z_G in the bounded-Lipschitz distance, uniformly in $x \in \mathbb{T}^3_L$.*
2. *If $m = 1$ and $v = \Sigma_{11} > 0$, then*

$$\liminf_{\varepsilon\to 0} \inf_{x\in\mathbb{T}^3_L} \frac{\operatorname{Var}_\lambda W_{x+\varepsilon\ell_1,\sigma\varepsilon^2}}{(g_3^2\varepsilon)^2} \geq \frac{3v^2}{32}.$$

3. *For every bounded Borel function* $G : \mathcal{X}_L \to \mathbb{R}$,

$$\lim_{\varepsilon \to 0} \sup_{x \in \mathbb{T}_L^3} \sup_f \left| \mathbb{E}_\lambda[f(Z_\varepsilon(x))G] - \mathbb{E}[f(Z_G)]\, \mathbb{E}_\lambda[G] \right| = 0,$$

where the supremum is over functions f *with* $\|f\|_\infty \le 1$ *and Lipschitz constant at most one.*

This is proved in Theorems 32.13 and 32.17 and Corollary 32.14. In the notation of Section 31, $C_i = G_i$ and $(Z_G)_i = \mathsf{Z}_i$. The vector C is the heat-smoothed circulation of a Gaussian free field (Maxwell field) with three independent colors, so the theorem says that at short distances the flowed Wilson loops of λ behave as those of the free field, up to the quadratic map $V \mapsto |V|^2/8$ coming from $1 - \operatorname{tr} e^V/2 = |V|^2/8 + O(|V|^4)$. As an intermediate step, we prove a Gaussian limit for the normalized heat-smoothed circulations of the reconstructed field. This holds in a fixed gauge, under the conditioned Wilson measure, at every sufficiently large fixed coarse side (Theorem 32.8). These circulations are not gauge-invariant functions on $\mathcal{X}_L$; the gauge-invariant conclusion is the theorem above. Part (2) is a lower bound only, since the proof does not give uniform integrability.

2.7 Weak coupling

We now let $\gamma \to 0$ with L, M, and n fixed, and write $\lambda_\gamma = \lambda_{L,\gamma,[n]_M}$. Fix $\theta > 0$ and the flow time $t = \theta L^2$. For $X \in \mathcal{X}_L$, let $H = (H_1, H_2, H_3) \in \mathrm{SU}(2)^3$ be the holonomies of $X(t)$ around the three coordinate cycles of $\mathbb{T}_L^3$ based at the origin; the triple H is defined up to simultaneous conjugation. Every continuous function of H that is invariant under simultaneous conjugation is a continuous function of the seven traces of H_i, $H_i H_j$ $(i < j)$, and $H_1 H_2 H_3$ (Lemma 5.6). Such functions are bounded and $\mathcal{T}_W$-continuous on $\mathcal{X}_L$. In the proofs we fix, before γ varies, a coarse side in the class $[n]_M$ that is larger than certain thresholds; by Theorem 2.3(5) this choice does not change λ_γ. Each of the following theorems holds for all sufficiently small γ, with a threshold that depends on the theorem, and in each the continuum limit is taken first, at fixed γ.

A connection is flat if $F_A = 0$. Flat connections on $\mathbb{T}_L^3$ modulo gauge are classified by their holonomies, which form a commuting triple; the moduli space is

$$\mathrm{Hom}(\mathbb{Z}^3, \mathrm{SU}(2))/\mathrm{SU}(2) \simeq (\mathbb{R}/4\pi\mathbb{Z})^3/\{\boldsymbol{\vartheta} \sim -\boldsymbol{\vartheta}\},$$

where $\boldsymbol{\vartheta}$ parametrizes the triple $(e^{\vartheta_1 u}, e^{\vartheta_2 u}, e^{\vartheta_3 u})$ for a unit vector $u \in \mathfrak{su}(2)$. The eight central triples $H \in \{\pm I\}^3$ are the singular points.

Theorem 2.9. *Fix* $L > 0$, *an odd integer* $M \ge 3$, *and* n *divisible by four. Then the following statements hold.*

1. *For every* $t > 0$ *and* $\delta > 0$, $\lambda_\gamma(E_L(X(t)) > \delta) \to 0$ *as* $\gamma \to 0$.

2. *There exists* $\gamma_0 \in (0,1]$ *such that the family* $(\lambda_\gamma)_{0<\gamma\le\gamma_0}$ *is tight: for every* $\eta > 0$ *there exist* $R_j < \infty$ *such that* $\lambda_\gamma(E_L(X(L^2 2^{-j})) \le R_j \text{ for all } j \ge 1) \ge 1-\eta$ *for all* $0 < \gamma \le \gamma_0$. *The sets in this display are compact for* $\mathcal{T}_W$ *and for* d_c, *so every sequence* $\gamma_k \to 0$ *has a subsequence along which* λ_{γ_k} *converges against bounded* $\mathcal{T}_W$*-continuous functions and weakly for* d_c.
3. *Every subsequential limit of* λ_γ *as* $\gamma \to 0$, *against bounded* $\mathcal{T}_W$*-continuous functions or weakly for* d_c, *is supported on the stationary flat trajectories* $\{X : X(t) = [A] \text{ for all } t > 0,\ F_A = 0\}$.

This is Theorem 34.13. The theorem does not identify the limiting distribution on the moduli space of flat connections. The next two theorems describe the fluctuations near the regular and the singular points of this moduli space.

Regular commuting triples. In a fixed neighborhood of the identity, write $X = (x_1, x_2, x_3) = (\operatorname{Log} H_1, \operatorname{Log} H_2, \operatorname{Log} H_3) \in \mathfrak{su}(2)^3 \simeq \mathbb{R}^9$. The commuting triples correspond to the cone $\mathcal{M} = \{(\vartheta_1 u, \vartheta_2 u, \vartheta_3 u) : \boldsymbol{\vartheta} \in \mathbb{R}^3,\ u \in S^2\}$. On a regular patch $0 < r_0 \le |\boldsymbol{\vartheta}| \le r_1 < \pi$ the normal space to $\mathcal{M}$ at $y = (\vartheta_i u)_i$ is

$$\mathcal{N}_y = \Big\{ b = (b_1, b_2, b_3) :\ b_i \perp u,\ \sum_i \vartheta_i b_i = 0 \Big\},$$

which has dimension four, and near the patch we write $X = y + b$ with $y \in \mathcal{M}$ and $b \in \mathcal{N}_y$. Let $\Sigma_\theta(y)$ be the normal covariance, the positive definite covariance on $\mathcal{N}_y$ defined in (4.12). It is the covariance, divided by γ, of the linear response of the flowed logarithms X at the flat connection y, and it does not depend on γ. Let ψ be a smooth function of X that is invariant under simultaneous conjugation and supported in a small tube around a compact regular patch. We assume that ψ has the form (tangential bump)$\times$(normal cutoff equal to one near $b = 0$), and that its tangential factor takes values in $[0,1]$, vanishes on a nonempty open subset, and is positive on another. Set

$$q_*(y+b) = \tfrac{1}{2}\, b^{\mathsf{T}} \Sigma_\theta(y)^{-1} b, \qquad B_{\mathrm{obs}} = \psi, \qquad A_{\mathrm{obs}} = \psi\, q_*,$$

where the formula for q_* is used on a fixed normal tube that contains the supports of all the functions ψ and $\widetilde{w}$ below, and q_* is extended outside this tube by a bounded nonnegative invariant function. The functions A_{obs} and B_{obs} are extended by zero outside the chart. We define the normalized regression residual variance

$$\mathscr{C}_\gamma = \frac{\operatorname{Var}(A_{\mathrm{obs}}) - \operatorname{Cov}(A_{\mathrm{obs}}, B_{\mathrm{obs}})^2 / \operatorname{Var}(B_{\mathrm{obs}})}{\mathbb{E}(B_{\mathrm{obs}}^2)},$$

with all moments under λ_γ. This is the mean square error of the best affine predictor of A_{obs} from B_{obs}, normalized by $\mathbb{E} B_{\mathrm{obs}}^2$.

Theorem 2.10. *Fix $L > 0$, an odd integer $M \geq 3$, n divisible by four, $\theta > 0$, and ψ as above with a sufficiently small tube. Then the following statements hold.*

1. *There exists $c > 0$ such that $\mathbb{E}_{\lambda_\gamma} B_{\mathrm{obs}}^2 \geq c$ and $\mathrm{Var}_{\lambda_\gamma} B_{\mathrm{obs}} \geq c$ for all sufficiently small $\gamma > 0$, and*
$$\mathscr{C}_\gamma = 2\gamma^2 + o(\gamma^2) \qquad (\gamma \to 0).$$
2. *Let $w \geq 0$ be a nonzero smooth invariant function on $\mathcal{M}$ supported in the interior of the regular patch, let χ_w be a smooth normal cutoff invariant under simultaneous conjugation, with $0 \leq \chi_w \leq 1$, supported in the tube and equal to one near $b = 0$, and set $\widetilde{w}(y + b) = w(y)\chi_w(b)$. Then $\mathbb{E}_{\lambda_\gamma} \widetilde{w} \geq c_w > 0$ for small γ, and for every bounded continuous $f : [0, \infty) \to \mathbb{R}$,*
$$\frac{\mathbb{E}_{\lambda_\gamma}[\widetilde{w}\, f(q_*/\gamma)]}{\mathbb{E}_{\lambda_\gamma} \widetilde{w}} \longrightarrow \int_0^\infty f(s)\, s\, e^{-s}\, ds \qquad (\gamma \to 0).$$
3. *More generally, on $\{\widetilde{w} \neq 0\}$ write $X = y_\gamma + b_\gamma$ and $z_\gamma = \gamma^{-1/2} \Sigma_\theta(y_\gamma)^{-1/2} b_\gamma$, and define products with $\widetilde{w}$ to be zero where $\widetilde{w} = 0$. For every bounded continuous function $F(y, z)$ on the normal bundle that is invariant under simultaneous conjugation,*
$$\frac{\mathbb{E}_{\lambda_\gamma}\left[\widetilde{w}\left(F(y_\gamma, z_\gamma) - \overline{F}(y_\gamma)\right)\right]}{\mathbb{E}_{\lambda_\gamma} \widetilde{w}} \longrightarrow 0, \qquad \overline{F}(y) = \int F(y, z)\, \mathcal{N}(0, I_{\mathcal{N}_y})(dz).$$

This is Theorems 35.2 to 35.4. Part (3) is a Gaussian approximation for the normal component of the flowed holonomies near a regular commuting triple, with covariance $\gamma \Sigma_\theta(y)$, in the sense of the displayed ratio of weighted expectations. The tangential component keeps its own law under the weighting, and we do not claim that this law converges. Part (2) is the special case $F = f(|z|^2/2)$, since $|z|^2/2$ has density se^{-s} when z is a standard Gaussian vector in four dimensions. The coefficient 2 in part (1) comes from the first two moments 2 and 6 of this density. It is the coefficient of the Gaussian approximation around a regular commuting flat background, and the theorem does not identify corrections beyond it. For comparison, consider the reference measures of Definition 4.13. For the Abelian Maxwell measure with Haar cycle holonomies, the holonomy triples commute and the statistic vanishes identically. For the Gaussian holonomies with independent Haar factors, $H_i = U_i^0 \operatorname{Hol}_i(a)$, where a is a smoothed Gaussian field and U_1^0, U_2^0, U_3^0 are independent Haar distributed elements of $\mathrm{SU}(2)$, independent of a, the triple is exactly Haar distributed, and the statistic is a positive constant independent of γ (Lemma 35.17).

Central triples. Near the central triples the cone of commuting triples is singular, and the constant modes are no longer Gaussian. Let
$$Q(Y) = \tfrac{1}{2} \sum_{i<j} |y_i \times y_j|^2, \qquad Y = (y_1, y_2, y_3) \in \mathbb{R}^9, \qquad r_\gamma = \gamma^{1/4},$$

where $\times$ is the cross product, which corresponds to the Lie bracket under $\mathfrak{su}(2) \simeq \mathbb{R}^3$. We call Q the constant-mode quartic form. The measure $e^{-Q(Y)}dY$ on $\mathbb{R}^9$ is locally finite but has infinite total mass. For a function φ on $\mathbb{R}^9$ we write $\mathcal{I}_{\gamma,\varphi} = \varphi(X/r_\gamma)$, extended by zero outside the fixed neighborhood of the identity in which X is defined. A radial cutoff is a function $\chi(|Y|)$ with $\chi \geq 0$ smooth, compactly supported, not identically zero, and constant near zero.

Theorem 2.11. *Fix $L > 0$, an odd integer $M \geq 3$, n divisible by four, and $\theta > 0$. Then the following statements hold.*

1. *For every continuous compactly supported function φ on $\mathbb{R}^9$ invariant under simultaneous conjugation and every radial cutoff χ,*

$$\lim_{\gamma\to 0} \frac{\mathbb{E}_{\lambda_\gamma}\mathcal{I}_{\gamma,\varphi}}{\mathbb{E}_{\lambda_\gamma}\mathcal{I}_{\gamma,\chi(|\cdot|)}} = \frac{\int_{\mathbb{R}^9} \varphi(Y)e^{-Q(Y)}\,dY}{\int_{\mathbb{R}^9} \chi(|Y|)e^{-Q(Y)}\,dY}. \tag{2.7}$$

   If $\varphi \geq 0$ is not identically zero, then $c_\varphi r_\gamma \leq \mathbb{E}_{\lambda_\gamma}\mathcal{I}_{\gamma,\varphi} \leq C_\varphi r_\gamma$ for small γ.
2. *For every $R < \infty$ and radial cutoff χ there exist $C, \gamma_0 > 0$ such that for all $0 < \gamma \leq \gamma_0$ and all invariant Lipschitz functions φ supported in the ball of radius R, the difference of the two sides of* (2.7) *is at most $C(\|\varphi\|_\infty + \operatorname{Lip}\varphi)\gamma^{1/4}$.*
3. *Let $W_\chi(Y) = [4Q(Y) - 9]\chi(|Y|) - |Y|\chi'(|Y|)$. Then*

$$\frac{\mathbb{E}_{\lambda_\gamma}\mathcal{I}_{\gamma,W_\chi}}{\mathbb{E}_{\lambda_\gamma}\mathcal{I}_{\gamma,\chi(|\cdot|)}} = O(\gamma^{1/4}).$$

4. *The same statements hold, with the same constants, near each of the eight central triples $z \in \{\pm I\}^3$, with X replaced by $(\operatorname{Log}(z_i^{-1}H_i))_{i=1}^3$; at each fixed γ the corresponding expectations near different central triples are equal.*

This is proved in Theorems 36.7, 36.10, and 36.12. Part (3) is the dilation integration-by-parts identity, $\int \operatorname{div}(Y\chi(|Y|)e^{-Q(Y)})\,dY = 0$, which follows from the homogeneity $Y \cdot \nabla Q = 4Q$. For the reference measures of Definition 4.13, and for radial cutoffs with $\chi(0) > 0$, the same statistic has the following limits (Theorem 36.19). It tends to -6 for the Abelian Maxwell measure with Haar cycle holonomies, and to -9 for the Gaussian holonomies with Gaussian constant modes. For the mixture of normalized conditional normal Gaussian measures over commuting backgrounds, with a fixed prior density that is continuous and positive at the tip of the cone of commuting triples, its limit is strictly larger than 4. Hence the statistic distinguishes λ_γ from these comparison measures. In Section 36 we also prove joint versions of (2.7) at finitely many flow times, for test functions that are invariant under independent simultaneous conjugations at the different times (Theorem 36.15). Finally, let $0 < \tau < T$, and weight λ_γ by $\mathcal{I}_{\gamma,\chi(|\cdot|)}$ evaluated at time τ, normalized to a probability measure. Under this measure, the rescaled holonomy paths

on $[\tau, T]$, defined with a fixed smooth equivariant extension of the logarithm and taken modulo conjugation at each time, converge in the uniform topology to constant paths. The value of the limiting path has the law with density proportional to $\chi(|Y|)e^{-\mathrm{Q}(Y)}$, and the error against bounded Lipschitz path functionals is $O(\gamma^{1/4})$ (Theorem 36.18).

Constants in Theorems 2.10 and 2.11 may depend on L, M, n, θ, and the test functions, but not on γ.

SECTION 3

Outline of the proof

This section explains the main steps of the proof and the ideas behind them. It is meant to be read before the technical parts, and it fixes the vocabulary used there. We describe the proof of Theorem 2.3 in Sections 3.1 to 3.7. The proofs of the results on short distances and on weak coupling are outlined in Sections 3.8 and 3.9. Throughout, L and γ are fixed, $g_3^2 = \gamma/L$, and $M \geq 3$ is a fixed odd integer.

3.1 Strategy

The Wilson measure $\mu_{N,\gamma}$ at fine mesh a_N lives on a space whose dimension grows like N^3. The observables we care about, flowed Wilson loops at a fixed positive time t, depend on the configuration at length scales of order $\sqrt{t}$ and larger. The renormalization group organizes the integration over the configuration scale by scale, from the finest lattice to a coarse lattice of fixed side. At each scale, we only need to control a weakly coupled and approximately Gaussian integral. In three dimensions the effective coupling at lattice side m is $g_m^2 = \gamma/m$, which is small when m is large. For this reason the renormalization group is a convergent procedure in the ultraviolet, as Bałaban showed [15]. However, this is true only as long as the field is close to a pure gauge at every scale. Configurations for which this fails, the large fields, have to be treated separately.

We organize the proof as a limit in two stages.

1. We fix a coarse side u and a large integer K, and let $N = uB^K$, where $B = M^J$ is the blocking factor of one renormalization group step. We condition $\mu_{N,\gamma}$ on the small-field event $S_{N,u,\gamma}$ of Section 2.5, which gives the conditioned Wilson measure $\nu_{N,u,\gamma} = \mu_{N,\gamma}(\,\cdot \mid S_{N,u,\gamma})$. On this event we can run the renormalization group exactly from side N down to side u, without any analysis of large fields. We prove that, for each fixed u, the laws of flowed Wilson loops under $\nu_{uB^K,u,\gamma}$ converge as $K \to \infty$.
2. By Theorem 2.7, we have $\mu_{uB^K,\gamma}(S^c_{uB^K,u,\gamma}) \leq F(u)$ for all K, where $F(u) \to 0$ as $u \to \infty$. For a bounded observable G we have the elementary inequality

$$\left|\mathbb{E}_{\mu_{N,\gamma}} G - \mathbb{E}_{\nu_{N,u,\gamma}} G\right| \leq 2\|G\|_\infty \, \mu_{N,\gamma}(S^c_{N,u,\gamma}). \tag{3.1}$$

If $u = nB^r$, the sequence of sides uB^K is the sequence nB^K shifted by r. Then the first stage shows that, under $\mu_{nB^K,\gamma}$, the expectations of a fixed bounded continuous function of finitely many flowed Wilson loops form a Cauchy sequence up to an

error $4\|G\|_\infty F(u)$. Letting $u \to \infty$, we obtain convergence under the unconditioned Wilson measure.

This order of limits, first $K \to \infty$ at fixed u and then $u \to \infty$, appears throughout the paper. Configurations outside the small-field event enter only through the bound on large fields. We prove that bound directly under $\mu_{N,\gamma}$, without conditioning. In particular, we never need to show that a conditioned measure is reflection positive.

The rest of the proof of Theorem 2.3 consists of three tasks. The first is the renormalization group analysis on the small-field event, and its consequences at a fixed number of steps (Sections 3.2 and 3.3). The second is the bound on large fields (Section 3.4). The third is the passage from the renormalization group variables to flowed Wilson loops, and then to a measure on the trajectory space (Sections 3.5 to 3.7).

3.2 The renormalization group on the small-field event

Averaging. The renormalization group step is built from Bałaban's averaging operation for lattice gauge fields [12]. Fix a configuration on a lattice of side Mm. We divide the lattice into cubic blocks of M^3 sites, centered at the points of a sublattice of side m. For each link c of the coarse lattice, we consider the M^3 paths of length M parallel to c that start at the sites of the block at the initial point of c. They are joined to the endpoints of c by fixed connecting paths along the coordinate directions. We take the logarithms of their transports relative to the transport along c, average them, and multiply the exponential of the average by the transport along c; see (4.3). When some relative transport equals $-I$, the logarithm is not defined, and we use the reference transport instead. In this way the block averaging map T_M is a Borel map on the whole configuration space. It is gauge covariant, and it commutes with translations of the coarse lattice and with reflections of coordinates that preserve it. (Because the connecting paths change coordinates in a fixed order, we do not claim that it commutes with permutations of coordinates.) Since M is odd, the blocks are centered, and the blocks of successive averaging steps are nested. As a consequence, iterated averages of a configuration supported on one side of a reflection plane depend only on that side (Section 6). In Part II we prove the basic properties of the block averaging map, including an exact formula for the integral over a fiber $\{U : T_M U = b\}$ in local coordinates and an estimate that controls the curvature of $T_M U$ by that of U (Theorem 7.3). One renormalization group step consists of J consecutive averaging steps, $V^{(k+1)J} = T_M^J V^{kJ}$. The integer J is fixed at the start of the proof.

Background fields. Let c be a coarse configuration close to the identity. The integral over fine configurations U with $T_M^J U = c$ is dominated by a neighborhood of the minimizer of the Wilson action subject to this constraint. Following Bałaban [16], we call this minimizer the background field. We construct it in a gauge-fixed chart near the identity, by solving the constrained Euler–Lagrange equation with a contraction argument (Part III). It is a

specific branch of local constrained minimizers; we do not claim that it minimizes the action over the whole fiber of the averaging map. We prove that it depends analytically on c, with estimates that are uniform in the number of averaging steps between the fine and coarse lattices. The value of the constrained minimum defines the effective classical action $E_d(c)$ at depth d, the number of averaging steps. Minimizing in stages gives the nested minimization identity

$$E_{d+1}(c) = M \min_z E_d(b(c,z)).$$

Here $b(c,z)$ parametrizes, in the chart, the configurations on the intermediate lattice whose average is c, the minimum is over that chart, and the factor M is the change of units in three dimensions. The effective classical action E_0 is the Wilson action. Since $g_{d+1}^2 = Mg_d^2$, the ratio E_d/g_d^2 is invariant under this change of scale. The main technical point is that the analytic norms of E_d and of the background field do not grow with d. This rests on two facts. The first is the linear theory: the effective Maxwell quadratic form has an exponentially decaying kernel, and its restriction to the next constrained fluctuation space has a positive lower bound and an exponentially decaying inverse, uniformly in the depth and the lattice side (Theorem 8.3). Bałaban's propagator estimates [10, 11, 13] are used separately, in the constrained linear extension and the scalar gauge inverse of Theorem 9.3 and Lemma 9.8. The second is that the linearized averaging operator, acting on connections after a gauge correction, has row sums one and column sums M^{-3} ((10.12)). As a result the nonlinear errors are summable over scales.

Fluctuations and the effective interaction. We fix a renormalization group step from side $M^J m$ to side m. We parametrize the fine configuration by the coarse configuration c and by free logarithmic coordinates z_i at each of the J intermediate scales. We then center these coordinates at the background field and normalize them by the constrained Hessian:

$$z_i = z_i^*(c, z_{>i}) + g_i K_i(c, z_{>i})^{-1/2} w_i.$$

Here z_i^* is the conditional constrained minimizer, K_i is the constrained Hessian of the action, and g_i is the coupling at that scale. We call the w_i the normalized fluctuation variables. The change of variables is triangular, from the coarsest intermediate scale to the finest. We compute its Jacobian exactly, including the Haar density and the Jacobian of the constraint (Section 12). In the variables w the integrand is $\exp(-V(c,w))$. The interaction $U(c,w) = V(c,w) - |w|^2/2$ contains the higher-order terms of the action, the Jacobians, and the effective interaction inherited from finer scales. On the small-field event every w_i is bounded by $A_{\mathrm{w}} \log(1/t)$, where t is the largest coupling of the step. On this product of balls the interaction U is small, and we expand the integral over w in a convergent polymer expansion. We use the cluster expansion in the form of Kotecký and Preiss [120], with the tree estimates that go back to Penrose [136], as presented by Fernández

and Procacci [87] and Dimock [68]. After imposing the small-field tests through the k-th renormalization group step, we obtain an exact formula, relative to product Haar measure, for the unnormalized stopped density of the averaged configuration:

$$\mathbf{1}_{D_r}(c)\exp\Big(\Lambda_k - \frac{E_{kJ,\mathrm{sat}}(c)}{g_{kJ}^2} - \overline{R}_{kJ,\mathrm{sat}}(c)\Big). \tag{3.2}$$

Here $g_{kJ}^2 = \gamma/n_{kJ}$ is the coupling of the lattice of side n_{kJ}, and D_r, the gauge-invariant small-field domain, is the set of configurations that are gauge equivalent to configurations with all link variables close to the identity. The subscript sat denotes the gauge-invariant extension to D_r of a function defined near the identity. The function E_{kJ} is the effective classical action. The centered effective interaction $\overline{R}_{kJ}$ is generated by the integration of the fluctuations, and it is normalized so that $\overline{R}_{kJ}(I) = 0$. The normalization constant Λ_k collects all factors that do not depend on the field, including the vacuum energy (Sections 13 and 14). At $k = K$ the normalized stopped density is the law of the coarse field V^{JK} under the conditioned Wilson measure. At intermediate steps it does not include the remaining coarser restrictions of the small-field event.

Analytic norms and contraction. We control $\overline{R}_{kJ}$ by a norm that sums the absolute values of all Taylor coefficients at the identity (Definition 4.6). The coefficients of order k are weighted by $\rho^{k-2}/k!$ and by $\exp(a_{\mathrm{sp}}\mathrm{t})$, where t is the length of the shortest network that connects the lattice points on which the coefficient depends. The weighted coefficients measure spatial locality. Connected products and compositions are controlled by the coefficient calculus, using output row bounds and volume-normalized input column bounds, under the required image conditions for compositions (Lemma 13.1); derivative estimates hold on strictly smaller analytic domains. Products of interactions whose coefficient networks are not connected, such as products of two extensive interactions, are not controlled in this way. The key estimate is Theorem 13.5, which says that one renormalization group step maps a centered effective interaction R to

$$R_+ = Q + \mathcal{P}R + \mathcal{D}R, \qquad \|R_+\| \le C_G + q\|R\| + C_T t^2 \|R\|(p^4 + \|R\|p^2).$$

In the notation of that theorem, $Q = Q^{\mathrm{w}}_{d_0,J}$, $\mathcal{P} = \mathcal{P}_\delta$, and $\mathcal{D} = \mathcal{D}_J$ for the step under consideration; in this paragraph only, Q does not denote the constant-mode quartic form. The term Q is the newly generated effective interaction, produced by the step itself. The term $\mathcal{P}R$, the pullback at zero fluctuation, is R evaluated on the background field. It contracts by a factor $q = O(M^{-J})$, because R is gauge invariant, invariant under translations, global color rotations, and inversion, and has no linear term at the identity (Theorem 11.10). The term $\mathcal{D}R$ is the fluctuation correction to the pullback. It gains two powers of the coupling, because the linear term of the fluctuation integral vanishes on each connected support. We choose J so that $q < 1/4$, and then we choose the coupling

small. The ball $\|R\| \leq E_*$ is then invariant, uniformly in the number of steps. Gauge invariance also enters in another way. At each step we choose a gauge transformation that depends only on the coarse configuration, and that brings the whole reconstructed fine configuration, fluctuations included, into a fixed analytic neighborhood of the identity (Theorem 13.2).

The conditional law of the fluctuations. Given the coarse configuration c, the normalized fluctuation variables w of one step have a conditional law, the conditional fluctuation kernel, with density proportional to $\mathbf{1}_{\Omega_p}(w)e^{-V_c(w)}$. Here Ω_p is a product of three-dimensional balls, and $D_w^2 V_c \geq I/2$ (Theorem 13.8). We emphasize that this law is not Gaussian, and that the variables are not independent. It is, however, uniformly log-concave on a convex set. Using the Bakry–Émery criterion [8] with reflecting boundary conditions and the Helffer–Sjöstrand representation of covariances [110], we obtain a logarithmic Sobolev inequality and exponentially decaying covariance estimates, with constants that do not depend on the dimension (Theorem 5.4). These estimates, together with bounds on the conditional means, are the probabilistic input for everything that follows. The conditional means are small, of order $t\|\log c\|_\infty$; at $c = I$ they vanish by the global $\mathrm{SU}(2)$ symmetry (Theorem 13.10).

3.3 Convergence at fixed resolution and reconstruction

Convergence of the effective interactions. The effective interaction after one step depends on the effective interaction at finer scales only through the contraction above. The influence of the finest scales therefore decays geometrically with the number of steps. In Section 15 we use this to prove convergence at fixed resolution. We fix the coarse side and a number of steps counted from the coarse side. Then the effective interactions, the conditional laws of the fluctuations, and the joint laws of the coarse configuration and the fluctuations of these steps converge as the total number of steps $K \to \infty$. This is a statement about finitely many variables. A subtle point is that gauge invariance allows different choices of gauge representatives at different K. We fix, once and for all, a family of gauge transformations that depend only on the coarse configuration and are chosen by a compactness argument. For this family the reconstructed configurations at each fixed resolution converge (Theorem 15.12).

Reconstruction of the fine field. From the coarse configuration and the fluctuations of all steps, we reconstruct the fine configuration step by step, from coarse to fine. We write A for the logarithm of the reconstructed fine configuration in the chosen gauge, divided by the mesh, so that A approximates a connection. In Part V we estimate how A changes when we add the fluctuations of one more step. The change has three parts: a conditionally centered linear part, a nonlinear part, and the difference between the

background field and the interpolation of the coarser field. The key deterministic fact concerns the last part. For each input direction and color, the linearized background field has the same signed volume-normalized column integral as the piecewise constant embedding of the coarse field. Their difference therefore has mean zero in each input column, and after heat smoothing at time s it gains a factor $\min(1, a/\sqrt{s})$, where a is the coarse mesh (Section 17). The key probabilistic fact is concentration for Lipschitz functions of the strongly log-concave law of the fluctuations (Section 16). Together, these two facts show that the heat evolution of A is controlled in norms of negative regularity, with summable contributions from the fine scales.

3.4 The bound on large fields

Theorem 2.7 has two parts. The second term in (2.5) accounts for configurations whose curvature is small at every scale, but for which some normalized fluctuation variable exceeds its cutoff $A_{\mathrm{w}} \log(1/t)$. By concentration for the law of the fluctuations, this event has conditional probability at most $\exp(-a \log^2(1/t))$ at each step. The sum over steps converges, because the effective coupling t decreases geometrically toward the ultraviolet. The point that needs care is that we condition only on the preceding scales being good, and never on good behavior at later scales. The probability of the preceding event is multiplied, never divided (Sections 22 and 23).

The first term accounts for configurations with a plaquette of large curvature at some scale. Here the argument has three steps.

Step 1: exponential moments of blocked actions. Under the fixed-parameter hypotheses of Theorem 22.1, fix $0 < \Gamma < \infty$, take $u \in 4\mathbb{N}$ with $u \geq n_{\min}(\Gamma)$, and let $N = uB^K$ and $1 \leq j \leq JK$. Fix a tiling of the lattice of side n_j into cells. Let Q_j be the Wilson action, divided by the coupling, of the averaged configuration V^{j-1} on the plaquettes that determine the curvature of the faces inside the cells. We prove that

$$\log \mathbb{E}_{\mu_{N,\gamma}} e^{sQ_j} \leq C_v n_{j-1}^3 + C_s n_{j-1}^2 \log(1/g_{n_{j-1}}) + C_b, \qquad 0 \leq s \leq s_0,$$

with constants that do not depend on the number of averaging steps or on $\gamma \in (0, \Gamma]$ (Theorem 22.1). The surface term comes from the difference between the numbers of independent plaquette variables of the periodic and the open lattice, in a comparison of partition functions, and it has to be kept. This is a stability bound in the spirit of Bałaban, but for an exponential moment under the unconditioned measure. Its proof is the most involved part of the paper. We partition the configurations according to the regions where some averaged plaquette has large curvature, recorded scale by scale; we call this partition the large-field decomposition (Theorem 21.5). Outside these regions we run the renormalization group in a localized form. We construct background fields, fluctuation integrals, and effective interactions on arbitrary unions of blocks, with the link variables

in the bad regions held fixed as parameters (Sections 18 to 20). The estimates are uniform in the shape, the number of components, and the age of the bad regions. In Section 21 we bound the density of the fine configurations on each piece of this partition by the localized effective density with the same normalization. The bound holds pointwise on gauge sections that contain every point of the relevant fibers (Theorems 21.9 and 21.12). The difference between the localized effective interactions and those on the full torus decays exponentially away from the bad regions. The missing coordinates, the boundaries, and the frozen coordinates contribute to the normalization constant, and we keep track of these contributions separately. Inside the bad regions we use only a crude bound: the effective classical action of the coarse configuration dominates both the Wilson action of the omitted links and a positive cost for each recorded bad plaquette (Section 22). This cost grows linearly in n_j/γ, while the entropy of the bad regions grows only like the square of a logarithm.

Step 2: chessboard estimates. The Wilson measure is reflection positive with respect to reflections in lattice planes through sites and through links, as Osterwalder and Seiler showed [134]. We use this separately for each of the eight shifted tilings of the lattice of side n_j into cells of $2 \times 2 \times 2$ sites. For a cell C, let I_0 be the event that some internal plaquette of C at level j has large curvature. Let R_0 be the event that every plaquette at a finer level whose full dependence set on the fine lattice lies in C has small curvature; plaquettes whose dependence sets cross the boundary of the cell are not tested. Both indicators are bounded, gauge-invariant Borel functions of the fine links in the cell. Because the blocks of the averaging map are centered and nested, the reflections between cells map these dependence sets and tests to their reflected placements in the other cells. Then the chessboard estimate of Fröhlich, Israel, Lieb, and Simon [92, 93], in the form given by Biskup [29], applies to this tiling (Theorem 6.6 and Lemma 22.11). Let R and I_{all} be the intersections of the reflected placements of R_0 and of I_0 over all cells of the tiling. The chessboard estimate gives

$$\mu_{N,\gamma}(R_0 \cap I_0) \le \mu_{N,\gamma}(R \cap I_{\mathrm{all}})^{8/n_j^3}.$$

The regularity events stay inside the root, so no division by their probability occurs. On R, the estimate on the curvature of averaged configurations shows that each cell with a plaquette of large curvature contributes at least a fixed multiple of n_j/γ to Q_j. By Step 1 and Markov's inequality, the probability of $R \cap I_{\mathrm{all}}$ is then at most $\exp(-cn_j^4/\gamma + Cn_j^3 + Cn_j^2 \log(1/g_{n_j}))$. Taking the root, we find that $R_0 \cap I_0$ has probability at most $\exp(-c'n_j/\gamma)$, once n_j/γ is large.

Step 3: first failure. We decompose the event that some scale has a bad cell according to the first scale, counted from the finest lattice toward the coarse lattice, at which a bad cell occurs. On each piece of this decomposition all finer scales are good, which implies

the regularity events R_0 of Step 2. We sum the bounds of Step 2 over cells and scales (Theorem 23.6). Since the bound at side n_j decays like $\exp(-cn_j/\gamma)$ and the sides grow geometrically toward the ultraviolet, the sum is dominated by the coarsest side u, which gives the first term in (2.5). On the complementary event the curvature is small at every scale. By Theorem 7.7, at every scale there exists a gauge representative with all link variables close to the identity. The remaining conditions of the small-field event reduce to the cutoffs on the fluctuations treated above.

The parameters are the integer J, the analytic radii, the cutoff amplitude A_{w}, the widths of the boundary layers in the localized analysis, and the minimum coarse side. We choose them in a fixed order: first the quantities that are uniform in J, then J, then the constants that depend on J, and finally the minimum side (Theorem 23.2). One of the tasks of Section 23 is to check that this order is free of circularity.

3.5 The gradient flow

To pass from the renormalization group variables to flowed Wilson loops, we need a theory of the lattice gradient flow for rough initial data that is uniform in the mesh. We write a lattice configuration near the identity as $U_e = \exp(aA_e)$. We apply a time-dependent gauge transformation that adds a damping term, in the spirit of the method of Zwanziger [157], DeTurck [66], and Donaldson [76]. Then the Wilson flow becomes a parabolic equation whose linear part is the lattice heat equation,

$$\partial_t A = \Delta_a A + \mathcal{N}_a(A, A) + (\text{higher order}),$$

where $\mathcal{N}_a$ is a quadratic nonlinearity involving one lattice derivative. For the initial data of interest, A has regularity just below $-1/2$, and the quadratic term is not defined by naive multiplication. We follow the approach of Da Prato and Debussche [63], which Cao and Chatterjee used for the Yang–Mills heat flow with random data [42], and write

$$A(t) = x(t) + y(t) + r(t), \qquad x(t) = e^{t\Delta_a} A(0), \qquad y(t) = \int_0^t e^{(t-s)\Delta_a} \mathcal{N}_a(x(s), x(s))\, ds.$$

We then solve for the remainder r, which is more regular. We call the pair (x, y), consisting of the linear heat evolution and the quadratic Picard term, the flow data. For a fixed $\alpha \in (1/2, 2/3)$ and horizon T, we measure it in the norms

$$\sup_{0 \le t \le T} \big\{ (t + a^2)^{\alpha/2} \|x(t)\|_\infty + (t + a^2)^{(\alpha+1)/2} \|D_a x(t)\|_\infty \big\}$$

and

$$\sup_{0 \le t \le T} \big\{ (t + a^2)^{\alpha - 1/2} \|y(t)\|_\infty + (t + a^2)^{\alpha} \|D_a y(t)\|_\infty \big\},$$

where D_a includes the lattice differences and shifts that the equation requires (Definition 4.8). Part VII proves the deterministic theory. It consists of local existence of r on a short time interval with bounds uniform in the mesh (Theorem 24.5); smoothing after a positive time; continuation to any fixed time interval, by comparison with finitely many smooth solutions of the continuum flow (Theorems 24.10 and 25.7); and Lipschitz dependence of the flowed holonomies on the flow data (x, y) (Corollary 25.11). For smooth initial data the lattice flow converges to the continuum flow. Here we use the deterministic results of Cao and Chatterjee [42, 43], which rest on the global theory of Råde [139] and of Charalambous and Gross [47].

3.6 Stochastic estimates and convergence of flowed loops

In Part VIII we prove two facts about the flow data (x, y) of the reconstructed fine field under the conditioned Wilson measure. First, it is bounded in the norms of Section 3.5 with high probability, uniformly in the number of steps. Second, it is well approximated by the flow data of the field reconstructed from finitely many steps. At each step the new fluctuations contribute four terms: a conditionally centered linear term, a conditionally centered nonlinear term, an interpolation defect, and a predictable term (Lemma 26.2). We estimate all sixteen ordered products of these terms in the quadratic Picard term y (Sections 26 and 27). We keep their conditional means, which are nonzero, and we treat both orders of each product, since $\mathcal{N}_a$ is not symmetric. At mesh a the linear fluctuation contributes $g_3 a^{\alpha-1/2}\sqrt{\log(2 + L/a)}$, which is summable over the geometric sequence of meshes since $\alpha > 1/2$.

Given these estimates, we compare the flowed Wilson loops of the fine configuration with those of the configuration reconstructed from the coarse field and the fluctuations of a fixed number q of steps. They are close in probability, uniformly in the total number of steps. The latter configuration is a smooth interpolation of a finite-dimensional random variable whose law converges as $K \to \infty$, by Section 3.3. Further, the flow of a fixed smooth field converges to the continuum flow. Letting first $K \to \infty$ and then $q \to \infty$, we find that the laws of flowed Wilson loops under the conditioned Wilson measure converge (Theorem 28.1). Together with (3.1) and the bound on large fields, this gives convergence under the Wilson measure (Theorem 28.2). We first prove these results when the coupling of the coarse lattice is below a small ceiling, and then extend them to every fixed γ by taking the coarse side large (Lemma 28.11 and Theorem 29.21). This proves part (1) of Theorem 2.3 along the subsequences $N_K = n_* B^K$.

3.7 Construction of the limiting measure

Convergence of finite families of flowed Wilson loops does not by itself produce a measure on $\mathcal{X}_L$. We obtain one as follows (Section 29). For each fixed number q of steps, the field reconstructed from q steps is smooth after interpolation, and its continuum flow defines a random element of $\mathcal{X}_L$. These random trajectories have energies that are tight uniformly in q at each of the times $s_j = L^2 2^{-j}$. Indeed, the lattice energy along the flow is controlled by the stochastic estimates, and it does not increase in time. The sets of trajectories whose energies at the times s_j are bounded by given numbers R_j, for all j, are compact, by results of Cao and Chatterjee that rest on Uhlenbeck's compactness theorem. Hence these laws converge along subsequences, and the joint laws of flowed Wilson loops identify the limit. The joint convergence of energies and Wilson loops follows from a comparison with the smooth fields reconstructed from finitely many steps, together with the continuity of the energy after a positive time in the Sobolev setting of Cao and Chatterjee (Theorem 29.18).

We also want to realize the limit as a limit of the lattice measures themselves. For this purpose we construct measurable gauge-invariant maps π_K from lattice configurations to $\mathcal{X}_L$. We enumerate the trajectories of the continuum flow started from trigonometric polynomials with rational coefficients. Given a lattice configuration, π_K selects the first trajectory in this list with the following two properties: its first m determining coordinates are within 2^{-m} of the flowed lattice Wilson loops, and its energies at m fixed positive times are at most the lattice energies plus 2^{-m}. If there is no such trajectory, π_K selects the zero trajectory. With $m = m(K)$ increasing slowly, these maps have the properties in part (3) of Theorem 2.3, and the energy constraint gives the tightness in part (4) (Theorems 29.19 and 29.20).

Finally, the passage from the subsequences $n_* B^K$ to the full sequence nM^k is arithmetic. Since the construction works for every sufficiently large J, we may take two consecutive values J and $J+1$. Every residue class of k modulo J contains infinitely many k for which nM^k also belongs to a sequence of the form $n' M^{(J+1)K}$, and hence the limits along the different residue classes coincide (Theorem 29.28). We prove the remaining parts of Theorem 2.5 in Section 30.

3.8 Short distances

For the short-distance theorem we fix γ and a coarse side. We study the heat-smoothed circulation of the reconstructed field around a small loop $x + \varepsilon\ell$, normalized by $\sqrt{g_3^2 \varepsilon}$. Adding the fluctuations step by step, we write this circulation as the sum of three terms: a contribution from the coarse field, a martingale whose increments are linear in the new normalized fluctuations, and a small nonlinear error (Section 31). A useful observation is that the linearized successive background fields differ from a single background field

by a periodic gradient, which the closed circulation does not see. We compare each martingale increment to a Gaussian, by an integration by parts adapted to the cutoff on the fluctuations, in the spirit of Stein's method [147]. The sum of the conditional covariances converges to the covariance (2.6) of the free field, as $\varepsilon \to 0$ after the lattice spacing (Theorem 31.6 and Section 32). The contribution of the coarse field vanishes in the limit because the loop shrinks. We then compare the flowed Wilson loop with the circulation, using the stability of the flow and the expansion $1 - \operatorname{tr} e^V/2 = |V|^2/8 + O(|V|^4)$ (Lemma 32.11). We carry out this analysis under the conditioned Wilson measure and in the fixed gauge of the reconstruction. To obtain the gauge-invariant statement under λ, we take the limits in the following order: the lattice spacing to zero; then $\varepsilon \to 0$ at a fixed coarse side and with a fixed cutoff on the flow data; then the removal of that cutoff; and finally the coarse side to infinity. The asymptotic independence from macroscopic observables has a simple reason: the Gaussian approximation holds uniformly conditionally on any fixed number of coarse steps, while a macroscopic flowed observable is close to a function of finitely many coarse steps.

3.9 Weak coupling

For the weak-coupling results we fix, before γ varies, the parameters of the construction and a coarse side u in the class $[n]_M$, larger than certain thresholds; by Theorem 2.3(5) this does not change λ_γ. As $\gamma \to 0$ at this fixed coarse side, every scale of the hierarchy becomes weakly coupled, and the analysis takes place on the coarse lattice. Section 33 develops the geometry near flat connections and Laplace's method on the coarse lattice. The density of the coarse configuration at the end of the renormalization group is proportional to $\mathbf{1}_{D_r} \exp(-uE_d/\gamma - R + R(I))$, and its normalizing constant is comparable to γ^{3u^3-1}, uniformly in the number of finer steps (Theorem 33.10). Near a regular flat connection, the integral over the directions transverse to the flat connections is Gaussian. In Section 34 we compare the reconstructed field with the field in which all fluctuations beyond a fixed number of steps are set to zero. Under the conditioned Wilson measure, their flowed holonomies differ by $O(\sqrt{\gamma})$ in L^p, uniformly in the number of steps and in small γ (Theorems 34.9 and 34.10). This gives the concentration on flat connections in Theorem 2.9.

For Theorem 2.10, recall that the normal covariance Σ_θ is the covariance of the linear response of the flowed logarithms at a regular flat connection. We compute it explicitly in Theorem 33.11. The theorem then follows from Gaussian integration at finitely many scales and the transfer estimates of Section 34 (Section 35). We take the limits in the following order: the continuum limit, then $\gamma \to 0$ at a fixed number of scales, and then the number of scales to infinity.

For Theorem 2.11, the starting point is an exact Taylor expansion of the effective classical action of a constant configuration, $E_d(e^{X/u}) = Q(X)/u + O(|X|^5)$, where Q is the constant-mode quartic form and the remainder is uniform in the depth d (Theorem 36.2). We integrate out the nonconstant modes with Gaussian estimates. This leaves a nine-dimensional integral against $e^{-Q(Y)}$ on the scale $Y = X/\gamma^{1/4}$, multiplied by a positive factor that is bounded above and below (Theorem 36.6). This factor is the same for all test functions, so it cancels in the ratios (2.7). The expectation of a compactly supported test function at this scale is of order $\gamma^{1/4}$, which comes from the volume $\gamma^{9/4}$ of the constant modes, compared with the order γ^2 of the normalization. We then transfer the result from the reconstructed holonomies to the flowed holonomies of the field. For this we use an estimate that is conditional on the coarse configuration (Theorem 34.11). An estimate averaged over the coarse configuration would lose the factor $\gamma^{1/4}$ when divided by this small expectation.

3.10 Order of choices and dependence of constants

Many statements in the paper are uniform in some parameters and not in others, and the order in which parameters are chosen matters. We describe the convention used throughout in Definition 4.14. In brief, we choose the integer J first, using only estimates that are uniform in J. Then we compute all local constants at that J. They are uniform in the lattice side, the number of averaging steps, the coupling below the relevant ceiling, and, in the localized analysis, the shape of the regions. Finally we choose the minimum coarse side. Statements at fixed γ may have constants that depend on γ; these include the convergence of flowed loops, the construction of λ, and the short-distance theorem. The bound on large fields and the weak-coupling estimates are uniform in γ below fixed ceilings.

SECTION 4

Notation and conventions

This section fixes the notation and conventions used in the rest of the paper. Section 2 introduced the lattice model, the Wilson flow, admissible approximations of loops, and the trajectory space, and Section 3 described the objects of the renormalization group analysis informally. Here we give the precise definitions that the later sections cite. A definition here fixes the meaning of a symbol; the existence of the object, its analytic properties, and the probability estimates for it are proved where it is constructed, and we say where in each case. A choice of letter never implies a uniformity: the parameters on which a constant depends are listed in each statement, or by reference to an item of Definition 4.14. We write $\mathbb{N} = \{1, 2, \dots\}$; depths and the index K may also be zero.

Sections 4.1 to 4.3 fix the lattice model, the block averaging map, and the measures of the renormalization group analysis: the Wilson measure, the small-field event, the conditioned Wilson measure, the stopped measure, and the conditional fluctuation kernel. Sections 4.4 to 4.9 fix the analytic coefficient norms, the conventions for polymer expansions and exponential moments, the flow conventions, the heat-smoothed circulation, the continuum trajectory space, and the weak-coupling observables, and Section 4.10 describes the dependence of constants.

4.1 The periodic lattice and the Wilson measure

The following definition restates the model of Section 2.1 in the notation of the later sections, where n denotes a lattice side.

Definition 4.1. Let $L > 0$ and let $n \geq 4$ be an integer. Set

$$\Lambda_n = (L/n)\mathbb{Z}^3/(L\mathbb{Z})^3, \qquad a_n = L/n.$$

A positive link is a pair $(x, x + a_n e_i)$ with $x \in \Lambda_n$ and $i \in \{1, 2, 3\}$, and $\mathcal{E}_n$ is the set of these $3n^3$ links. A positive plaquette is the positively oriented boundary $p_{ij}(x)$ of the square spanned by $a_n e_i$ and $a_n e_j$ at x, with $i < j$, and $\mathcal{P}_n$ is the set of these $3n^3$ plaquettes. A configuration is an element U of $\mathcal{U}_n = \mathrm{SU}(2)^{\mathcal{E}_n}$. For the reversed link $\bar{e}$ of a positive link e we set $U_{\bar{e}} = U_e^{-1}$, and the transport along a path $e_1 \cdots e_m$ is the ordered product $U_{e_1} \cdots U_{e_m}$. Writing $U_i(x)$ for the variable on the link $(x, x + a_n e_i)$, we have

$$U_{p_{ij}(x)} = U_i(x) U_j(x + a_n e_i) U_i(x + a_n e_j)^{-1} U_j(x)^{-1}.$$

Let H be the Haar measure on $\mathrm{SU}(2)$ with $H(\mathrm{SU}(2)) = 1$, and let $H_n = \bigotimes_{e \in \mathcal{E}_n} H$. Let $\gamma > 0$, and set

$$q(U) = 1 - \frac{1}{2}\operatorname{tr} U, \qquad S_W(U) = 4 \sum_{p \in \mathcal{P}_n} q(U_p), \qquad h_n = g_n^2 = \frac{\gamma}{n}, \qquad \gamma = g_3^2 L.$$

The Wilson measure is the probability measure

$$d\mu_{n,\gamma}(U) = Z_{n,\gamma}^{-1} e^{-S_W(U)/h_n}\, dH_n(U)$$

on $\mathcal{U}_n$, where $Z_{n,\gamma}$ is the normalizing constant.

Since $S_W/h_n = (4n/\gamma)\sum_p q(U_p)$, this is the measure (2.1). The parameter γ is the dimensionless coupling, $g_3^2 = \gamma/L$ is the continuum coupling, and $h_n = g_n^2 = g_3^2 a_n$ is the lattice coupling at side n; in the usual notation the inverse coupling is $\beta_n = 4/h_n$. The letter n always denotes a lattice side, the number of sites in each coordinate direction, and never a depth. We write d and d_0 for classical depths (numbers of preceding averaging steps over which the classical action has been minimized), and ℓ for the index of an averaging step. The plaquette action is Wilson's [153]; the factor four and the identification $h_n = g_3^2 a_n$ are our normalization, explained in the following remark.

Remark 4.2. Let A be a smooth $\mathfrak{su}(2)^3$-valued function on $\mathbb{T}_L^3$, and set $U_e = \exp(a_n A_i(x))$ for $e = (x, x + a_n e_i)$. By the Baker–Campbell–Hausdorff formula, $\operatorname{Log} U_{p_{ij}(x)} = a_n^2 F_{ij}(x) + O(a_n^3)$ uniformly in x, where $F_{ij} = \partial_i A_j - \partial_j A_i + [A_i, A_j]$. By (4.2) below, $q(e^X) = |X|^2/8 + O(|X|^4)$. Since $h_n = g_3^2 a_n$ and $|\mathcal{P}_n| = 3n^3$, we obtain

$$\frac{S_W(U)}{h_n} = \frac{1}{2g_3^2} \sum_{x \in \Lambda_n} \sum_{i<j} a_n^3 |F_{ij}(x)|^2 + O(a_n) \longrightarrow \frac{E_L(A)}{2g_3^2} \qquad (n \to \infty),$$

where $E_L(A) = \sum_{i<j} \int_{\mathbb{T}_L^3} |F_{ij}|^2\, dx$ is the Yang–Mills energy (2.3). This computation concerns smooth configurations only; it says nothing about typical configurations under $\mu_{n,\gamma}$.

Gauge transformations. A lattice gauge transformation is an element k of $\mathcal{G}_n = \mathrm{SU}(2)^{\Lambda_n}$. It acts on configurations by

$$(U^k)_{xy} = k_x U_{xy} k_y^{-1}, \qquad (U^k)^l = U^{lk}. \tag{4.1}$$

A based gauge transformation is a lattice gauge transformation equal to the identity at specified vertices, its roots. Under a gauge transformation, the transport around a closed path is conjugated by the value at its basepoint. Hence, among the functions of a tuple of holonomies along closed paths with a common basepoint, only those invariant under simultaneous conjugation are gauge invariant, while a based gauge transformation whose roots include the basepoint leaves these holonomies unchanged. All gauge transformations in this paper are periodic; we do not consider twisted boundary conditions.

The Lie algebra. Let $\tau_a = -i\sigma_a/2$, where $\sigma_1, \sigma_2, \sigma_3$ are the Pauli matrices. For $X = x^a\tau_a$ and $Y = y^a\tau_a$ in $\mathfrak{su}(2)$ we use

$$[\tau_a, \tau_b] = \epsilon_{abc}\tau_c, \qquad \langle X, Y\rangle = -2\,\mathrm{tr}(XY), \qquad |X| = |x|.$$

Then (τ_a) is an orthonormal basis, and the bracket corresponds to the cross product in $\mathbb{R}^3$. This is the inner product of Section 2.1, and on $\mathcal{U}_n$ we use the product of the corresponding bi-invariant Riemannian metrics. The group distance from the identity is

$$\rho_G(U) = \min\{|X| : e^X = U\} \in [0, 2\pi].$$

In analytic calculations, Log denotes the logarithm near the identity, continued holomorphically only inside a specified complex neighborhood of the identity. The principal real logarithm is defined on $\mathrm{SU}(2) \setminus \{-I\}$ and satisfies $|\mathrm{Log}\, U| < 2\pi$. There is no continuous logarithm on all of $\mathrm{SU}(2)$.

In these coordinates the Haar measure and the plaquette function are given by

$$\begin{aligned} dH(e^X) &= \frac{1}{16\pi^2}\,\mathrm{sinc}^2(|X|/2)\,d^3X \quad (|X| < 2\pi), \\ q(e^X) = 1 - \cos(|X|/2) &= \frac{|X|^2}{8} + O(|X|^4), \qquad \mathrm{sinc}\, z = \frac{\sin z}{z}, \quad \mathrm{sinc}\, 0 = 1. \end{aligned} \tag{4.2}$$

Integrating the first formula in polar coordinates, we find $H\{\rho_G < \varepsilon\} = (\varepsilon - \sin\varepsilon)/(2\pi)$ for $0 \le \varepsilon \le 2\pi$; for $\varepsilon \ge 2\pi$ this probability is one. These identities, and the estimates for products of finitely many group elements near the identity, are proved in Lemma 5.1. We write $c_{\mathrm{Haar}} = 1/(16\pi^2)$ for the constant in the coordinate density and $j_H(X) = \mathrm{sinc}^2(|X|/2)$ for its variable factor. The constant c_{Haar} is unrelated to the lower-bound constants in partition-function estimates with open boundary conditions.

4.2 Lattice refinements and the block averaging map

Fix an odd integer $M = 2R_M + 1 \ge 3$ and an integer $J \ge 1$, and set $B = M^J$. At total depth $K \ge 0$ the fine side is $N = n_* B^K$ with $n_* \in 4\mathbb{N}$, and for $0 \le \ell \le JK$ we set

$$n_\ell = N/M^\ell, \qquad a_{n_\ell} = L/n_\ell, \qquad g_\ell^2 = h_\ell = \gamma/n_\ell, \qquad V^\ell = T_M^\ell U,$$

where T_M is the block averaging map of Definition 4.3 below. Increasing ℓ moves toward the infrared. Since M is odd, all the sides n_ℓ are divisible by four. Schematically,

$$U \in \mathcal{U}_N \xrightarrow{T_M} V^1 \in \mathcal{U}_{n_1} \xrightarrow{T_M} \cdots \xrightarrow{T_M} V^{JK} \in \mathcal{U}_{n_*},$$

and the scales are as follows.

averaging step ℓ	side n_ℓ	mesh a_{n_ℓ}	coupling g_ℓ^2
0	N	L/N	γ/N
ℓ	$NM^{-\ell}$	LM^ℓ/N	$\gamma M^\ell/N$
JK	n_*	L/n_*	γ/n_*

As in Section 3.2, one application of T_M is an averaging step, and a renormalization group step (RG step) consists of J consecutive averaging steps, $V^{(k+1)J} = T_M^J V^{kJ}$, with blocking factor B.

We also use compositions of s averaging steps, $1 \le s \le J$, from an input side $M^s m$ to an output side $m \ge 4$, with an arbitrary preceding classical depth d_0. The fields on the s lattices of sides $Mm, \dots, M^s m$ are integrated. We call these lattices the integrated scales of the composition, and reserve the term intermediate scales for the J lattices of an RG step. The largest coupling of an integrated scale is attained at side Mm and is denoted by

$$t_{\max}^2 = \frac{\gamma}{Mm}.$$

If the integrated scales are numbered $i = 0, \dots, s-1$, from side $M^s m$ for $i = 0$ to side Mm for $i = s-1$, then the coupling g_i of scale i (not its square) satisfies $g_i / t_{\max} = M^{(i-s+1)/2}$. These ratios lie between $\lambda_* = M^{-(J-1)/2}$ and 1. The physical mesh is always denoted by a, never by h.

The equivalence relation $n \sim_M n'$ and the classes $[n]_M$ were defined in Section 2.3, and the index $[n_*]$ of the continuum measure $\lambda_{L,\gamma,[n_*]}$ refers to the class $[n_*]_M$. The measure is first constructed along the sides $n_* B^K$; by Theorem 29.28, it is the measure attached to the whole class. The small-field event and the bounds on its complement are always formulated with RG steps of J averaging steps.

Definition 4.3. We work in fine lattice units, so that the fine lattice is $\mathbb{Z}^3$ with its periodic identification and the coarse vertices are the points of $M\mathbb{Z}^3$. For a coarse vertex v, the centered block of v is

$$\mathsf{B}_M(v) = v + \big([-R_M, R_M]^3 \cap \mathbb{Z}^3\big).$$

For $x \in \mathsf{B}_M(v)$, let $\sigma_{v,x}$ be the lattice path from v to x that changes the coordinates in the order $1, 2, 3$, each monotonically. For the coarse link $c = (v, v + Me_i)$, let C_c be the straight path from v to $v + Me_i$, called the reference path, and for $x \in \mathsf{B}_M(v)$ let

$$F_{c,x} = \sigma_{v,x}[x, x + Me_i]\, \sigma^{-1}_{v+Me_i, x+Me_i}.$$

The paths $F_{c,x}$ and C_c both go from v to $v + Me_i$, so $U(F_{c,x})U(C_c)^{-1}$ is the holonomy of the closed path $F_{c,x}C_c^{-1}$ based at v; we call these matrices the based loop holonomies of c. If none of the based loop holonomies $U(F_{c,x})U(C_c)^{-1}$, $x \in \mathsf{B}_M(v)$, equals $-I$, define

$$(T_M U)_c = \exp\Big\{ M^{-3} \sum_{x \in \mathsf{B}_M(v)} \operatorname{Log}\big(U(F_{c,x})U(C_c)^{-1}\big) \Big\} U(C_c), \tag{4.3}$$

where Log is the principal logarithm. If one of these based loop holonomies equals $-I$, set $(T_M U)_c = U(C_c)$. The variable on a reversed coarse link is the inverse of the variable on the positive link. For $J \geq 1$, T_M^J denotes the J-fold iterate of T_M.

The second clause, the Borel extension of the block averaging map, is part of the definition: T_M is defined on the whole configuration space. The iterate T_M^J is never replaced by a separately defined average with blocking factor B.

This construction follows Bałaban's averaging operation [12, (15), p. 19, and (42), p. 23]: one transports the fine link variables to a reference path, averages the logarithms of the based loop holonomies, and exponentiates. The centered blocks, the particular paths, and the Borel extension are specific to this paper. Under a gauge transformation k, every based loop holonomy is conjugated by k_v. The principal logarithm commutes with conjugation, and the exceptional value $-I$ is invariant under conjugation. Hence $T_M(U^k) = (T_M U)^{k'}$, where k' is the restriction of k to the coarse vertices. The following properties are proved in Proposition 6.2: T_M is Borel and gauge covariant; it is covariant under translations by coarse vectors and under the reflections preserving the coarse lattice, including at the exceptional values; the identity $T_M U_0(b) = b$ below holds; and the blocks of iterates of T_M are nested. The constraint coordinates described next are constructed in Lemma 6.3.

Constraint coordinates. Let b be a coarse configuration. The coarse-field lift $U_0(b)$ is the fine configuration equal to I on every link inside a block and to b_c on every link from $\mathsf{B}_M(v)$ to $\mathsf{B}_M(v + Me_i)$, for $c = (v, v + Me_i)$. Each path $F_{c,x}$, and the path C_c, crosses exactly one such interface link, so all based loop holonomies of $U_0(b)$ equal I and $T_M U_0(b) = b$. In each block, the links of the paths $\sigma_{v,x}$ form a spanning tree rooted at the coarse vertex (Proposition 6.2). A based gauge transformation with roots at the coarse vertices sets the variables on these block trees equal to I; this is the block axial gauge. For the coarse link $c = (v, v + Me_i)$, the eliminated edge is the interface link

$$e_c^* = (v + R_M e_i,\, v + (R_M + 1)e_i)$$

on the reference path. We write $U = e^X U_0(b)$ on the links outside the block trees. The block averaging constraint for c reads

$$\mathsf{C}_{b,c}(X) = \mathrm{Log}\big((T_M U)_c b_c^{-1}\big) = 0, \qquad D_{X_{e_c^*}} \mathsf{C}_{b,c}(0) = M^{-2} I_3.$$

To compute the derivative, note that $X_{e_c^*}$ enters $U(C_c)$ and, through $U(C_c)^{-1}$, the $M^3 - M$ based loop holonomies with x off the line through v in direction e_i; those with x on this line do not depend on $X_{e_c^*}$. At $X = 0$ the derivative is therefore $(1 - (M^3 - M)M^{-3})I_3 = M^{-2} I_3$. Near $X = 0$ the constraints are solved by local constraint coordinates $X = \Gamma_b(z)$, where the free logarithmic coordinates z are the logarithms on the links outside the block

trees other than the eliminated edges. On this branch, the Haar disintegration density with respect to $dH_m(b)\,dz$ is

$$\mathscr{J}_b(z) = c_{\text{Haar}}^f \frac{\prod_{e \text{ outside the block trees}} j_H(\Gamma_{b,e}(z))}{\prod_c \det D_{X_{e_c^*}} \mathsf{C}_{b,c}(\Gamma_b(z))}, \tag{4.4}$$

where f is the number of independent free group variables; for one averaging step from side Mm to side m, $f = 2((Mm)^3 - m^3)$. The numerator includes the Haar factors j_H of the eliminated edges, and there is no additional Haar density for the coarse field, no Gram determinant, and no residual gauge-volume factor. The formula is used only on the local branch, on which the determinants are positive, and with all domain indicators retained; the precise statement, with its domain, is Lemma 6.3. This change of variables is the spanning-tree-gauge form of the disintegration of Haar measure for this averaging constraint. Spanning-tree gauges are standard in lattice gauge theory, and Bałaban used them in the renormalization group context [14].

Under product Haar measure, the integral over the gauge transformations at the vertices of the block trees other than their roots has mass one. We keep this integral explicitly until the gauge invariance of the integrand has been established. In the constructions on block regions of Sections 18 to 21, some group variables are frozen coordinates. The based transport of a frozen coordinate b_e, which carries it to its basepoint, is $\widehat{b}_e = U(\sigma_e)b_e$. If the variables of the block region are held fixed, the change $b_e \mapsto \widehat{b}_e$ is a triangular Haar translation, and it preserves product Haar measure. Frozen coordinates remain indexed by the lattice on which they were frozen.

4.3 Effective actions, the small-field event, and conditioned measures

The effective classical action and the effective interaction. For $d \geq 0$, E_d denotes the effective classical action at preceding classical depth d, and $E_0 = S_W$. It is the value of the constrained minimization problem on the local branch constructed in Sections 9 and 10, and it satisfies

$$E_{d+1}(c) = M \min_z E_d(b(c,z))$$

on the common domain of these local constructions (Theorem 10.10). Here $b(c,z)$ parametrizes the configurations on the intermediate lattice whose average is c, and the factor M is the change of units in three dimensions. This notation does not refer to an unrestricted minimum over the compact fiber of T_M^d. Following Bałaban [16], we call the constrained minimizer the background field. We write R_d for the effective interaction that accompanies E_d in the effective density, and Λ for the normalization constant in the log density, which collects the factors independent of the field. The analytic norm of R_d controls no additive constant.

Normalized fluctuation variables. In an RG step, the free logarithmic coordinates z_i of the intermediate scale i are written as

$$z_i = z_i^*(c, z_{>i}) + g_i K_i(c, z_{>i})^{-1/2} w_i, \tag{4.5}$$

where c is the coarse field, $z_{>i}$ are the coordinates of the coarser intermediate scales, and z_i^* is the conditional constrained minimizer. Further, K_i is the constrained Hessian (a positive definite matrix) in the free coordinates of scale i at z_i^*, $K_i^{-1/2}$ is the inverse of its positive square root, and g_i is the coupling of scale i. The w_i are the normalized fluctuation variables; they differ from z_i/g_i. The map $w \mapsto z$ is triangular, with diagonal blocks $g_i K_i^{-1/2}$. Its Jacobian is therefore exactly

$$\prod_i g_i^{3f_i} \det K_i(c, z_{>i})^{-1/2},$$

where f_i is the number of free group variables of scale i. Its value at $w = 0$ and the logarithm of its ratio to that value are two parts of this single factor; neither is counted twice. The change of variables is carried out in Lemma 12.3.

Reconstruction maps. We write $\widehat{\mathscr{R}}$ for the fixed family of reconstruction maps of Theorem 15.12. These maps differ from the reconstructions in the depth-dependent gauge representatives by gauge transformations that depend only on the coarse field and equal the identity at the coarse roots. On each fixed lattice, the depths at which the family switches representatives are finite and deterministic, and they do not depend on the coupling, on configurations, or on observables. The family preserves the conditional fluctuation kernels and the fluctuation cutoffs defined below. Its construction, and the preservation of the analytic coefficient bounds on the larger domains, are in Section 15. The hat does not assert equality with the depth-dependent representatives.

The small-field event. The following definition makes the description in Section 2.5 precise.

Definition 4.4. Let $0 < r < \rho$, where ρ is the analytic radius of Section 4.4, and set

$$B_r = \{\exp A : \max_e |A_e| < r\}, \qquad D_r = \mathcal{G}B_r,$$

where $\mathcal{G}B_r$ is the set of all U^k with $U \in B_r$ and k a lattice gauge transformation. We call B_r the small-link domain and D_r the gauge-invariant small-field domain. Fix the parameters of Definition 14.4; in particular J, r, ρ, and $A_{\mathrm{w}} > 0$ are fixed. Let $u \in 4\mathbb{N}$, $K \geq 0$, $N = uB^K$, $V^\ell = T_M^\ell U$, and let $\gamma > 0$ be such that $t_k < 1$ for $0 \leq k < K$, where

$$t_k^2 = \frac{\gamma}{M n_{(k+1)J}}, \qquad p_{\mathrm{w}}(t) = A_{\mathrm{w}} \log(1/t).$$

For $0 \le k < K$, let $\mathcal{A}_{k,J}(U)$ be the event that the k-th RG step, from V^{kJ} to $V^{(k+1)J}$ at preceding classical depth kJ, is defined at U. This means that each pair formed by an intermediate coarse field and the free coordinates of the next finer scale lies in the local branch of the constraint coordinates and in the domains of the background field and of the Haar disintegration density, with positive Jacobian determinants, as specified in Definition 14.4. On $\mathcal{A}_{k,J}(U)$, let $w_{k,i,e}(U)$ be the normalized fluctuation variables of this step, obtained by inverting the step. The small-field event is

$$S_{N,u,\gamma} = \{U \in D_r\} \cap \bigcap_{k=0}^{K-1} \Big[\mathcal{A}_{k,J}(U) \cap \Big\{ \max_{i,e} |w_{k,i,e}(U)| \le p_{\mathrm{w}}(t_k) \Big\} \cap \{V^{(k+1)J} \in D_r\} \Big]. \tag{4.6}$$

For $K = 0$, the event is $\{U \in D_r\}$.

The domain conditions in $\mathcal{A}_{k,J}$ are the inverse-branch, classical-domain, and positive-Jacobian conditions of the construction, with their fixed radii. There is no additional D_r condition at an intermediate scale inside an RG step. The coupling t_k is the largest coupling of an integrated scale in the k-th RG step, and it is largest for $k = K - 1$, where $t_{K-1}^2 = \gamma/(Mu)$. The condition $t_k < 1$ for all k therefore means $\gamma < Mu$ when $K \ge 1$, and it ensures that the thresholds $p_{\mathrm{w}}(t_k)$ are positive. The analysis in Section 14 restricts γ further, by requiring $t_k \le t_*$ for a small upper bound t_*.

Lemma 4.5. *Under the assumptions of Definition 4.4, $\mu_{N,\gamma}(S_{N,u,\gamma}) > 0$.*

Proof. We show that $S_{N,u,\gamma}$ contains a nonempty open set. Near the identity configuration I all based loop holonomies in (4.3) are close to I, so the first clause of Definition 4.3 applies and the iterates T_M^ℓ are real analytic on a neighborhood of I, with $T_M^\ell(I) = I$. At $U = I$, every intermediate coarse field equals I and every free coordinate vanishes. The background field of the coarse field I is I, since I minimizes the Wilson action, so the conditional constrained minimizers vanish as well. Each domain condition in Definition 14.4 is a strict inequality on the logarithms of the coarse fields, on the free coordinates, on $\Gamma_c(z)$, and on the classical data, or the positivity of a determinant. At $U = I$ these quantities equal zero, and the determinants equal $\det(M^{-2} I_3) = M^{-6} > 0$. By Lemma 6.3 and the constructions of Sections 10 and 12, the inverse coordinates of the RG steps are continuous functions of U near I. Hence there exists a neighborhood O_1 of I contained in $\bigcap_{k<K} \mathcal{A}_{k,J}$. On O_1, the variables $w_{k,i,e}$ are continuous and vanish at I. Since $p_{\mathrm{w}}(t_k) > 0$ for every k, there exists a smaller neighborhood $O_2 \subset O_1$ of I on which $\max_{i,e} |w_{k,i,e}| \le p_{\mathrm{w}}(t_k)$ for all $k < K$. Finally, B_r is open, $I \in B_r \subset D_r$, and the maps $T_M^{(k+1)J}$ are continuous at I with value I. Hence there exists a neighborhood $O \subset O_2$ of I on which U and all $V^{(k+1)J}$ lie in B_r, and $O \subset S_{N,u,\gamma}$.

Since $0 \le q \le 2$, we have $S_W \le 24N^3$, and $Z_{N,\gamma} \le 1$. The density of $\mu_{N,\gamma}$ with respect to H_N is therefore at least e^{-24N^3/h_N}. The Haar measure of a compact group gives positive mass to every nonempty open set, so

$$\mu_{N,\gamma}(S_{N,u,\gamma}) \ge e^{-24N^3/h_N} H_N(O) > 0. \qquad \square$$

The three measures. Let $m \ge 4$ be a lattice side and $d \ge 0$ a preceding classical depth for which E_d and R_d have been constructed. Let $E_{d,\mathrm{sat}}$ be the gauge-invariant extension of E_d to D_ρ, $E_{d,\mathrm{sat}}(U) = E_d(U^k)$ for $U^k \in B_\rho$ (Theorem 11.6), and let $\overline{R}_d = R_d - R_d(I)$ be the centered effective interaction, extended to D_r in the same way. The stopped measure at side m and depth d is

$$d\widehat{\nu} = \widehat{Z}^{-1} \mathbf{1}_{D_r} e^{-E_{d,\mathrm{sat}}/g_m^2 - \overline{R}_d}\, dH_m, \qquad \overline{R}_d = R_d - R_d(I).$$

Under the hypotheses of Theorem 14.8, we have $E_{d,\mathrm{sat}} \ge \kappa_* E_0 \ge 0$ and $|\overline{R}_d| \le C$ on D_r, for constants κ_*, C depending on the fixed lattice. The integrand is then a strictly positive bounded Borel function. Since D_r contains the nonempty open set B_r, we have $0 < \widehat{Z} < \infty$. The stopped measure is defined only in this situation.

Whenever $\mu_{N,\gamma}(S_{N,u,\gamma}) > 0$, in particular under the assumptions of Definition 4.4, we compare the three measures

$$\mu_{N,\gamma}, \qquad \nu_{N,u,\gamma} = \mu_{N,\gamma}(\,\cdot \mid S_{N,u,\gamma}), \qquad \widehat{\nu}, \tag{4.7}$$

namely the Wilson measure, the conditioned Wilson measure, and the stopped measure just defined. At an intermediate stopping side, the marginal of the conditioned Wilson measure generally differs from the stopped measure, because it also includes the restrictions of the remaining coarser RG steps. At the terminal side $m = u$ no such restriction remains, and the law of V^{KJ} under $\nu_{N,u,\gamma}$ is the stopped measure at depth KJ (Theorem 14.8(9)). An exponential-moment estimate over a range of scales that starts from the unconditioned Wilson measure uses $\mu_{N,\gamma}$ itself, without a D_r restriction.

The auxiliary integral. For coarse fields outside B_r, in the larger analytic domain, the effective interaction is defined recursively by an analytic, positive product integral, the auxiliary integral of Theorem 14.6. It is not the conditional integral of the preceding restricted measure, although the two agree for coarse fields in B_r. The reconstructions it uses for coarse fields in the larger domain need only take values in B_ρ. This distinction between the radii r and ρ is part of the construction in Section 14.

The conditional fluctuation kernel. Fix a coarse field c in the domain of an RG step. The conditional fluctuation kernel of the normalized fluctuation variables $w = (w_{i,e})$ of the step is

$$k(c, dw) = \frac{\mathbf{1}_{\Omega_p}(w) e^{-V(c,w)}\, dw}{\int_{\Omega_p} e^{-V(c,w)}\, dw}, \qquad \Omega_p = \prod_{i,e} \{w_{i,e} \in \mathbb{R}^3 : |w_{i,e}| \le p_i\}. \tag{4.8}$$

Here the conditional fluctuation potential $V(c, w)$ contains $|w|^2/2$, all higher-order terms of the classical action in the fluctuations, the terms from the Haar disintegration density and from the Jacobian of (4.5) that depend on w, and the input effective interaction, produced by the integrations at finer scales, evaluated at the reconstructed field. Terms that depend on c but not on w cancel in the normalized kernel, and only there. For the kernels arising from the small-field event, $p_i = p_{\mathrm{w}}(t_k)$ for all intermediate scales of the k-th RG step. Products of truncated Gaussian measures serve as reference measures in expansions; they are not the conditional law. All conditional means, covariances, and derivatives of the conditional log-density refer to $k(c, dw)$ on its convex domain Ω_p. In particular, for a differentiable parameter λ on which V depends, with the coupling, the radii p_i, and the coordinates w held fixed, the normalized log-density derivative on Ω_p is $\partial_\lambda \log k = -\partial_\lambda V + \mathbb{E}_k \partial_\lambda V$ (Lemma 13.6). The kernel and its potential are constructed in Theorem 13.8.

The comparison lattice. For the index $s \geq 0$ of the comparison lattice we write $n_s = n_* B^s$ for its side, $H_s = L/n_s$ for its mesh, and $\nu_{K,s} = \nu_{N_K, n_s, \gamma}$ for $K \geq s$, where $N_K = n_* B^K$. The corresponding backward reconstruction sequence has physical meshes $a_j = H_s B^{-j}$, $0 \leq j \leq K - s$, and preceding classical depths $J(K - s - j)$. Once the coarse field of a step is fixed, its conditional fluctuation kernel is not changed by the restrictions at coarser scales, since these are functions of the coarse field alone.

4.4 Analytic coefficient norms

Effective interactions, background fields, and reconstruction maps are controlled by weighted sums of absolute values of Taylor coefficients. A bound of this kind controls derivatives on smaller domains (Lemma 5.3), is stable under products and substitutions, and measures locality through an exponential weight in the length of a network connecting the locations of the coefficient. Norms of this type are used throughout constructive renormalization group methods [17, 38, 96]; the coefficient norm with boundary decay (4.11) is specific to this paper. All indices below are scalar indices, which include orientation and color.

Definition 4.6. *Indices and networks.* Let I_σ be finite index sets, each with a location map $x : I_\sigma \to \mathbb{T}_L^3$, a mesh $a_\sigma > 0$, and the volume $v_\sigma = a_\sigma^3$, and write $v_i = v_\sigma$ for $i \in I_\sigma$. The assigned location $x(i)$ of an index is its position on the lattice on which it was introduced. Different indices may have the same location, and index sets introduced at different scales remain different. Distances and network lengths in the coefficient weights are measured in units of the current output lattice spacing a_{ref}, that is, $d(x, y) = d_{\mathrm{phys}}(x, y)/a_{\mathrm{ref}}$, where d_{phys} is the periodic Euclidean distance on $\mathbb{T}_L^3$; all index sets are embedded in this common metric, and dist below denotes d. The boundary graph distance d_Ω and the

boundary widths below are also expressed in output-mesh units. For a finite set S of locations let

$$\mathtt{t}(S) = \inf\{\mathrm{length}(\mathcal{N}) : \mathcal{N} \text{ a finite connected metric network containing } S\}.$$

Lengths are measured with d. Internal vertices are allowed, networks may wrap around the torus, and $\mathtt{t}(\{x\}) = 0$.

Tensor norms. Let $a_{\mathrm{sp}} \geq 0$. For a tensor $T(o; i_1, \dots, i_k)$ with an output index o and input indices $i_1, \dots, i_k$, set

$$\begin{aligned} R_{a_{\mathrm{sp}}}(T) &= \sup_{o} \sum_{i_1,\dots,i_k} e^{a_{\mathrm{sp}}\mathtt{t}(x(o),x(i_1),\dots,x(i_k))} |T(o; i_1, \dots, i_k)|, \\ C_{a_{\mathrm{sp}},r}(T) &= \sup_{i_r} \sum_{o,(i_s)_{s\neq r}} \frac{v_o}{v_{i_r}} e^{a_{\mathrm{sp}}\mathtt{t}(x(o),x(i_1),\dots,x(i_k))} |T(o; i_1, \dots, i_k)|, \qquad 1 \leq r \leq k, \\ |T|_{a_{\mathrm{sp}}} &= \max\{R_{a_{\mathrm{sp}}}(T), C_{a_{\mathrm{sp}},1}(T), \dots, C_{a_{\mathrm{sp}},k}(T)\}. \end{aligned} \tag{4.9}$$

The row norm $R_{a_{\mathrm{sp}}}$ fixes the output and sums over all inputs; the volume-normalized column sum $C_{a_{\mathrm{sp}},r}$ fixes the r-th input and sums over all other indices, including the output. For a kernel $K(x, y)$ from mesh a_{in} to mesh a_{out}, this reads

$$\|K\|_{\mathrm{row},a_{\mathrm{sp}}} = \sup_x \sum_y e^{a_{\mathrm{sp}}\,\mathrm{dist}(x,y)} |K(x,y)|, \qquad \|K\|_{\mathrm{col},a_{\mathrm{sp}}} = \sup_y \frac{a_{\mathrm{out}}^3}{a_{\mathrm{in}}^3} \sum_x e^{a_{\mathrm{sp}}\,\mathrm{dist}(x,y)} |K(x,y)|.$$

For positive input radii r_i we write $T[r](o; \mathbf{i}) = T(o; \mathbf{i}) \prod_s r_{i_s}$, so that every input, including a fixed one, contributes its radius. Normalizations of fields by couplings are written separately.

Majorant series. For an analytic map

$$F_o(u) = \sum_{k\geq 0} \frac{1}{k!} \sum_{i_1,\dots,i_k} F_k(o; i_1, \dots, i_k) u_{i_1} \cdots u_{i_k}, \qquad F_k = D^k F(0),$$

an absolute majorant is a convergent series $\widehat{F}(s) = \sum_k f_k s^k$ with $f_k \geq 0$ and $|F_k|_{a_{\mathrm{sp}}}/k! \leq f_k$. There is exactly one Taylor factorial.

Scalar functions. For a symmetric tensor $A(i_1, \dots, i_k)$ without output, $k \geq 1$, set

$$|A|^{\mathrm{sc}}_{a_{\mathrm{sp}}} = \max_r \sup_{i_r} \sum_{(i_s)_{s\neq r}} e^{a_{\mathrm{sp}}\mathtt{t}(x(i_1),\dots,x(i_k))} |A(i_1, \dots, i_k)|, \tag{4.10}$$

and write $\|D^k R(0)\|_{a_{\mathrm{sp}},\mathrm{root}} = |D^k R(0)|^{\mathrm{sc}}_{a_{\mathrm{sp}}}$. For an analytic scalar function R of the link coordinates on the torus with $DR(0) = 0$, set

$$\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R) = \sum_{k\geq 2} \frac{\rho^{k-2}}{k!} \|D^k R(0)\|_{a_{\mathrm{sp}},\mathrm{root}}.$$

Functions on a block region. Let Ω be a set of scalar labels of the variables that are still varied or integrated in a block region, let W be its boundary as in Section 18.1, and let $0 < \phi_i \le \rho$ be a radius profile. Here $d_\Omega(i)$ is the graph distance, on the refined position graph of Section 18.2, from the position of i to the set of positions outside Ω, as in Definition 18.1; it is expressed in units of the current output mesh. It differs from the periodic Euclidean distance d used for the connecting networks. Sections 18–20 use the graph-metric variant of (4.11) fixed before Definition 18.1, in which network lengths are also measured in the ℓ^1 metric of that graph; a coefficient bound at a Euclidean decay rate is used there at that rate divided by $\sqrt{3}$. Let b_{rec} range over the admissible set of real frozen coordinates of Definition 18.1. For $f(v; b_{\mathrm{rec}}) = \sum_\nu f_\nu(b_{\mathrm{rec}}) v^\nu$, with $v = (v_i)_{i\in\Omega}$ and $\phi^\nu = \prod_i \phi_i^{\nu_i}$, set

$$\mathcal{X}^{\phi}_{\Omega}(f) = \sup_{b_{\mathrm{rec}}\ \mathrm{real}} \rho^{-2} \sum_{k\ge 1} \sup_{i\in\Omega} e^{\alpha_{\mathrm{bd}} d_\Omega(i)} \sum_{|\nu|=k} \frac{\nu_i}{k} |f_\nu(b_{\mathrm{rec}})| e^{a_{\mathrm{sp}}\mathfrak{t}(\nu)} \phi^\nu, \tag{4.11}$$

where $\mathfrak{t}(\nu)$ is the network length of the locations of the indices in the support of ν, and $a_{\mathrm{sp}}, \alpha_{\mathrm{bd}} > 0$. The order of the operations in (4.11), namely the supremum over frozen coordinates, the sum over degrees, the supremum over the fixed label, and the sum over coefficients, is part of the definition. Constants have norm zero, and degree one is included. If Ω is empty, the norm is zero. If Ω has no boundary, (4.11) is applied only to functions with vanishing nonconstant part, whose norm is then zero; effective interactions on the full torus are measured by $\mathcal{B}_{\rho,a_{\mathrm{sp}}}$. The classical version of these norms has its own radius ρ_{cl} and its own profile and rate parameters.

A bound on $|T|_{a_{\mathrm{sp}}}$ controls the row and every volume-normalized column; it is stronger than a bound on the output rows alone or on an operator norm of T contracted with given directions. In (4.10) the sums with one index fixed are counting sums. We write $|A|^{\mathrm{sc},*}_{a_{\mathrm{sp}}}$ for the convention that multiplies each summand with the index i_r fixed by v_*/v_{i_r}, for a reference volume v_*. Then

$$|A|^{\mathrm{sc}}_{a_{\mathrm{sp}}} \le \max_i \frac{v_i}{v_*} |A|^{\mathrm{sc},*}_{a_{\mathrm{sp}}}, \qquad |A|^{\mathrm{sc},*}_{a_{\mathrm{sp}}} \le \max_i \frac{v_*}{v_i} |A|^{\mathrm{sc}}_{a_{\mathrm{sp}}},$$

where the maxima are over the possible fixed indices. On one mesh we choose v_* equal to its volume, and the two conventions agree; on several meshes the conversion is kept explicitly. The assumption $DR(0) = 0$ in the definition of $\mathcal{B}_{\rho,a_{\mathrm{sp}}}$ concerns the effective interactions. A constant is stored separately in Λ and is never bounded by $\mathcal{B}_{\rho,a_{\mathrm{sp}}}$. The precise definitions on block regions, including the frozen coordinates and the labels, are in Definition 18.1.

Remark 4.7. The weight ν_i/k in (4.11) is the sum (4.10) with the index i fixed, for a single monomial. Indeed, let $|\nu| = k$ and $\nu_i > 0$. The derivative $D_i D_{i_2} \cdots D_{i_k} (f_\nu v^\nu)(0)$ is nonzero

for exactly $(k-1)!/[(\nu_i-1)!\prod_{j\neq i}\nu_j!]$ ordered tuples $(i_2,\dots,i_k)$, and each nonzero value has modulus $|f_\nu|\prod_j \nu_j!$. Hence

$$\frac{1}{k!}\sum_{i_2,\dots,i_k}|D_iD_{i_2}\cdots D_{i_k}(f_\nu v^\nu)(0)| = \frac{\nu_i}{k}|f_\nu|.$$

Multiplying by ϕ^ν shows that (4.11) is the profile version of the scalar norm (4.10), with the index i fixed. Replacing ν_i/k by ν_i, or adding a factor $1/k!$ to the multiindex coefficients, would change the norm.

Rescaling an input transfers its locations, its network lengths, and its volume factors explicitly. Replacing a shortest connecting network by a tree on the locations of the external indices reduces the exponent once, from a_{sp} to $a_{\mathrm{sp}}/2$ (Lemma 5.3); there is no loss at every derivative order. Derivatives in analytic series are divided by $k!$. A bound on the values of a holomorphic function, or a pointwise bound on its Hessian, does not replace a bound on its absolute coefficients.

Radius profiles. For a boundary width w_{bd}, the spatially varying analytic radius is

$$\phi(i) = \begin{cases} \rho_\partial, & d_\Omega(i) < w_{\mathrm{bd}}, \\ \rho, & d_\Omega(i) \geq w_{\mathrm{bd}}, \end{cases} \qquad \psi_{\mathrm{prof}} = \sqrt{K_*}\,\phi, \qquad \widehat{\phi} = K_*\phi,$$

where $0 < \rho_\partial \leq \rho$ and $K_* \geq 2$ is a fixed enlargement factor of the analytic radii. The classical profile is defined separately. The symbol ψ without a subscript is reserved for an observable cutoff (Definition 4.11). We keep the following radii distinct.

r	radius of the small-link domain B_r in the small-field event
ρ, ρ_{cl}	analytic radii for the effective interaction and the effective classical action
R_{raw}	larger radius of the initial construction
$R_{\mathrm{buf}} = C_{\mathrm{map},J}r$	radius of the analytic extension around coarse fields
$R_{\mathrm{cell}} = \lceil A_8/r \rceil$	side length of the enlarged cells
R_W	radius imposed on the variables $g_i w_i$
R_{en}	radius of the enclosing product domain
β_{rec}	bound on the frozen coordinates

Here A_8 is the sufficiently large constant of Theorem 21.3. None of these radii is the inverse coupling $\beta_n = 4/h_n$. The width s_{er} of a removed boundary layer, the separation widths, and the numbers of elapsed RG steps are distinct geometric variables. Frozen coordinates from earlier steps are fixed real parameters; they are neither differentiated nor continued to complex values. Newly frozen variables were analytic variables before the substitution.

Normalization constants. Effective densities have the form $\exp(\Lambda - E/g^2 - R)$, multiplied by domain indicators. The centered effective interaction is $R - R(I)$, and in such a density the constant $R(I)$ is moved into Λ. If some variables are fixed at the value c by substitution, we set

$$R_{\mathrm{new}}(v) = R(v,c) - R(0,c), \qquad \Lambda_{\mathrm{new}} = \Lambda - R(0,c),$$

which is the identity $e^{\Lambda - R(v,c)} = e^{\Lambda - R(0,c)} e^{-[R(v,c) - R(0,c)]}$. The classical action is kept in full. A substitution does not remove a first derivative by translating a conditional minimizer, so R_{new} has in general terms of degree one, which (4.11) includes. The full determinant and the normalization factor of every eliminated Gaussian coordinate are included exactly once in the density. Their field-independent factors are collected in Λ; their remaining field dependence is kept in the effective interaction and in the conditional fluctuation potential. This is proved in Lemma 18.9 and Theorem 20.13. A comparison of densities on block regions is first a statement at representatives satisfying the reconstruction identities of Theorem 21.12; only the resulting gauge-invariant bound in terms of the Wilson action is afterwards extended to all representatives (Theorem 22.10).

4.5 Polymers and exponential moments of blocked actions

Polymer expansions. A polymer $\mathfrak{X}$ is a nonempty connected set of the specified block labels. Polymer activities $\mathfrak{z}(\mathfrak{X}; c)$ arise from the finite product expansion displayed at each use. The hard-core polymer partition function is

$$\Xi(c) = \sum_{\{\mathfrak{X}_1, \dots, \mathfrak{X}_m\} \text{ pairwise compatible}} \prod_{i=1}^{m} \mathfrak{z}(\mathfrak{X}_i; c),$$

where the empty family contributes one. Compatibility is determined by the incompatibility relation specified at each expansion (disjointness of supports, or the exclusion relation). The norm of the polymer activities combines absolute coefficient majorants on the given radii, the spatial weight $e^{a_{\mathrm{sp}} \mathfrak{t}}$, and a size weight $e^{\kappa_{\mathrm{pol}} |\mathfrak{X}|}$, and it takes the supremum over sites v of the sum over the polymers containing v, $\sup_v \sum_{\mathfrak{X} \ni v}$. The precise incompatibility relation and size weight are part of the corresponding theorem (Lemma 12.9 and Theorem 12.6). Boundary visits and fixed inputs of a coefficient are kept in the networks through the expansion of the product into polymer activities (Lemma 12.9) and the cluster expansion of $\log \Xi$ (Theorem 12.6), and through their analogues on block regions in Section 20. The support of a polymer activity alone does not give a new decay rate. We use the cluster expansion in the form of Kotecký and Preiss [120], with the tree-graph bound as presented by Fernández and Procacci [87] and by Dimock [68, Appendix B, Theorem 27, p. 39, and (323), p. 42]; see also Brydges [38].

Reflected block tilings. These conventions are used in the bound on large fields in Sections 22 and 23. At averaging step j, a reflected block tiling $\mathcal{T}$ consists of $\mathfrak{m}_j = n_j^3/8$ disjoint coarse cells of $2 \times 2 \times 2$ sites. Each cell contains the sets of finer plaquettes on which the internal coarse plaquettes of the cell depend; the plaquettes crossing between cells are not tested in this tiling. The eight translates of $\mathcal{T}$ cover all plaquettes. We write

$$Q_j^{\mathcal{T}} = \frac{4}{h_{n_{j-1}}} \sum_{p \in \mathcal{P}_{j-1}^{\mathcal{T}}} q(V_p^{j-1})$$

for the blocked action of the finer plaquettes of the cells, and $R_{<j}^{\mathcal{T}}(d_{\mathrm{cut}})$ for the product over the cells of the indicators of the earlier small-field conditions. The threshold for a bad cell is $d_* = d_{\mathrm{cut}}/2$. The indicator stays inside the expectation that is raised to the power $1/\mathfrak{m}_j$ in the chessboard estimate. Reflection positivity of the unconditioned Wilson measure was proved by Osterwalder and Seiler [134]. By Theorem 6.6, it holds for the bounded Borel gauge-invariant functions of the fine links with both endpoints in the union of the blocks over the coarse vertices of one open half torus. For an observable supported in a reflection half, the pullback by the iterated block averaging map belongs to this class and intertwines the reflection, including at the exceptional values. This gives reflection positivity of the averaged measure. We never use reflection positivity for a fixed fiber or for a conditioned measure. The chessboard estimate is that of Fröhlich, Israel, Lieb, and Simon [92, 93], in the form of Biskup [29, Theorem 5.8, p. 44].

Exponential moments. The bound on the exponential moments of blocked actions has the form

$$\log \mathbb{E}_{\mu_{N,\gamma}}\big[e^{s Q_j^{\mathcal{T}}}; R_{<j}^{\mathcal{T}}\big] \le 3 C_v n_{j-1}^3 + C_s n_{j-1}^2 \log(1/g_{n_{j-1}}) + C_b', \qquad 0 \le s \le s_0,$$

with fixed constants C_v, C_s, C_b', s_0. It is proved, together with the induction over averaging steps under the Wilson measure, in Theorem 22.1 and Section 23. If a stopped side is $m = \chi_{\mathrm{stop}} n_{j-1}$, a coefficient 9 of m^2 becomes $9\chi_{\mathrm{stop}}^2$ in units of n_{j-1}^2. At the finest, unconditioned scale the bound contains the correction $36 \log \beta_N / N$, with $\beta_N = 4/h_N$, which is kept until the parameters are chosen uniformly in the coupling (Theorem 6.6).

4.6 Heat semigroup, Wilson flow, and flow data

For a physical mesh a, let $D_{a,i}^{\pm}$ be the componentwise forward and backward differences in direction i, in physical units, and let $\Delta_a = \sum_i D_{a,i}^- D_{a,i}^+$. The lattice heat semigroup is the componentwise scalar semigroup $P_t^a = e^{t\Delta_a}$, which retains the constant mode. The cardinal interpolation of directed-edge fields (Lemma 16.3) preserves constants and integrals of columns, and it is the identity when the input and output meshes coincide; its volume-normalized columns use its own input mesh.

The Wilson flow Φ^{W}_s is the flow of the vector field $-\nabla \sum_p q(U_p)$, where the gradient is taken with respect to the product metric on $\mathcal{U}_n$ given by $\langle X, Y\rangle = -2\,\mathrm{tr}(XY)$. Its version in physical time is

$$\Psi^{(N)}_t = \Phi^{\mathrm{W}}_{4t/a_N^2},$$

as in Section 2.1. This conversion of time contains no coupling factor; the factor $4/a_N^2$ is the normalization for which the linear part of the flow is the heat equation in physical units. The flow is Lüscher's [128]. In logarithmic coordinates $U = e^{aA}$, after we add the gauge-damping term of Lemma 24.2 (a lattice version of the gauge fixing of Zwanziger [157], DeTurck [66], and Donaldson [76]), the linear part of the equation is the scalar heat equation $\partial_t A = \Delta_a A$ in each component. We write $\mathcal{N}_a$ for the bilinear coefficient of this gauge-damped lattice equation, in the order in which its arguments appear and with all its lattice shifts (Lemma 24.2). Set

$$\mathcal{Q}_a(u,v)(t) = \int_0^t P^a_{t-s}\mathcal{N}_a(u(s),v(s))\,ds, \qquad \mathcal{B}_a(u,v) = \mathcal{Q}_a(u,v) + \mathcal{Q}_a(v,u).$$

The coefficient $\mathcal{N}_a$ and the bilinear Duhamel term $\mathcal{Q}_a$ need not be symmetric in their two arguments; their symmetrization $\mathcal{B}_a$ is symmetric. The letter Q alone is reserved for the constant-mode quartic form of Section 4.9.

Definition 4.8. Fix $1/2 < \alpha_{\mathrm{fl}} < 2/3$, and set $\beta_{\mathrm{fl}} = \alpha_{\mathrm{fl}} - 1/2$ and $\kappa_{\mathrm{fl}} = 1 - 3\alpha_{\mathrm{fl}}/2 > 0$. For a fixed time horizon $T > 0$ and a mesh a, let $v_a(t) = t + a^2$, and define, with $\alpha = \alpha_{\mathrm{fl}}$,

$$\mathsf{X}^a_\alpha(x) = \sup_{0\le t\le T}\big\{v_a(t)^{\alpha/2}\|x(t)\|_\infty + v_a(t)^{(\alpha+1)/2}\|D_a x(t)\|_\infty\big\},$$
$$\mathsf{Y}^a_\alpha(y) = \sup_{0\le t\le T}\big\{v_a(t)^{\beta_{\mathrm{fl}}}\|y(t)\|_\infty + v_a(t)^{\alpha}\|D_a y(t)\|_\infty\big\}.$$

Here $\|D_a x\|_\infty$ is the maximum over all componentwise differences $D^{\pm}_{a,i}x$ and their shifts occurring in the Wilson-flow equation. For $0 < \sigma_{\mathrm{sm}} < 1 - \alpha_{\mathrm{fl}}$ and $\sigma = \sigma_{\mathrm{sm}}$, set

$$\mathsf{H}^a_\sigma(f) = \sup_{0\le t\le T}\big\{v_a(t)^{\sigma/2}\|P^a_t f\|_\infty + v_a(t)^{(\sigma+1)/2}\|D_a P^a_t f\|_\infty\big\},$$
$$\mathsf{V}^a_\sigma(f) = \sup_{0\le t\le T} v_a(t)^{\sigma/2}\|P^a_t f\|_\infty.$$

For a physical initial potential A_0 on mesh a, the linear heat evolution is $x(t) = P^a_t A_0$, the quadratic Picard term is $y = \mathcal{Q}_a(x,x)$, and together they form the linear and quadratic flow data, measured in the norms X^a_α and Y^a_α.

The weights express heat scaling: $x(t)$ is of size $v_a(t)^{-\alpha/2}$ and $y(t)$ of size $v_a(t)^{1/2-\alpha}$, and each difference costs a further factor $v_a(t)^{-1/2}$. Flow data on different meshes are compared by the cross-mesh comparison (24.11) of Definition 24.3, whose four components are interpolated separately and weighted in time.

Further exponents. The constant C_{CP}, which controls finitely many derivatives of the conditional constrained minimizers and of their propagated contributions, is uniform in J. It is chosen before J, including every enlargement used later in an amplitude bound or a derivative bound, and J is then chosen with $C_{\mathrm{CP}}^2/B \le 1/4$. We write $a_{\mathrm{cap}} = C_{\mathrm{CP}}/B$ for the contraction factor in the amplitude bound (15.20) of the backward reconstruction (Lemma 15.10). The decay exponent at the coarse end of the reconstruction is a different number: $\kappa_{\mathrm{term}} = -\log a_{\mathrm{cap}}/\log B > 1/2$ when $a_{\mathrm{cap}}\sqrt{B} < 1$, and the contraction factor of the propagated contributions of coarser scales is $q_{\mathrm{anc}} = B a_{\mathrm{cap}}^2 < 1$. A localization exponent is denoted by ξ, not by γ. A tail exponent τ_{tail} is chosen with

$$0 < \tau_{\mathrm{tail}} < \min\{\sigma_{\mathrm{sm}}, 1/2, -\log q_{\mathrm{anc}}/\log B\}.$$

Logarithms along the flow. Let $A = x + y + r$ be the solution on $[0,T]$ of the gauge-damped flow equation on mesh a whose linear and quadratic flow data satisfy $\mathsf{X}_\alpha^a(x) + \mathsf{Y}_\alpha^a(y) \le R$, with the remainder r bounded as in Theorem 24.5. Then

$$a \sup_{t\le T}|A(t)| \le C_R a^{1-\alpha_{\mathrm{fl}}} + C_R a^{2-2\alpha_{\mathrm{fl}}} + C_R a (T + a^2)^{1-3\alpha_{\mathrm{fl}}/2} \longrightarrow 0 \qquad (a \to 0),$$

at fixed T. The first two terms come from $a\|x(t)\|_\infty \le R a\, v_a(t)^{-\alpha/2}$ and $a\|y(t)\|_\infty \le R a\, v_a(t)^{1/2-\alpha}$, evaluated at $t = 0$. The last term increases with time; its maximum is $O_R(a)$, attained at $t = T$, and does not keep the mesh power of its value at $t = 0$. The smooth solutions of the continuum flow are constructed from deterministic results for the flow with smooth data and from heat-kernel calculus [42, Theorem 1.2 and Lemma 1.3, p. 3; Lemmas C.2–C.3, pp. 55–56; Corollary C.6, p. 58; Lemmas C.12–C.13, p. 61]. We do not use the theorem of Cao and Chatterjee on random initial data as a hypothesis on Wilson fields.

4.7 The heat-smoothed circulation

The short-distance results are proved for the following linear functional of the reconstructed field.

Definition 4.9. Fix $L > 0$, $\gamma > 0$, $g_3^2 = \gamma/L$, $\sigma > 0$, smooth loops $\ell_1, \dots, \ell_m$ in $\mathbb{R}^3$, and the index s of the comparison lattice, and let $K \ge s$ and $N_K = n_* B^K$. Let $\widehat{\theta}_{K-s}$ be the link logarithm, in the gauge fixed by the reconstruction maps $\widehat{\mathscr{R}}$, of the configuration on Λ_{N_K} reconstructed from the lattice of side n_s by $K - s$ RG steps, and let $A^{K,s} = a_{N_K}^{-1}\widehat{\theta}_{K-s}$ be the corresponding physical initial potential. For $a_{N_K} \le \varepsilon$ and $x \in \mathbb{T}_L^3$, let $\ell_{i,K,\varepsilon}$ be the closed lattice path in Λ_{N_K} approximating $x + \varepsilon\ell_i$ that is specified in Definition 31.1. The heat-smoothed circulation is

$$I_i^{K,s}(\varepsilon, x) = \frac{a_{N_K}}{\sqrt{g_3^2\varepsilon}} \sum_{e \in \ell_{i,K,\varepsilon}} \mathrm{sgn}(e)\big(P_{\sigma\varepsilon^2}^{a_{N_K}} A^{K,s}\big)_{\mathrm{dir}(e)}\big(x_{\mathrm{positive}}(e)\big).$$

Here $\mathrm{dir}(e)$ is the direction of the link e, $x_{\mathrm{positive}}(e)$ is the starting point of its positive orientation, and $\mathrm{sgn}(e) = 1$ if e is traversed in the positive direction and -1 otherwise; a backward edge thus contributes the negative of the value on its positive edge.

In this range, the paths $\ell_{i,K,\varepsilon}$ have physical length and diameter at most $C_\ell \varepsilon$, and they have zero winding for $\varepsilon \le \varepsilon_{\mathrm{loop}}$ of Definition 31.1. The functional annihilates periodic lattice gradients. Indeed, if $A_j(y) = D^+_{a,j} f(y)$ with $a = a_{N_K}$, then $P^a_t A = D^+_a P^a_t f$. Each traversed edge contributes $\pm(P^a_t f(\mathrm{end}) - P^a_t f(\mathrm{start}))/a$, with the sign making it the increment along the path, and these increments sum to zero around a closed path. The zero winding also removes the pairing with constant one-forms. The scalar heat semigroup acts on the field at the finest mesh. It is not the nonlinear Wilson flow, and the comparison with flowed Wilson loops is a separate result (Lemma 32.11). The normalization $1/\sqrt{g_3^2 \varepsilon}$ is the scale of the circulation of the Gaussian free field after heat smoothing at time $\sigma\varepsilon^2$; the analysis is in Sections 31 and 32.

4.8 Gauge orbits and the trajectory space

Definition 4.10. A smooth connection is an element A of $\mathcal{A}_L = C^\infty(\mathbb{T}^3_L; \mathfrak{su}(2)^3)$. We write

$$F_{ij}(A) = \partial_i A_j - \partial_j A_i + [A_i, A_j], \qquad D_i = \partial_i + [A_i, \cdot\,].$$

A gauge transformation $k \in \mathcal{G}_L = C^\infty(\mathbb{T}^3_L; \mathrm{SU}(2))$ acts by $A^k = kAk^{-1} - (dk)k^{-1}$. The parallel transport along a piecewise C^1 path ℓ is the solution of $H'(s) = H(s)A(\ell(s))\dot{\ell}(s)$, $H(0) = I$; it transforms by $H^k(s) = k(\ell(0))H(s)k(\ell(s))^{-1}$. The Yang–Mills heat flow is $\partial_t A_i = \sum_j D_j F_{ji}$, and $(\Phi_t)_{t \ge 0}$ is the semigroup it induces on $\mathcal{A}_L/\mathcal{G}_L$. The trajectory space $\mathcal{X}_L$, the regularized Wilson loops $W_{\ell,\chi,t}$, and the Wilson topology $\mathcal{T}_W$ are as in Definition 2.2. Let $(\ell_j, t_j)_{j \ge 1}$ be the fixed enumeration used in Theorem 29.3, formed from its countable dense family of piecewise C^1 loops, which contains loops in every winding class, and the times in $L^2\mathbb{Q}_{>0}$. Set $w_j(X) = \mathrm{tr}\,\mathrm{Hol}_{\ell_j} X(t_j)/2$ and

$$d_c(X, Y) = \sum_{j \ge 1} 2^{-j} |w_j(X) - w_j(Y)|, \qquad X, Y \in \mathcal{X}_L.$$

Differentiating $k(\ell(0))H(s)k(\ell(s))^{-1}$ shows that it solves the transport equation for A^k, which confirms the sign of the gauge action and the order of the transport. Our gauge transformation k is the inverse of the gauge variable used by Cao and Chatterjee [43, (1.1), p. 2]. The trajectory space follows the proposal of Charalambous and Gross [47] and is a version of the state space of Cao and Chatterjee [43]. By definition d_c is a pseudometric. In Theorem 29.3 we prove that it separates points of $\mathcal{X}_L$, that both topologies are separable, and that they have the same Borel σ-algebra. We do not assert that $(\mathcal{X}_L, d_c)$ is complete.

The Yang–Mills energy is

$$E_L(A) = \sum_{i,j} \int_{\mathbb{T}^3_L} -\operatorname{tr}\big(F_{ij}(A)^2\big)\, dx = \sum_{i<j} \int_{\mathbb{T}^3_L} |F_{ij}(A)|^2\, dx,$$

since $-\operatorname{tr}(F_{ij}^2) = |F_{ij}|^2/2$. It carries no coupling factor; for smooth configurations the exponent of the Wilson measure tends to $E_L/(2g_3^2)$ (Remark 4.2). Under the rescaling to the unit torus, $\widetilde{A}(y) = LA(Ly)$, the flow time becomes t/L^2 and $E_1(\widetilde{A}) = LE_L(A)$.

The maps π_K of Theorem 29.19 are Borel maps on the lattice configuration space, invariant under all periodic lattice gauge transformations. They are chosen by a deterministic diagonal sequence of matching levels, fixed before any configuration is sampled. Their Wilson-loop coordinates approximate the flowed lattice Wilson loops in the sense of Theorem 2.3(3); the maps do not embed lattice holonomies exactly. We use the compactness of energy sublevel sets and the continuity of the flow semigroup under the hypotheses of the cited results, which concern the quotient of Sobolev connections in H^1 by gauge transformations in $W^{2,2}$ [43, Theorem 3.51, pp. 35–36; Lemma 3.68, p. 40].

4.9 Observables near commuting holonomies

Definition 4.11. Fix $\theta > 0$ and the flow time $t = \theta L^2$. Let $H_1, H_2, H_3 \in \mathrm{SU}(2)$ be the holonomies of $X(t)$ around the three coordinate cycles, based at a common point. Their seven trace coordinates are the normalized traces of H_i, of H_iH_j for $i < j$, and of $H_1H_2H_3$. In a fixed neighborhood of the identity write $X = (x_i)_{i=1}^3 = (\operatorname{Log} H_i)_{i=1}^3 \in \mathfrak{su}(2)^3 \simeq \mathbb{R}^9$. The cone of commuting triples is

$$\mathcal{M} = \{(y_i) = (\vartheta_i u)_{i=1}^3 : \boldsymbol{\vartheta} \in \mathbb{R}^3,\ u \in S^2\}, \qquad (\boldsymbol{\vartheta}, u) \sim (-\boldsymbol{\vartheta}, -u).$$

Fix $0 < r_0 < r_1 < \pi$, and let $\mathsf{P} = \{(\vartheta_i u)_i \in \mathcal{M} : r_0 \le |\boldsymbol{\vartheta}| \le r_1\}$, a compact subset of the regular part of $\mathcal{M}$ with nonempty relative interior. For $y = (\vartheta_i u)_i \in \mathsf{P}$, the normal space to $\mathcal{M}$ at y is

$$\mathcal{N}_y = \Big\{ b = (b_1, b_2, b_3) : b_i \perp u,\ \sum_i \vartheta_i b_i = 0 \Big\}, \qquad \dim \mathcal{N}_y = 4,$$

and on a fixed tubular neighborhood of P we use the unique coordinates $X = y + b$ with $y \in \mathcal{M}$ and $b \in \mathcal{N}_y$. Let $\Pi_{\boldsymbol{\vartheta}} = I - \boldsymbol{\vartheta}\boldsymbol{\vartheta}^{\mathsf{T}}/|\boldsymbol{\vartheta}|^2$. In unit-torus variables put, for $m \in \mathbb{Z}^3$,

$$k_m = 2\pi m + \boldsymbol{\vartheta}, \qquad \lambda_m = |k_m|^2, \qquad R_i(m, \boldsymbol{\vartheta}) = \begin{cases} 1, & m_i = 0, \\ \vartheta_i/(2\pi m_i + \vartheta_i), & m_i \neq 0, \end{cases}$$

$$d_i(\boldsymbol{\vartheta}, \theta) = \sum_{m \in \mathbb{Z}^3} \frac{e^{-2\theta\lambda_m}}{\lambda_m} R_i(m, \boldsymbol{\vartheta})^2, \qquad D = \operatorname{diag}(d_1, d_2, d_3),$$

and define the normal covariance

$$\Sigma_\theta(y) = \big(\Pi_{\boldsymbol{\vartheta}} D\Pi_{\boldsymbol{\vartheta}}\big)\big|_{\boldsymbol{\vartheta}^\perp} \otimes I_{u^\perp}. \tag{4.12}$$

Let $0 \le \psi_0 \le 1$ be a smooth function on P, invariant under simultaneous conjugation and compactly supported in the relative interior of P, that vanishes on a nonempty open set and is bounded below by a positive constant on another nonempty open set. Multiply it by a fixed smooth function χ of the normal variable, invariant under simultaneous conjugation, supported in the tube, with $0 \le \chi \le 1$ and $\chi = 1$ near $b = 0$ (for example a function of $|b|$), to obtain $\psi(y + b) = \psi_0(y)\chi(b)$. Fix a larger tube containing the support of ψ and the supports of all tangential insertions used later, and set

$$q_*(y + b) = \frac{1}{2}\, b^{\mathsf{T}} \Sigma_\theta(y)^{-1} b$$

throughout this larger tube, with a fixed bounded, continuous, nonnegative extension outside it that is invariant under simultaneous conjugation. All these functions are invariant under simultaneous conjugation, and they are extended by zero outside the identity chart, so that they define invariant functions of (H_1, H_2, H_3). The observables $B_{\mathrm{obs}} = \psi$ and $A_{\mathrm{obs}} = \psi q_*$ are fixed bounded functions, and the normalized regression residual variance $\mathscr{C}_\gamma$ is defined from them as in Section 2.7.

The tangent vectors to $\mathcal{M}$ at a regular point are $(\delta\vartheta_i u + \vartheta_i \delta u)_i$ with $\delta u \perp u$; their orthogonal complement is $\mathcal{N}_y$. Hence the regular part of the cone has dimension five and its normal space has dimension four. By the tubular neighborhood theorem, the coordinates $X = y + b$ near P are unique; the tip of the cone is excluded. The matrix $\Sigma_\theta(y)$ is the covariance, divided by γ, of the linearized response of the flowed logarithms at the flat connection y. It is derived and compared with the lattice in Theorem 33.11; its definition does not assert that the nonlinear law of b is Gaussian. The regression coefficient $\mathrm{Cov}(A_{\mathrm{obs}}, B_{\mathrm{obs}})/\mathrm{Var}(B_{\mathrm{obs}})$ in $\mathscr{C}_\gamma$ depends on the measure, and $\mathscr{C}_\gamma$ is defined for measures under which $\mathrm{Var}(B_{\mathrm{obs}}) > 0$ and $\mathbb{E}B_{\mathrm{obs}}^2 > 0$. We prescribe q_* on the larger tube, and not only on the support of ψ, so that q_* equals the prescribed quadratic form on the support of every insertion of Theorem 2.10(2).

Remark 4.12. The series defining d_i converges uniformly on P, and $\Sigma_\theta(y)$ is positive definite. Indeed, $|\vartheta_i| \le |\boldsymbol{\vartheta}| < \pi$, so $|k_m| \ge 2\pi|m| - \pi \ge \pi|m|$ for $m \ne 0$, while $k_0 = \boldsymbol{\vartheta} \ne 0$. For $m_i \ne 0$ we have $|2\pi m_i + \vartheta_i| > \pi > |\vartheta_i|$, so $|R_i| \le 1$. Since $\theta > 0$, the sum of $e^{-2\theta\lambda_m}/\lambda_m$ over $m \ne 0$ converges uniformly. The summand with $m = 0$ gives $d_i \ge e^{-2\theta|\boldsymbol{\vartheta}|^2}|\boldsymbol{\vartheta}|^{-2} > 0$ for each i, hence $\Pi_{\boldsymbol{\vartheta}} D\Pi_{\boldsymbol{\vartheta}} \ge e^{-2\theta|\boldsymbol{\vartheta}|^2}|\boldsymbol{\vartheta}|^{-2}$ on $\boldsymbol{\vartheta}^\perp$. The hypothesis $\theta > 0$ is needed: at $\theta = 0$, the summands with $m_i = 0$ have $R_i = 1$, and the sum of $1/|2\pi m + \boldsymbol{\vartheta}|^2$ over this plane diverges logarithmically.

Central triples. The central triples are the triples $(\pm I, \pm I, \pm I)$ of central elements; they are points of the moduli space of flat connections. Near them we set $r_\gamma = \gamma^{1/4}$ and define the constant-mode quartic form

$$Q(Y) = \frac{1}{2}\sum_{i<j}|y_i \times y_j|^2, \qquad Y = (y_1, y_2, y_3) \in \mathbb{R}^9.$$

The quartic reference measure $m_Q = e^{-Q(Y)}\,dY$ is locally finite and has infinite total mass; it is never normalized globally. The divergence of the corresponding reduced SU(2) integral is known from the matrix-integral literature [7, 122]; we give a proof in our coordinates in Sections 33 and 36. Test functions are compactly supported and invariant under the simultaneous adjoint rotation of the three vectors y_i. A radial cutoff is a function $\chi(|Y|)$ with χ smooth, nonnegative, not identically zero, compactly supported, and constant near zero; the comparison of the dilation statistic with the reference measures (Theorem 36.19) additionally requires $\chi(0) > 0$. Every observable expressed in logarithmic coordinates vanishes outside a fixed identity chart. We write $\rho_{\mathrm{rad}} = |X|/r_\gamma$ for the rescaled radial variable, to distinguish it from the analytic radius ρ.

Definition 4.13. The following comparison measures are distinct constructions. Each depends on the fixed choices stated in it, and the results about them hold for every such fixed choice.

1. *Abelian Maxwell measure with Haar cycle holonomies.* Embed a fixed $U(1)$ subgroup in SU(2). Take the transverse Maxwell Gaussian field of the nonconstant modes with values in this subgroup, with a fixed normalization of its covariance, and independent uniformly distributed constant phases in $(\mathbb{R}/4\pi\mathbb{Z})^3$. Smooth at the fixed observation time and take the Abelian holonomies around the three coordinate cycles. All these triples commute. A common random conjugation does not change invariant test functions.
2. *Gaussian holonomies with independent Haar factors.* Let a be a centered Gaussian field with three colors and covariance γC, for a fixed covariance C, and let S_t be a fixed smoothing. Let U_1^0, U_2^0, U_3^0 be independent Haar distributed elements of SU(2), independent of a, and set $H_i = U_i^0\,\mathrm{Hol}_i(\mathsf{S}_t a)$. The triple (H_1, H_2, H_3) has the product Haar law at every coupling.
3. *Gaussian holonomies with Gaussian constant modes.* Set $H_i = \mathrm{Hol}_i(\mathsf{S}_t a)$, without the Haar factors, where a includes Gaussian constant modes with covariance proportional to γ. Assume that the scalar color projections $(x, i, v) \mapsto \langle v, (\mathsf{S}_t a)_i(x)\rangle/\sqrt{\gamma}$, indexed by $\mathbb{T}_L^3 \times \{1,2,3\} \times S^2$, have a centered separable Gaussian realization with continuous paths and bounded variance, whose law does not depend on γ. Its supremum is then measurable and almost surely finite. The resulting Gaussian supremum estimate is Lemma 35.16, and it is used only for this measure.

4. *Conditional normal Gaussian measure.* On the patch P of Definition 4.11, choose a fixed smooth positive probability density for y that charges two nonempty open sets O_0 and O_+, invariant under simultaneous conjugation, with $\psi_0 = 0$ on O_0 and ψ_0 bounded below by a positive constant on O_+, as in Definition 35.1. Conditionally on y, let $b \sim N(0, \gamma\Sigma_\theta(y))$ on $\mathcal{N}_y$, and push the joint law forward by $X = y + b$. A fixed tube cutoff equal to one near the zero section, followed by normalization, changes bounded moments by exponentially small amounts. For these choices $\mathscr{C}_\gamma$ is defined for all sufficiently small γ and has leading term $2\gamma^2$ (Lemma 35.17).
5. *Mixture of normalized conditional normal Gaussian measures.* Let y have a fixed probability density $\alpha(y)\, d\mathrm{vol}_{\mathcal{M}}(y)$ on a small neighborhood of the tip of $\mathcal{M}$, with $\alpha \geq 0$ continuous and strictly positive at the tip. Given $y \neq 0$, let $b \sim N(0, \gamma\Sigma_\theta(y))$ be the normalized Gaussian measure on $\mathcal{N}_y$, and push the joint law forward by $X = y + b$. Assume that $|y|^2\Sigma_\theta(y) \to I_{\mathcal{N}_y}$ as $y \to 0$, uniformly in the direction of y, with the corresponding uniform upper and lower bounds on $|y|^2\Sigma_\theta(y)$; here $|y| = |\boldsymbol{\vartheta}|$. The associated weighted normal-bundle measure is

$$d\mu_{13} \;\propto\; |y|^4 e^{-|y|^2|b|^2/2}\, d\mathrm{vol}_{\mathcal{M}}(y)\, db.$$

Expectations of the form $\langle\cdot\rangle_{\chi,\mu_{13}}$ are normalized by $\int \chi(|y+b|)\, d\mu_{13}$.

The factor $|y|^4$ in μ_{13} comes from the normalization of the four-dimensional Gaussian measure: $\det(\gamma\Sigma_\theta(y))^{-1/2}$ is of order $\gamma^{-2}|y|^4$, since $|y|^2\Sigma_\theta(y) \to I$. Under the scaling $(y, b) = \gamma^{1/4}(Y, B)$, the tangential volume, the normal volume, and this normalization contribute the factor $\gamma^{5/4}$. After division by $\gamma^{5/4}$, the joint densities converge for $Y \neq 0$ to $(2\pi)^{-2}\alpha(0)|Y|^4 e^{-|Y|^2|B|^2/2}$ relative to $d\mathrm{vol}_{\mathcal{M}}(Y)\, dB$. Since $y \perp b$, we have $|y+b|^2 = |y|^2 + |b|^2$, and the uniform covariance bounds give dominated convergence on compact sets of outputs $Y + B$; this is the scaling limit of Theorem 36.19. The weighted volume element has dilation degree $5 + 4 + 4 = 13$, which explains the index of μ_{13}. The mixture differs from the quartic reference measure m_Q, and omitting the conditional normalization would change the comparison. The value of α at $y = 0$ is irrelevant, since $\{y = 0\}$ is a null set.

4.10 Dependence of constants

Each quantitative statement in this paper either lists the parameters on which its constants depend, or refers to one of the items of the following definition, with any additional fixed parameters listed in the statement. In quantifier form, all fixed data precede the choice of the constants, and every quantity said to vary follows that choice.

Definition 4.14. A constant has the dependence described in item (k) if the corresponding statement holds as follows.

(1) *Finite-dimensional estimates.* Algebraic identities hold in every finite dimension stated. Constants in analytic estimates for products of a bounded number of group elements depend only on the number of factors and on the distance to the boundary of the logarithmic chart. Estimates for measures on products of convex balls depend only on the stated bounds on the Hessian of the potential in the free coordinates and on the weighted interaction, and not on the dimension or on the radii of the individual balls.

(2) *Classical estimates on the torus.* Constants depend on M, on the fixed larger physical and analytic domains, on the spatial decay rates, and on fixed upper bounds for the norms involved. Bounds stated uniformly in depth are independent of the lattice side, of the preceding classical depth, and of the coarse field in the stated domain. The explicitly named constants controlling finitely many derivatives, and the Taylor coefficient majorant Z of the aligned zero-fluctuation minimizer in Lemma 11.9, together with its radius, its coefficient constant, and its spatial rate, are uniform in J: they are fixed before J is chosen. Joint coefficient bounds in the coarse field and the free coordinates, and coefficient bounds for the gauge transformations of the reconstruction maps, are bounds at fixed J; for the reconstruction maps, only the specified finitely many derivatives of the zero-fluctuation reconstruction are uniform in J.

(3) *Local estimates on block regions.* Each constant C_J, c_J, λ_J, local radius, or upper bound for an output norm depends only on M and J, on the fixed larger initial and analytic domains and their radius ratios, on the spatial and boundary decay rates and the stated margins, on a bound on the number of indices per lattice cell, and on fixed upper bounds for the norms on the torus and of the perturbations. It is independent of L, γ, m, N, K, d_0, of the number of elapsed RG steps, of the shape and topology of the block region, of the numbers of connected components of the block region and of the fixed complement, and of the values of the real frozen coordinates. Where a theorem says so, it is also independent of the later boundary widths, widths of removed boundary layers, separation widths, and enlarged-cell widths; such a constant is evaluated on the larger domain before these widths are chosen. This applies only to the theorems on block regions proved in this paper; it does not extend an estimate on the full torus to arbitrary regions.

(4) *Estimates for the small-field failure probability.* Constants may depend on L, on the coupling ceiling γ_0 and the parameter tuple Θ of Theorem 23.2, on M and J, and on the fixed allowed number of averaging steps and enlargement of the stopping scale, but not on the coupling γ, on the lattice side, on the number of RG steps on the fine side or the preceding depth, or on the age, geometry, or widths of a large-field decomposition. The constant $C_{u,q}$ may in addition depend on fixed u and q. In a statement uniform in $0 < \gamma \leq \Gamma$, these constants and the minimal admissible

side may in addition depend on the fixed ceiling $\Gamma < \infty$; they are independent of $\gamma \in (0, \Gamma]$. This does not change the dependence of the constants in items (3) and (7).

(5) *Short-distance estimates.* Constants may depend on fixed L, γ, M, J, on the family of loops, on σ, and on the fixed index s of the comparison lattice. They are uniform in the remaining number of RG steps on the fine side, in the point x, and in the allowed lattice offsets, in the range $a \le \varepsilon \le \varepsilon_0(s)$. No uniformity as $s \to \infty$ or as $\gamma \downarrow 0$ is asserted.

(6) *Weak-coupling estimates.* Constants may depend on fixed n, L, θ, M, J, on the compact subsets of the regular part of $\mathcal{M}$, on the test functions, and on the larger margins, all fixed before γ. They are independent of the number of RG steps on the fine side, of the preceding depth, and of the coupling below the ceiling. Constants C_m attached to a fixed number m of RG steps may grow with m; constants in tail bounds at the coupling-dependent scale may not. These are estimates on the full torus.

(7) *Flow estimates.* Deterministic estimates for the flow on a set where the linear and quadratic flow data are bounded by R may depend on R, on positive waiting times, on the time horizon, and on the margins within the chosen coordinate charts. Constants in stochastic estimates and in convergence statements at fixed coupling, and the deterministic diagonal sequence of matching levels, may also depend on that coupling, on the coarse side, and on the observables. No rate that is uniform as a restart time tends to zero, or as the coupling varies, is implied.

We claim no useful bound as $J \to \infty$ for the joint constants at fixed J or for the constants on block regions; this concerns only these fixed-J constants, and not the constants in item (2) that are stated to be uniform in J. The order in which the parameters are chosen is established in Theorem 23.2: first the constants uniform in J, then J, then the local constants at fixed J, and then the geometric widths. In particular, J is not enlarged after the constants on block regions at fixed J have been computed.

Probabilistic conventions. For a random vector in a finite-dimensional space, the bounded-Lipschitz distance uses the test functions bounded by one with Lipschitz constant at most one with respect to the Euclidean norm. For probability measures we use $\|\mu - \nu\|_{\mathrm{TV}} = \sup_A |\mu(A) - \nu(A)|$, so that $|\mathbb{E}_\mu f - \mathbb{E}_\nu f| \le 2\|f\|_\infty \|\mu - \nu\|_{\mathrm{TV}}$ for every bounded measurable f. The covariance $\mathrm{Cov}(F, G) = \mathbb{E}(FG) - \mathbb{E}F\,\mathbb{E}G$ is complex bilinear when complex sources are used. Whenever a real minimum or a positive density is asserted, the holomorphic continuations involved take real values at real arguments, that is, $f(\bar{z}) = \overline{f(z)}$ in the chosen coordinates.

PART II

Lattice gauge measures and block averaging

SECTION 5

Finite-dimensional integration and concentration inequalities

This section collects the finite-dimensional tools used throughout the renormalization group analysis. Each statement concerns a fixed finite lattice, a finite set of coordinates, or a fixed finite-dimensional measure; where we say so, the constants do not depend on the dimension. The results fall into three groups. The first group concerns gauge integration and Gaussian algebra. Lemma 5.1 records the normalization of Haar measure on $\mathrm{SU}(2)$, exact integration in a spanning-tree gauge, and analytic estimates for products of group elements near the identity, and Lemma 5.2 decomposes closed periodic one-cochains and eliminates positive definite quadratic blocks. The second group is the calculus of the analytic coefficient norms of Definition 4.6: compositions, localized inverses and square roots, logarithms of determinants, and implicit functions (Lemma 5.3). The third group is probabilistic. Theorem 5.4 proves logarithmic Sobolev, covariance, and quadratic concentration inequalities for uniformly log-concave measures on products of balls, Lemma 5.5 controls conditioning, parameter derivatives, and gauge-invariance identities, and Lemma 5.6 shows that seven traces determine a triple of $\mathrm{SU}(2)$ matrices up to simultaneous conjugation.

The only inputs are the definitions of Section 4: the Wilson measure and the normalization of the Lie algebra (Definition 4.1), the coefficient norms (Definition 4.6), and the convention on constants (Definition 4.14). Spanning-tree gauges and the estimates for products of group elements enter the construction of the block averaging map and the gauge fixing in Sections 6 and 7, and the local Wilson flow in Section 24. The Gaussian elimination is used for the linearized theory in Section 8. The coefficient calculus underlies all analytic estimates in Sections 6, 8 to 10, 12, and 18. The concentration theorem is the probabilistic input for the conditional fluctuation kernels in Sections 13, 16, 17, 20, 26 to 28, and 34. The conditioning lemma is used in Sections 15, 28, 29, and 32, and the seven traces in Sections 33, 35, and 36.

5.1 Haar measure, spanning-tree gauges, and products of group elements

The following facts are standard for the compact group $\mathrm{SU}(2)$ and for lattice gauge theory; we record them with the normalizations of Section 4.1, which fix the constants

used later. Gauge fixing along a spanning tree is the maximal-tree gauge, which we call the spanning-tree gauge. Bałaban used such gauges systematically in the renormalization group context [14].

Lemma 5.1. *Let $\mathcal{K}$ be a finite oriented cubical complex, with vertex set $\mathcal{V}$, set of positive links $\mathcal{E}$, and set of positive plaquettes $\mathcal{P}$. Then the following statements hold.*

1. *For every $\beta \geq 0$,*

$$Z_{\mathcal{K}}(\beta) = \int e^{-\beta \sum_{p \in \mathcal{P}} q(U_p)} \prod_{e \in \mathcal{E}} dH(U_e) \quad \text{satisfies} \quad e^{-2\beta|\mathcal{P}|} \leq Z_{\mathcal{K}}(\beta) \leq 1,$$

   and the normalized density defines a gauge-invariant Borel probability measure.

2. *The measure H is the Haar probability measure, and for $X = x^a \tau_a$ with $0 \leq r = |X| < 2\pi$,*

$$\frac{1}{2} \operatorname{tr} e^X = \cos(r/2), \qquad dH(e^X) = c_{\mathrm{Haar}} j_H(X)\, d^3x,$$

   where $c_{\mathrm{Haar}} = 1/(16\pi^2)$ and $j_H(X) = \operatorname{sinc}^2(r/2)$. For $0 \leq u \leq 2\pi$ and $U, V \in \mathrm{SU}(2)$,

$$H\{\rho_G < u\} = \frac{u - \sin u}{2\pi}, \qquad \frac{\rho_G(U)^2}{2\pi^2} \leq q(U) \leq \frac{\rho_G(U)^2}{8},$$

   and $\rho_G(UV) \leq \rho_G(U) + \rho_G(V)$. Further, $q(e^X) \geq (r^2/8)(1 - r^2/48)$ for $0 \leq r \leq 2\pi$, and on every ball $\{|X| \leq r_0\}$ with $r_0 < 2\pi$ we have $q(e^X) = r^2/8 + O(r^4)$ and $\log j_H(X) = -r^2/12 + O(r^4)$, with constants depending only on r_0. For $0 < u \leq 1$,

$$c_{\mathrm{ball}} u^3 \leq H\{\rho_G < u\} \leq \frac{u^3}{12\pi}, \qquad c_{\mathrm{ball}} = \frac{\operatorname{sinc}^2(1/2)}{12\pi} \geq \frac{1}{16\pi}.$$

3. *Left and right translations preserve Haar measure. For every $k \in \mathrm{SU}(2)$, $\mathrm{Ad}(k) \in \mathrm{SO}(3)$; it preserves the norm of $\mathfrak{su}(2)$, Lebesgue measure, and the balls centered at the origin. The map $\mathrm{Ad} : \mathrm{SU}(2) \to \mathrm{SO}(3)$ is surjective. These statements concern $\mathrm{SU}(2)$, not conjugation by elements of its complexification $\mathrm{SL}(2, \mathbb{C})$.*

4. *Choose a spanning tree in each connected component of $\mathcal{K}$, with one root per component. Let h_x be the transport from the root to x along the tree, and set $V_{xy} = h_x U_{xy} h_y^{-1}$. The map*

$$U \longmapsto \big((h_x)_{x \text{ not a root}}, (V_e)_{e \text{ not in the forest}}\big)$$

   is a smooth bijection, and it carries product Haar measure to product Haar measure; $V_e = I$ on the forest. Hence, for an integrand invariant under the gauge transformations equal to I at the tree roots, integration over the tree variables contributes a factor one and leaves the same integrand expressed in the remaining variables V. If $\mathcal{K}$ is connected, there remain $|\mathcal{E}| - |\mathcal{V}| + 1$ independent group variables, together with the simultaneous conjugation at the root, and no stabilizer volume is divided out. The same statements hold for a partition of $\mathcal{K}$ into blocks, each equipped with a rooted spanning tree, with gauge transformations equal to I at every tree root.

5. *Fix a length ℓ, a distance from the singularity of the logarithm (the eigenvalue -1), and a smaller complex coordinate polydisc inside the larger domain. Every map given by a product of at most ℓ factors of the form $e^{\pm X_j}$, and every logarithm of such a product relative to a reference product on the specified chart, has absolute Taylor derivatives of order s bounded by $s!C^s$ for all $s \geq 1$, where C depends only on ℓ, these domains, and the norm of $\mathfrak{su}(2)$. Factors in $\mathrm{SU}(2)$ may be included if the relative products keep the same distance from the singularity. For small complex $u, v, a \in \mathfrak{su}(2)_{\mathbb{C}}$ and $0 \leq \epsilon \leq 1$,*

$$\epsilon^{-1} \operatorname{Log}(e^u e^{\epsilon a} e^{-u-\epsilon v}) = \operatorname{Ad}(e^u)a - \int_0^1 \operatorname{Ad}(e^{tu})v \, dt + \epsilon \mathscr{R}_\epsilon(u, v, a),$$

where the left side at $\epsilon = 0$ is defined by analytic continuation, and the remainder $\mathscr{R}_\epsilon$ is holomorphic, has bounds of the same type, vanishes to order at least two in (a, v), and satisfies $\mathscr{R}_\epsilon(u, 0, a) = 0$.

All constants have the dependence described in item (1) of Definition 4.14; for a fixed length ℓ they do not depend on the number of cells, on L, on the coupling, or on the depth.

Proof. Quaternions and Haar measure. Let $t_a = 2\tau_a$. Multiplying the Pauli matrices, we find

$$t_a t_b = -\delta_{ab} I + \epsilon_{abc} t_c, \qquad (aI + v \cdot t)(bI + w \cdot t) = (ab - v \cdot w)I + (aw + bv + v \times w) \cdot t. \tag{5.1}$$

Then $\mathrm{SU}(2)$ is the unit sphere $\{a^2 + |v|^2 = 1\}$ in $\mathbb{R}^4$, and inversion is $(a, v) \mapsto (a, -v)$. Left and right multiplications by a unit quaternion are linear maps of $\mathbb{R}^4$ preserving the norm, so the normalized surface measure on the sphere is left and right invariant. It is the unique invariant probability measure. Indeed, if H_1, H_2 are two such measures, integrating a continuous function $f(uv)$ against $H_1(du)H_2(dv)$ in the two orders gives $H_1(f) = H_2(f)$. Equality on continuous functions identifies the Borel measures, since continuous approximations of the indicators of closed and open sets give equality on these sets, and hence on the σ-algebra they generate.

Since $(x \cdot \tau)^2 = -r^2 I/4$, we have $e^{x \cdot \tau} = \cos(r/2)I + \sin(r/2)(x/r) \cdot t$, with the value at $r = 0$ obtained by continuity; in particular $\operatorname{tr} e^X/2 = \cos(r/2)$. In the polar coordinates $a = \cos\vartheta$, $v = \sin\vartheta\,\omega$, $0 < \vartheta < \pi$, the area element of the sphere is $\sin^2\vartheta \, d\vartheta \, d\omega$, where ω ranges over the unit two-sphere of area 4π; the total area is $2\pi^2$. Substituting $r = 2\vartheta$ and $d^3x = r^2 dr \, d\omega$, we obtain

$$\frac{\sin^2(r/2)}{4\pi^2 r^2} \, d^3x = \frac{1}{16\pi^2} \operatorname{sinc}^2(r/2) \, d^3x.$$

The omitted point $-I$ has measure zero. The radial density is $\pi^{-1}\sin^2(r/2)\,dr$, and integrating it from 0 to u, we obtain the formula for $H\{\rho_G < u\}$, including $u = 0$ and $u = 2\pi$.

The distance. The quantity r is twice the round-sphere distance from I. By the exponential formula, every logarithm of $U = aI + v \cdot t$ has norm at least $2 \arccos a$, and

the logarithm displayed above attains this value. Great-circle arcs are shortest: for a curve $z(s)$ on the sphere, the derivative of its polar angle has absolute value at most $|z'(s)|$, as one sees by differentiating its scalar product with the initial point. Left multiplication preserves the round metric. Concatenating a shortest arc from I to U with the left translate by U of a shortest arc from I to V, we obtain $\rho_G(UV) \le \rho_G(U) + \rho_G(V)$.

The plaquette function. For $r \in [0, 2\pi]$ we have $q(e^X) = 2\sin^2(r/4)$. On $[0, \pi/2]$, the sine lies above its chord by concavity, $\sin x \ge 2x/\pi$, and $\sin x \le x$. These two inequalities imply the quadratic lower and upper bounds. Integrating $\sin x \ge x - x^3/6$, we obtain $1 - \cos x \ge x^2/2 - x^4/24$, and the inequality for the sine follows by integrating $x - \sin x \ge 0$ twice. Setting $x = r/2$ yields the additional lower bound. By Taylor's formula with integral remainder, $|q(e^X) - r^2/8| \le r^4/384$. The function $g(r) = \log \operatorname{sinc}^2(r/2) + r^2/12$ is even and satisfies $g(0) = g''(0) = 0$, as the expansion $\operatorname{sinc}(r/2) = 1 - r^2/24 + O(r^4)$ shows; its odd derivatives at 0 vanish as well. Its fourth derivative is bounded on every interval $[-r_0, r_0]$ with $r_0 < 2\pi$, and by the same remainder formula $|g(r)| \le C(r_0) r^4$. For $0 < u \le 1$, the function $\operatorname{sinc} s$ decreases on $[0, 1/2]$, since $(s\cos s - \sin s)' = -s \sin s \le 0$. Writing $\sin^2(r/2) = (r^2/4)\operatorname{sinc}^2(r/2)$ in the radial density, we obtain the two bounds on $H\{\rho_G < u\}$. Finally $\operatorname{sinc}(1/2) \ge 1 - 1/24 = 23/24$, whose square exceeds $3/4$; this implies $c_{\mathrm{ball}} \ge 1/(16\pi)$.

Partition functions. The function q is continuous on $\mathrm{SU}(2)$ with values in $[0, 2]$. Every plaquette transport is a product of link variables and their inverses, and its trace is invariant under gauge transformations, since the intermediate vertex factors cancel. Under a gauge transformation each link variable undergoes a left and a right translation, so product Haar measure is invariant. The integrand lies between $e^{-2\beta|\mathcal{P}|}$ and 1. Integrating, we obtain the bounds on $Z_{\mathcal{K}}(\beta)$, and dividing by $Z_{\mathcal{K}}(\beta)$ gives a gauge-invariant probability measure. Neither connectedness nor periodicity of $\mathcal{K}$ is needed.

The adjoint representation. Conjugation preserves the inner product $-2\operatorname{tr}(XY)$ and the bracket, so $\mathrm{Ad}(k)$ is orthogonal on $\mathfrak{su}(2)$. Its determinant is $+1$, since $\mathrm{SU}(2)$ is connected and the determinant equals 1 at I. In particular, $\mathrm{Ad}(k)$ preserves the norm, Lebesgue measure, and the balls centered at the origin. For surjectivity, note that $R(\vartheta) = \mathrm{Ad}(e^{\vartheta n \cdot \tau})$ solves $R'v = n \times Rv$; it is the rotation by ϑ about the unit vector n. Since every element of $\mathrm{SO}(3)$ has a fixed unit vector (its nonreal eigenvalues come in conjugate pairs, and the remaining real eigenvalue is 1) and acts on the orthogonal complement as a plane rotation, it is one of these rotations.

Spanning-tree gauges. We orient each forest link from the parent to the child, replacing U_e by U_e^{-1} when the given orientation is opposite; inversion preserves Haar measure. Set $h_o = I$ at every root and recursively $h_y = h_x U_{xy}$. Then $V_{xy} = h_x U_{xy} h_y^{-1} = I$ on the forest. Conversely, arbitrary h_x at the vertices that are not roots and arbitrary V_e off the forest determine U uniquely by $U_{xy} = h_x^{-1} V_{xy} h_y$, with $V_{xy} = I$ on forest links. All these maps are finite products and inverses, hence smooth. We list the vertices in increasing distance

from their roots along the forest. Conditionally on the earlier forest links, $h_y = h_x U_{xy}$ is Haar distributed and independent of all earlier h's. By induction, the joint law of the forest variables is product Haar measure. Conditionally on them, every link off the forest is translated on the left and on the right by fixed matrices. Its Haar factor is therefore unchanged, and these factors remain independent. This proves the product identity, first for products of functions and then by approximation for all integrable functions.

If the integrand is invariant under the gauge transformations equal to I at the roots, substituting the gauge transformation h makes it a function of V alone, and the product Haar integral over h contributes a factor one. A connected complex has $|\mathcal{V}| - 1$ tree links, which gives the stated number of remaining group variables. For a gauge transformation k we have $h_x(U^k) = k_o h_x(U) k_x^{-1}$ and $V_e(U^k) = k_o V_e(U) k_o^{-1}$, which leaves the conjugation at the root. We do not take a quotient by it, and no stabilizer factor appears. Applying the recursion in every block, with the links between blocks among the variables off the forest, proves the version for blocks with rooted spanning trees.

Products of group elements. Matrix exponentials are given by their absolutely convergent series, and inversion on $\mathrm{SL}(2,\mathbb{C})$ is polynomial in the matrix entries. In a complex neighborhood of a compact set of unitary matrices whose eigenvalues stay at a fixed distance from -1, the formula

$$\operatorname{Log} W = \int_0^1 (W - I)\big((1-s)I + sW\big)^{-1}\, ds \tag{5.2}$$

defines a holomorphic logarithm. Indeed, on the compact real set the matrices $(1-s)I + sW$ have smallest singular value bounded below uniformly in $s \in [0,1]$, and half of this bound persists on a fixed smaller complex neighborhood, by the identity for differences of inverses. For diagonal unitary matrices the formula reduces to the scalar principal logarithm, by direct integration; conjugation extends it to all unitary matrices of the set, and the identity $e^{\operatorname{Log} W} = W$ continues to the neighborhood by analytic continuation. On a connected neighborhood of I its trace vanishes, since $\det W = 1$ and the trace is continuous with value zero at I.

A product of at most ℓ factors involves at most 3ℓ scalar coordinates. On the larger polydisc its matrix norm and the norms of the relevant logarithms are bounded by a constant B depending on ℓ and the domains: each exponential is bounded by the exponential of the matrix norm of its exponent, each logarithm by (5.2), and factors in $\mathrm{SU}(2)$ have matrix norm one. If the smaller polydisc has coordinate margin $\delta > 0$, the Cauchy integral in each coordinate bounds a derivative of multi-index α by $B\alpha!\delta^{-|\alpha|}$. To see this, we insert the absolutely convergent power series into the circle integrals; the integral of z^k/z^{j+1} over a circle around zero vanishes for $k \neq j$ and equals $2\pi i$ for $k = j$. Summing all ordered derivatives of total order s introduces at most a factor $(3\ell)^s$, which gives the bound $s!C^s$ for the absolute derivative tensor. Where the branches are

defined, $\operatorname{Log}(kWk^{-1}) = k(\operatorname{Log} W)k^{-1}$ and $\operatorname{Log}(W^{-1}) = -\operatorname{Log} W$, by the same formula and analytic continuation.

The expansion with a removable singularity. Let $B(\epsilon) = \operatorname{Log}(e^{u}e^{\epsilon a}e^{-u-\epsilon v})$. For small fixed complex u, v, a it is holomorphic in $|\epsilon| < 1 + \delta_0$, with uniform bounds, and $B(0) = 0$. Differentiating the exponential series, we obtain

$$\frac{d}{d\epsilon} e^{-u-\epsilon v}\Big|_{\epsilon=0} = -\int_0^1 e^{-(1-t)u} v e^{-tu}\, dt.$$

Since the derivative of Log at I is the identity, $B'(0) = \operatorname{Ad}(e^{u})a - \int_0^1 \operatorname{Ad}(e^{tu})v\, dt$. The product depends on a, v only through $(\epsilon a, \epsilon v)$, and the coefficient of ϵ^k in B is therefore homogeneous of degree k in (a, v). Hence

$$\mathscr{R}_\epsilon = \int_0^1 (1-t) B''(t\epsilon)\, dt$$

is holomorphic, vanishes to order at least two in (a, v), and satisfies the bounds just proved. Using Taylor's formula along the segment $t(a, v)$ and the bound on second derivatives, we find on a fixed smaller complex ball

$$\|\mathscr{R}_\epsilon(u, v, a)\| \le C(|a| + |v|)^2, \qquad 0 \le \epsilon \le 1, \tag{5.3}$$

with C depending only on the product, the larger complex domain, and its margin. At $v = 0$ the product is $\exp(\epsilon \operatorname{Ad}(e^{u})a)$, its logarithm is $\epsilon \operatorname{Ad}(e^{u})a$, and the remainder vanishes. Every argument concerns a fixed product or an exact identity, and the stated dependence of the constants follows. □

5.2 Closed one-cochains and Gaussian elimination

Parts (1) and (2) of the next lemma are the discrete Poincaré lemma and the fact that the first real cohomology of the three-torus is $\mathbb{R}^3$; part (3) is Gaussian elimination by Schur complements [27]. The harmonic part c is kept as data throughout.

Lemma 5.2. *The following statements hold.*

1. *On every finite contractible rectangular box in $\mathbb{Z}^3$, a real closed one-cochain is the coboundary of a function on the vertices.*
2. *On the periodic cubic lattice of side $n \ge 4$, every real closed one-cochain α has a unique decomposition $\alpha = \nabla f + c$, where f is periodic with mean zero and c is constant in each link direction. Moreover $c_i = n^{-3} \sum_x \alpha_i(x)$. The decomposition holds in each color separately and after rescaling to physical units. Thus requiring the spatial mean of α to vanish removes exactly c, and not a gauge degree of freedom.*

3. *Let a real symmetric nonnegative quadratic form on a finite-dimensional space of fixed coordinates c and integration coordinates $z \in \mathbb{R}^f$ have matrix*

$$\mathsf{A} = \begin{pmatrix} A & B \\ B^{\mathsf{T}} & K \end{pmatrix}, \qquad K > 0.$$

For every c, including all specified harmonic coordinates,

$$\frac{1}{2}(c,z)^{\mathsf{T}}\mathsf{A}(c,z) = \frac{1}{2}c^{\mathsf{T}}(A - BK^{-1}B^{\mathsf{T}})c + \frac{1}{2}(z + K^{-1}B^{\mathsf{T}}c)^{\mathsf{T}}K(z + K^{-1}B^{\mathsf{T}}c),$$

and

$$\int_{\mathbb{R}^f} e^{-\frac{1}{2}(c,z)^{\mathsf{T}}\mathsf{A}(c,z)}\,dz = (2\pi)^{f/2}(\det K)^{-1/2}e^{-\frac{1}{2}c^{\mathsf{T}}(A-BK^{-1}B^{\mathsf{T}})c}.$$

Successive minimization, or successive Gaussian integration, over the blocks of any ordered decomposition of z gives the same Schur complement and the same product of determinants as simultaneous elimination. Conditionally on c, the Gaussian measure in z has mean $-K^{-1}B^{\mathsf{T}}c$ and covariance K^{-1}. A Gaussian measure defined on a specified orthogonal complement of a null space, by a quadratic form positive there, has covariance equal to the inverse on that complement and zero on the null space.

These are exact finite-dimensional statements; in particular, no lower bound on eigenvalues uniform in the side n is asserted.

Proof. Boxes. We regard a one-cochain α as an antisymmetric function on oriented links; closedness means that its signed sum around every unit square vanishes. On $\mathbb{Z}^3$, a finite path can be sorted by coordinate direction by adjacent interchanges of steps in different directions. Each interchange crosses exactly one unit square and preserves the integral of α, and adjacent opposite steps in one direction cancel. Then every closed path has integral zero, since after sorting its total displacement in each direction is zero and all steps cancel. Inside a rectangular box we integrate from a fixed corner, first in direction 1, then in direction 2, then in direction 3. Interchanging an additional final step in direction i with the later coordinate segments uses only the squares of the intervening rectangle, which lies in the box, and closedness makes the two path integrals equal. The resulting vertex function has coboundary α on every link. Boxes with a side of length zero are covered by omitting the absent direction.

The periodic lattice. We lift a periodic closed cochain to $\mathbb{Z}^3$. The argument just given produces a function f_0 on $\mathbb{Z}^3$ with $f_0(x + e_i) - f_0(x) = \alpha_i(x)$. Since α is periodic, $f_0(x + ne_i) - f_0(x) = P_i$ does not depend on x, because its difference across every link is zero; equivalently, P_i is the integral of α along any straight cycle winding once in direction i. Set $c_i = P_i/n$. The function $f(x) = f_0(x) - \sum_i c_i x_i$ is periodic and satisfies $\alpha = \nabla f + c$; subtracting its average makes its mean zero. If $\nabla f + c = 0$, then summing over a winding cycle gives $nc_i = 0$. Then all differences of f vanish, and the mean-zero condition implies

$f = 0$, which proves uniqueness. Because the sum of $\nabla_i f$ over all periodic vertices telescopes to zero, we have $c_i = n^{-3} \sum_x \alpha_i(x)$, and the mean condition removes exactly the three constants. For cochains with values in $\mathfrak{su}(2)$, the argument applies to each real component. For physical potentials we use $\nabla_a = a^{-1}\nabla$ and integrate $a\alpha$ along paths; the conclusion has the same form, with $c_i = P_i/(na)$.

Gaussian elimination. If we expand the right side of the completion of the square, its cross term is $c^{\mathsf{T}} B z$, and the added constant $c^{\mathsf{T}} B K^{-1} B^{\mathsf{T}} c/2$ cancels the subtracted one. After the translation $z \mapsto z - K^{-1} B^{\mathsf{T}} c$, an orthogonal diagonalization of the positive matrix K reduces the integral to products of $\int_{\mathbb{R}} e^{-kt^2/2} dt = \sqrt{2\pi/k}$. To diagonalize K, we maximize its Rayleigh quotient on the unit sphere to obtain an eigenvector, restrict to the orthogonal complement of this eigenvector, and induct on the dimension. The value of the one-dimensional integral follows by squaring it and using polar coordinates in the plane. We obtain the Gaussian formula, with the convention that the integral is one if $f = 0$. The same completion of the square with a linear term in z, differentiated at zero, gives the conditional mean and covariance.

For successive elimination, write $z = (z_1, z_2)$ and $K = \left(\begin{smallmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{smallmatrix}\right)$. Both K_{11} and $K_{22} - K_{21} K_{11}^{-1} K_{12}$ are positive definite, since their quadratic forms are the restriction of the form of K and the minimum of that form over z_1. The change of variables $z_1 \mapsto z_1 + K_{11}^{-1} K_{12} z_2$ has determinant one, and by block multiplication we have

$$\det K = \det K_{11} \, \det\bigl(K_{22} - K_{21} K_{11}^{-1} K_{12}\bigr).$$

The unique joint minimizer in z solves $Kz = -B^{\mathsf{T}} c$; solving the first block and substituting gives the successive minimizers. The minimum value is therefore the same Schur form. By the determinant identity and the Gaussian formula, successive integration gives the same normalization. Induction over the blocks proves the statement for every ordered decomposition; for nonnegative integrands the repeated integrals are justified directly. No harmonic coordinate is discarded, since the vector c was arbitrary throughout.

On the given orthogonal complement of a null space, we diagonalize the restricted positive form. In the resulting coordinates the Gaussian measure is a product of independent one-dimensional Gaussian measures with variances equal to the inverse eigenvalues; embedding this measure by setting the null coordinates equal to zero, we obtain the stated covariance. This construction lives on the complement; it is not a Lebesgue integral along null directions. □

5.3 Analytic coefficient bounds and implicit functions

The following lemma is the calculus of the coefficient norms of Definition 4.6. Its first parts are combinatorial. A Taylor coefficient of a composite map is a finite or absolutely convergent sum of products of Taylor coefficients of the constituents. We bound the

absolute value of the sum by the sum of absolute values. The spatial weight survives because the connecting networks of the factors can be joined at the contracted indices, and the volume factors in the column sums telescope. The simplest instance is a product of two kernels, T from mesh a_{mid} to mesh a_{out} and S from mesh a_{in} to mesh a_{mid}. In counting coordinates the kernel of TS is $\sum_j T_{ij}S_{jk}$, without any volume factor, and its column sum at a fixed input k carries the factor

$$\frac{a_{\mathrm{out}}^3}{a_{\mathrm{in}}^3} = \frac{a_{\mathrm{out}}^3}{a_{\mathrm{mid}}^3} \cdot \frac{a_{\mathrm{mid}}^3}{a_{\mathrm{in}}^3},$$

so that column norms are submultiplicative. For a composition with one fixed input, we use column sums along the chain of factors that joins this input to the output, and row sums for all other factors. The later parts concern inverses and square roots of matrices with a spectral gap. The exponential decay of an inverse follows from the conjugation argument of Combes and Thomas [61], and square roots are represented by the standard resolvent integral [27]; the proof keeps track of the spatial weights and of all fixed indices. Bounds by coefficientwise majorant series are a classical tool of constructive renormalization group methods; the volume-normalized columns, the arbitrary fixed inputs, and the traces with a fixed external index are specific to our use.

Throughout this section, all indices are scalar indices and all sums are counting sums. A contraction identifies two indices of the same kind (same lattice and scale of introduction); an identification of indices of different kinds must first be represented by an explicitly bounded transfer kernel. We fix a rate $a_{\mathrm{sp}} \geq 0$ and write $|T| = |T|_{a_{\mathrm{sp}}}$ for the norm (4.9), $R(T)$ for its row norm, and $C_r(T)$ for its volume-normalized column sums. For a scalar tensor we use the sums (4.10) with one index fixed; on several meshes, a scalar tensor may instead be normalized by a reference volume v_*, which multiplies each summand with the index i_r fixed by v_*/v_{i_r}. Distances and network lengths are those of Definition 4.6, measured in units of the current output lattice spacing. For a matrix $B = (B_{xy})$ of blocks indexed by a finite metric space (X, d), we write

$$\|B\|_c = \max\Big\{\sup_x \sum_y e^{cd(x,y)}\|B_{xy}\|,\ \sup_y \sum_x e^{cd(x,y)}\|B_{xy}\|\Big\}, \qquad c \geq 0,$$

where $\|B_{xy}\|$ is the operator norm of the block.

Lemma 5.3. *The following statements hold.*

1. Substitution. *For tensors $T(o; j_1, \dots, j_k)$ and $S_r(j_r; \mathbf{l}_r)$, $1 \leq r \leq k$, the tensor*

$$U(o; \mathbf{l}_1, \dots, \mathbf{l}_k) = \sum_{j_1,\dots,j_k} T(o; j_1, \dots, j_k) \prod_{r=1}^{k} S_r(j_r; \mathbf{l}_r)$$

has every output-row norm and every volume-normalized input-column norm bounded by $|T| \prod_r |S_r|$. In particular compatible matrix products are submultiplicative in the row norm

and in the volume-normalized column norm; for counting-coordinate kernels from mesh a_{in} to mesh a_{out} the column factor is exactly $a_{\mathrm{out}}^3/a_{\mathrm{in}}^3$, and a contraction introduces no further volume factor. The same bound holds for a scalar outer tensor normalized by a reference volume. For a scalar outer tensor with counting sums on mesh a_{old}, the sum with a new input l fixed acquires the factor v_l/v_{old}, maximized over the possible kinds of the replaced inputs. Pointwise products with a common output index satisfy the product bound, and a shared index may be represented by the equality tensor $\mathbf{1}_{o=i_1=\cdots=i_r}$, whose norm is one when all its ports are of the same kind.

2. Contraction diagrams. *Consider a finite connected diagram of tensors, in which shared indices are represented by equality tensors and every contracted index identifies two ports, and fix one external index. Choose a spanning tree of the graph of factors, rooted at the factor containing the fixed index, and attach every other factor V to its parent through a port $j(V)$. For a vector factor V with output $o(V)$, let $A_V = |V|$ if $j(V) = o(V)$ and $A_V = (v_{j(V)}/v_{o(V)})|V|$ if $j(V)$ is an input; for the factor containing the fixed index use the same rule at that index; for a scalar factor use its sum with the corresponding port fixed. Then the sum over all indices except the fixed one of the absolute value of the diagram, weighted by $e^{a_{\mathrm{sp}}\mathtt{t}}$ of the locations of the external indices, is at most $\prod_V A_V$. If the fixed index is an external input l, the volume-normalized column of the diagram is obtained by multiplying by v_o/v_l, where o is the output of the diagram; for the substitution trees of part (1) the volume ratios cancel exactly. A diagram without a fixed external index is not covered; for example* $\mathrm{tr}\, I$ *equals the number of indices. An externally differentiated trace is covered if the differentiated tensor has the bound with the input fixed and* all *of its matrix ports and other Taylor inputs summed; a row bound alone does not suffice.*

3. Majorant series. *Products, substitutions, and summable connected diagrams of analytic maps with absolute majorants (in the sense of Definition 4.6) are bounded coefficientwise by the corresponding products, compositions, and diagram sums of the nonnegative scalar majorants, with the bounds of parts (1) and (2). The domain of the conclusion is the common product of polydiscs on which these scalar series converge absolutely. For $F \circ G$ it suffices that the scalar majorant of G maps the domain strictly inside the coefficient domain of F; for formal substitution take $G(0) = 0$, and otherwise require this absolute image condition, so that the substitutions into the constant terms also converge. The coefficients with one fixed input are bounded by the derivative of the same scalar majorant; no second Taylor factorial occurs.*

4. Smaller domains. *If $A(s) = \sum_n A_n s^n$ with $A_n \geq 0$ converges at $R > 0$, then for $0 < r < R$ and every fixed $j \geq 0$,*

$$A^{(j)}(r) \leq R^{-j} \sup_{n \geq j} (n)_j (r/R)^{n-j} A(R),$$

where $(n)_j = n(n-1)\cdots(n-j+1)$. *If the majorant* $\sum_k b_k s^k$ *satisfies* $\sum_k b_k R^k \le B$, *the coefficients of degree* s *of its translate to a background of size* $r_1 < R$ *are at most* $B(R-r_1)^{-s}$. *Thus evaluation, translation to a background, and a fixed finite number of derivatives are controlled on a smaller coefficient domain, at the same spatial rate. These statements concern absolute coefficient series; they are not Cauchy estimates for directional values.*

5. Resolution into occurrences. *Every expression built by these operations has an exact coefficient resolution, indexed by its constituent coefficient occurrences, its contracted indices, and its partitions of derivatives. Assign to each constituent occurrence a connected network through the locations of its ports and Taylor indices, and to each contraction the common location; the network of a resolved occurrence is the union of these networks. Its external monomial has its exact multi-index, and its fluctuation index set is the set of blocks of fluctuation variables with a positive exponent; the locations of background variables need not lie in that set. The weighted total variation of the resolution satisfies the same scalar diagram bounds, provided the assigned networks satisfy the constituent bounds. Let* W *be a specified boundary. If a designated constituent occurrence is assigned, by hypothesis, a connected network meeting* W, *then every resolved occurrence containing this designated factor has a connected network meeting* W, *and its weighted total variation satisfies the corresponding diagram bound, provided the constituent bounds include the weights of these assigned networks. Marking an input for differentiation does not by itself provide such a visit.*

6. Networks and trees. *Let* $\mathrm{t}_{\mathrm{MST}}(S)$ *be the length of a minimal spanning tree on a finite set* S *of locations. Then* $\mathrm{t}(S) \le \mathrm{t}_{\mathrm{MST}}(S) \le 2\mathrm{t}(S)$. *A bound at rate* a_{sp} *with shortest networks therefore gives a bound at rate* $a_{\mathrm{sp}}/2$ *with spanning trees on the locations of the external indices; this reduction is made once, independently of the order of the tensors.*

7. Inverses. *Let* (X,d) *be a finite metric space, with blocks of a fixed finite dimension, such that* $\#\{y : d(x,y) \le R\} \le D(1+R)^v$ *for all* $x \in X$ *and* $R \ge 0$. *Let* $K = K^* \ge \lambda I > 0$ *satisfy, for some* $a > 0$,

$$\max\Big\{\sup_x \sum_{y\neq x} e^{ad(x,y)}\|K_{xy}\|,\ \sup_y \sum_{x\neq y} e^{ad(x,y)}\|K_{xy}\|\Big\} \le H.$$

Let $b = \min\{a/2, a\lambda/(4H)\}$ *if* $H > 0$ *and* $b = a/2$ *if* $H = 0$; *then the same maximum with weights* $e^{bd(x,y)} - 1$ *is at most* $\lambda/2$. *For every* $0 < b' < b$,

$$\|(K^{-1})_{xy}\| \le 2\lambda^{-1}e^{-bd(x,y)}, \qquad \|K^{-1}\|_{b'} \le 2\lambda^{-1}\mathcal{S}(b-b';D,v),$$

where $\mathcal{S}(c;D,v) = D\sum_{k\ge 0}(k+2)^v e^{-ck}$. *No upper bound on the diagonal of* K *is needed, and the bounds do not depend on* $|X|$.

8. Perturbations and square roots. *In the setting of part (7), put* $C_{\mathrm{inv}} = \|K^{-1}\|_{b'}$. *For every complex matrix* E *with* $\|E\|_{b'} \le (2C_{\mathrm{inv}})^{-1}$, *we have* $\|(K+E)^{-1}\|_{b'} \le 2C_{\mathrm{inv}}$, *and the*

inverse is a holomorphic function of E. If also $K \le \Lambda I$, there exists $\eta_0 > 0$, depending only on $a, H, \lambda, \Lambda, D, v, b'$, such that for $\|E\|_a < \eta_0$ the branches $(K+E)^{1/2}$ and $(K+E)^{-1/2}$ continuing the positive roots exist and are bounded in $\|\cdot\|_{b'/2}$ by constants depending only on these data. If $E = E(\theta)$ has an absolute majorant with all fixed indices on a fixed analytic ball, the coefficients of these roots in θ have absolute bounds with every fixed index, with constants depending in addition only on that majorant and on the ratios of the analytic radii.

9. Logarithms of determinants. *In the setting of part (8), $D \log\det K = \operatorname{tr}(K^{-1}DK)$, and the derivatives of positive order of $\log\det(K+E(\theta))$ in θ have absolute bounds with any fixed external index, with one reduction of the rate independent of the order. The undifferentiated $\log\det K$ is not bounded independently of $|X|$.*

10. Implicit functions. *Let $\Phi(\theta, u)$ be an analytic map of input variables $\theta = (\theta_j)$ and unknowns $u = (u_o)$, with values indexed like u, defined on a product of polydiscs, with $\Phi(0,0) = 0$. Assume that for all $k, l \ge 0$ the output-row norm and every input-column norm, at any fixed input θ_j or u_o, of the coefficient tensor $D_\theta^k D_u^l \Phi(0,0)/(k!\,l!)$ are at most the coefficient of $t^k Y^l$ in*

$$\Phi^+(t,Y) = At + \kappa Y + \frac{A(t+Y)^2}{1 - C(t+Y)}, \qquad A, C > 0, \quad 0 \le \kappa < 1.$$

In particular the linear map $D_u\Phi(0,0)$ has row and column norms at most κ. Let $\delta = 1-\kappa$, $r = \min\{1, (4C)^{-1}, \delta/(32A)\}$, and $t_0 = \min\{r, \delta r/(4A)\}$, and assume that the domain of Φ contains a neighborhood of the closed product $\{\max_j|\theta_j| \le t_0,\ \max_o|u_o| \le r\}$. Then the scalar equation $Y = \Phi^+(t,Y)$ has a unique solution $Y(t)$ with $|Y(t)| \le r$ for $|t| < t_0$; it is analytic, $Y(0) = 0$, and its Taylor coefficients are nonnegative. For $\max_j|\theta_j| < t_0$ the system $u = \Phi(\theta, u)$ has a unique solution $u(\theta)$ with $\max_o|u_o| \le r$, and for every k the output-row norm and every input-column norm of $D^k u(0)/k!$ are at most the coefficient of t^k in $Y(t)$. For a fixed input θ_j, the derivative $\partial_{\theta_j} u$ has coefficient tensors bounded by the coefficients of

$$Y'(t) = \frac{A + A\varphi'(t+Y(t))}{1 - \kappa - A\varphi'(t+Y(t))}, \qquad \varphi(s) = \frac{s^2}{1 - Cs},$$

whose denominator satisfies $|1 - \kappa - A\varphi'(t+Y(t))| \ge 5\delta/8$ for $|t| < t_0$. In particular, all derivatives of positive order satisfy bounds $s! C_1^s$ at the same spatial rate, also after translation to a background in a fixed smaller ball, where C_1 depends only on A, C, κ and the radius ratios, and not on the number of coordinates. If a parameter enters Φ with a variation of majorant $H(t,Y)$, the variation of the solution has majorant $Z(t)$ with $Z(t) \le H(t, Y(t))/(1 - \partial_Y \Phi^+(t, Y(t)))$ for $0 \le t < t_0$; this bounds the value of the majorant series at t, and it is not a coefficientwise inequality.

The constants in parts (1)–(6) are as displayed. In parts (7)–(10) they have the dependence described in item (1) of Definition 4.14, through the displayed data. When the counting bound for

the indices depends on J (with $D = D_J$), the constants depend on this fixed J, and no uniformity as $J \to \infty$ follows. Bounds obtained from part (10) for a class of expressions require one common scalar majorant for the whole class; expressions of arbitrary algebraic complexity are not covered without such a majorant.

Proof of Lemma 5.3. We first prove parts (1)–(6), which are bookkeeping for absolute sums, then the inverse estimates (7)–(9), and finally the implicit function statement (10).

Step 1: substitution. For matrices, the row norm of $\sum_j T_{ij} S_{jk}$ satisfies

$$\sup_i \sum_k e^{a_{\mathrm{sp}} d(i,k)} \Big\| \sum_j T_{ij} S_{jk} \Big\| \le R(T) R(S),$$

since $d(i,k) \le d(i,j) + d(j,k)$. For columns, the exact identity

$$\frac{v_i}{v_k} = \frac{v_i}{v_j} \frac{v_j}{v_k}, \qquad \sup_k \sum_i \frac{v_i}{v_k} e^{a_{\mathrm{sp}} d(i,k)} \Big\| \sum_j T_{ij} S_{jk} \Big\| \le C(T) C(S) \tag{5.4}$$

holds. If indices of several kinds occur, the sums include them with their volumes. This proves submultiplicativity and explains why the column factor of a counting-coordinate kernel must be exactly $a_{\mathrm{out}}^3 / a_{\mathrm{in}}^3$.

For the substitution tensor U, the union of the networks of T and of the S_r, joined at the contracted indices, connects the locations of all external indices, which implies

$$\mathsf{t}(\text{locations of the external indices}) \le \mathsf{t}(o, \mathbf{j}) + \sum_r \mathsf{t}(j_r, \mathbf{l}_r).$$

We take absolute values before any summation. For an output row, we sum each inner branch by its row norm and then the outer tensor by its row norm. If an external input l belonging to branch r is fixed, we sum every other branch by its row norm, use the column of branch r at l, and the j_r-column of the outer tensor. The volume factors telescope, since $v_o / v_l = (v_o / v_{j_r})(v_{j_r} / v_l)$ by (5.4). For a scalar outer tensor normalized by a reference volume the same computation applies, and for counting sums the only change is the factor v_l / v_{old}. At a common output index the networks meet at that output, and a bound with an input fixed uses the column of the factor carrying the input and rows of the other factors. This proves part (1).

Step 2: diagrams. We replace every edge of the diagram outside the chosen spanning tree by two independently summed copies of its index, deleting the equality constraint between them; for nonnegative sums this can only increase the result. When a split edge is present we may enlarge the external network weight to include the locations of both copies, since the connected tree of factors still spans the locations of the given external indices. We orient the tree from the factor containing the fixed index. Starting at its

leaves, we sum each factor over all its ports except the port of attachment to its parent, using the bounds A_V; we continue toward this factor and finally sum it over all ports except the fixed index. This proves the bound without any count of the internal indices. In a substitution tree, the factors other than rows lie on the path from the fixed input to the output, and the product of their volume ratios is v_l/v_o, which the external column normalization cancels. A diagram without a fixed external index has no factor at which to start, and it is excluded. This proves part (2).

Step 3: majorant series and smaller domains. We first consider Taylor polynomials and finite diagrams. For $G(0) = 0$, the ordered derivative formula reads

$$D^N(F \circ G)(0)[u_1, \dots, u_N] = \sum_{n=0}^{N} \frac{1}{n!} \sum_{(B_1,\dots,B_n)} F_n\big[G_{|B_1|}[u_{B_1}], \dots, G_{|B_n|}[u_{B_n}]\big],$$

where $(B_1, \dots, B_n)$ runs over the ordered partitions of $\{1, \dots, N\}$ into nonempty blocks, and the term $N = n = 0$ is understood separately. For block sizes $m_1 + \cdots + m_n = N$ the number of ordered partitions is $N!/\prod_r m_r!$. Dividing by $N!$ therefore gives exactly the coefficient of s^N in $\widehat{F}(\widehat{G}(s))$, and parts (1) and (2) bound each summand. Marking one input chooses its block and its position in the block, exactly as in $(\widehat{F} \circ \widehat{G})' = (\widehat{F}' \circ \widehat{G})\widehat{G}'$. This shows that the coefficient of order N with one marked input is bounded by Nh_N, where h_N is the Taylor-divided coefficient of the composite majorant. Inputs of different kinds may be marked by separate scalar variables. For infinite orders and diagrams, the nonnegative majorant series converge on the stated domain, and Tonelli's theorem and absolute convergence justify every grouping, contraction, substitution, and derivative; equality of the analytic functions follows from equality of their coefficients. The case $G(0) \neq 0$ is handled in the same way under the absolute image condition. This proves part (3).

For part (4), we write $r^{n-j} = R^{n-j}(r/R)^{n-j}$ termwise; then $A^{(j)}(r) = \sum_{n \geq j} (n)_j A_n R^{n-j} (r/R)^{n-j} \leq R^{-j} \sup_{n \geq j} (n)_j (r/R)^{n-j} \sum_n A_n R^n$. The coefficient of degree s of the translate of the majorant to a background of size $r_1 < R$ is the binomial sum $\sum_{k \geq s} \binom{k}{s} b_k r_1^{k-s}$. By the binomial theorem, $\binom{k}{s} r_1^{k-s} (R - r_1)^s \leq R^k$ for each $k \geq s$; multiplying by b_k, summing, and using $\sum_k b_k R^k \leq B$, we obtain $\sum_{k \geq s} \binom{k}{s} b_k r_1^{k-s} \leq B(R - r_1)^{-s}$. Evaluating extra inputs at a background can only remove locations of external indices from a network, and the same spatial rate therefore remains valid.

For part (5), we keep a separate signed occurrence for every summand of the derivative formula, every tuple of contracted indices, and every refinement of a constituent network. Its coefficient is the product of the constituent coefficients and the displayed combinatorial factor, and its monomial is the product of their monomials. Grouping occurrences with equal multi-indices or equal networks is optional and can only decrease the total variation. The network inequality of Step 1 implies the weighted bound, and the convergence

argument of this step justifies the infinite sums. If a designated constituent occurrence has an assigned network meeting W, the network of a resolved occurrence containing it is a union that contains this assigned network, and it retains the visit to W.

Step 4: networks and trees. The inequality $\mathtt{t}(S) \le \mathrm{t}_{\mathrm{MST}}(S)$ holds since a spanning tree on S is a connecting network. Conversely, we delete the cycles of a competing network without increasing its length, traverse the resulting tree with every edge twice, shortcut the tour between successive points of S by the triangle inequality, and delete its last edge. The result is a path through S of length at most twice the length of the network. Taking infima, we find $\mathrm{t}_{\mathrm{MST}}(S) \le 2\mathtt{t}(S)$, which implies $e^{(a_{\mathrm{sp}}/2)\mathrm{t}_{\mathrm{MST}}} \le e^{a_{\mathrm{sp}}\mathtt{t}}$. Joining the constituent trees once proves the assertion that the rate is halved only once. This proves part (6).

Step 5: inverses. For a block matrix B with absolute row sums at most r and column sums at most c, the Cauchy–Schwarz inequality gives

$$\sum_{x}\Big|\sum_{y} B_{xy}u_y\Big|^2 \le r\sum_{x,y}\|B_{xy}\|\,|u_y|^2 \le rc\sum_{y}|u_y|^2,$$

which implies $\|B\|_{2\to 2} \le \sqrt{rc}$. For $0 < b \le a/2$ and $s \ge 0$ we have $e^{bs}-1 \le bse^{bs} \le (2b/a)e^{as}$, and with the choice of b in part (7) the weighted off-diagonal sums are at most $(2b/a)H \le \lambda/2$; any smaller positive choice also works. Fix $y_0 \in X$ and let $W_x = e^{bd(x,y_0)}I$ on the block of x. The matrix

$$B = WKW^{-1} - K, \qquad B_{xz} = \big(e^{b(d(x,y_0)-d(z,y_0))}-1\big)K_{xz},$$

has zero diagonal, and by the triangle inequality each scalar factor is at most $e^{bd(x,z)}-1$ in absolute value. By the bound just proved, $\|B\|_{2\to 2} \le \lambda/2$. Since $K \ge \lambda I$, we have $\|K^{-1}\|_{2\to 2} \le 1/\lambda$, and the geometric series for $(I+K^{-1}B)^{-1}$ yields $\|(WKW^{-1})^{-1}\|_{2\to 2} \le 2/\lambda$. The (x,y_0) block of this inverse is $e^{bd(x,y_0)}(K^{-1})_{xy_0}$, which proves the pointwise bound. The largest value of the weight never enters, and the diagonal of K cancels from B.

For $c > 0$, decomposing into the shells $k \le d(x,y) < k+1$ and using the counting bound, we obtain

$$\sup_{x}\sum_{y} e^{-cd(x,y)} \le D\sum_{k=0}^{\infty}(k+2)^{v}e^{-ck} = \mathcal{S}(c;D,v) < \infty. \tag{5.5}$$

With $c = b - b'$ this bounds both weighted row and column sums of K^{-1} by $2\lambda^{-1}\mathcal{S}(b-b';D,v)$. The fixed block dimension does not change the argument, since all entries were bounded in block operator norm. This proves part (7).

Step 6: perturbations and square roots. By submultiplicativity of $\|\cdot\|_{b'}$ (Step 1, without volume factors), when $\|E\|_{b'} \le (2C_{\mathrm{inv}})^{-1}$ the series

$$(K+E)^{-1} = \sum_{r=0}^{\infty} (-K^{-1}E)^r K^{-1} \tag{5.6}$$

converges absolutely in this norm, with sum bounded by $2C_{\mathrm{inv}}$. Uniform convergence on every smaller ball implies holomorphy by termwise differentiation, and multiplication of partial sums shows that the sum is the inverse.

For the square roots, let $c_2 = b'/2$. We apply the pointwise bound of Step 5 to $K + tI \ge (\lambda + t)I$, whose off-diagonal part is that of K and whose commutator bound $\lambda/2 \le (\lambda + t)/2$ persists. This gives, for all $t \ge 0$,

$$\|(K+tI)^{-1}\|_{c_2} \le \frac{C_0}{\lambda + t}, \qquad C_0 = 2\mathcal{S}(b - c_2; D, v). \tag{5.7}$$

Fix $\eta_0 < \min\{\lambda/(2C_0), \lambda/2\}$. Since $c_2 < a$, we have $\|E\|_{c_2} \le \|E\|_a < \eta_0$, and expanding the shifted resolvents as in (5.6), we obtain $\|(K+E+tI)^{-1}\|_{c_2} \le 2C_0/(\lambda+t)$. Hence the absolutely convergent integral

$$S(E) = \frac{1}{\pi} \int_0^\infty t^{-1/2} (K + E + tI)^{-1}\, dt \tag{5.8}$$

has $\|S(E)\|_{c_2} \le 2C_0\lambda^{-1/2}$ and is holomorphic in E. The scalar identity $\pi^{-1}\int_0^\infty t^{-1/2}(k+t)^{-1}dt = k^{-1/2}$ (substitute $t = ks^2$ and integrate $2/(1+s^2)$) and diagonalization show that $S(E)$ is the positive inverse square root when $K + E$ is real symmetric and positive. For an arbitrary complex, possibly nonsymmetric E, let $M = K + E$. By the bound of Step 5, $\|E\|_{2\to 2} < \eta_0 < \lambda/2$, which implies $\mathrm{Re}\langle u, Mu\rangle \ge (\lambda/2)|u|^2$. For real $d > \|M\|_{2\to 2}^2/\lambda$,

$$\|(I - M/d)u\|^2 \le \big(1 - \lambda/d + \|M\|_{2\to 2}^2/d^2\big)|u|^2 < |u|^2.$$

With $T = I - M/d$, expanding $(M + tI)^{-1}$ in powers of T and integrating termwise in (5.8), which is justified by $\|T\|_{2\to 2} < 1$, identifies $S(E)$ with $d^{-1/2}\sum_{r\ge 0} c_r T^r$, where $c_r = 4^{-r}\binom{2r}{r}$ are the coefficients of $(1-z)^{-1/2}$; indeed, differentiating $(1-z)^{-1/2}$ at zero gives $c_0 = 1$ and $c_{r+1} = (r + 1/2)c_r/(r+1)$. The square of this scalar series is $(1-z)^{-1}$, which gives $S(E)^2 M = I$; all factors commute with M, being limits of its resolvents. This proves the root identity without a symmetry assumption on E. Multiplying by $K + E$ gives the square root; since $K \le \Lambda I$ implies $\|K\|_{c_2} \le \Lambda + H$, this multiplication is bounded uniformly. All choices depend only on $a, H, \lambda, \Lambda, D, v, b'$.

Suppose now that $E = E(\theta)$ has an absolute majorant with all fixed indices on a fixed analytic ball. We insert its Taylor series into the shifted Neumann series before taking any norm. Every coefficient is a contraction, with one external index fixed, of resolvents

and differentiated factors E, to which Steps 1 and 2 apply with any fixed external index. For r insertions, the resolvent integral is bounded by

$$\frac{1}{\pi}\int_0^\infty t^{-1/2}\Big(\frac{C_0}{\lambda+t}\Big)^{r+1}dt \le C_0^{r+1}\lambda^{-r-1/2}.$$

Replacing E by its majorant and using this bound, we obtain a nonnegative scalar series that bounds every absolute coefficient of $S(E(\theta))$ with any index fixed; its radius does not depend on the number of indices. Multiplication by $K+E$ gives the statement for the square root. The constant coefficient is controlled by (5.7), and every coefficient of positive degree contains a differentiated factor E. This proves part (8).

Step 7: logarithms of determinants. Expanding the determinant in columns, we have $D\det K = (\det K)\operatorname{tr}(K^{-1}DK)$, since the linear term of $\det(I+tB)$ is $t\operatorname{tr}B$. To localize the trace, we keep its two matrix indices x, y open. By Steps 1 and 2, a joint coefficient $T_s(x,y;u_1,\dots,u_s)$ of the differentiated product has a weighted output-row bound B_s at some fixed rate $c>0$. Fix an external input $u_j = u$ and close the trace by setting $y = x$. The network length before the trace is closed is at least both the network length of the locations of the remaining external indices and $d(x,u)$. Using half the rate for each, we find that the sum over the other external inputs, with their external weight at rate $c/2$, is at most $B_s e^{-cd(x,u)/2}$ for fixed x. If $u \notin X$, let $x_0 \in X$ be a nearest point; then $d(x,x_0) \le 2d(x,u)$, and (5.5) sums the last bound over x with a factor at most $\mathcal{S}(c/4; D, v)$; for $u \in X$ take $x_0 = u$. This gives an absolute bound with any external index fixed, with one reduction of the rate independent of s. For any volume normalization of the fixed external index, the column factors are propagated by (5.4); no total count of internal indices is inserted. Higher derivatives follow by differentiating the inverse, or from

$$\log\det(K+E) - \log\det K = \sum_{r\ge1}\frac{(-1)^{r+1}}{r}\operatorname{tr}\big((K^{-1}E)^r\big),$$

which holds in the neighborhood of part (8); to see this, differentiate in a scalar multiple of E, use the geometric series for the inverse, and integrate from zero. At positive order a derivative of E provides the fixed external index. Without such an index the bound fails: $K = 2I$ gives $\log\det K = |X|\log 2$ times the block dimension. This proves part (9).

Step 8: the scalar equation. We write $\varphi(s) = s^2/(1-Cs)$, so that $\Phi^+(t,Y) = At + \kappa Y + A\varphi(t+Y)$. For $|t| \le t_0$ and $|Y| \le r$ we have $|t+Y| \le 2r$, $C|t+Y| \le 1/2$, and

$$|At| + A|\varphi(t+Y)| \le \frac{\delta r}{4} + 8Ar^2 \le \frac{\delta r}{2}.$$

Moreover $|\varphi'(s)| \le 2|s|/(1-C|s|) + C|s|^2/(1-C|s|)^2 \le 12r$ for $|s| \le 2r$. The map $Y \mapsto \Phi^+(t,Y)$ therefore maps the closed disc of radius r into itself, since $\kappa r + \delta r/2 < r$,

and its derivative is at most $\kappa + 12Ar \le 1 - 5\delta/8 < 1$. The iteration started at $Y = 0$ converges uniformly, since successive differences decrease by this ratio, and the same estimate implies uniqueness in the disc. Since each iterate is holomorphic, the limit is holomorphic, and $Y(0) = 0$. Every iterate has nonnegative Taylor coefficients, and they increase along the iteration; the limit therefore has nonnegative coefficients. Equivalently, the coefficient of degree s of Y is $(1-\kappa)^{-1}$ times a nonnegative expression in the earlier coefficients, with the source term at degree one.

Step 9: the system. For $\max_j|\theta_j| \le t$ and $\max_o|u_o| \le Y$, the row bounds of the hypothesis imply $\max_o|\Phi_o(\theta,u)| \le \Phi^+(t,Y)$, since the weights $e^{a_{\mathrm{sp}}\mathfrak{t}}$ are at least one; similarly the Lipschitz constant of $u \mapsto \Phi(\theta,u)$ in the maximum norm is at most $\partial_Y\Phi^+(t,Y)$. By Step 8, the Picard iteration $u^{(0)} = 0$, $u^{(n+1)} = \Phi(\theta,u^{(n)})$ stays in the ball of radius r and converges, and the small solution is unique. By part (3), each iterate $u^{(n)}$ has coefficient tensors bounded, in every output-row norm and every input-column norm, by the coefficients of the scalar iterate $Y^{(n)}$, where $Y^{(n+1)} = \Phi^+(t,Y^{(n)})$; the factorials cause no loss, since after division by $s!$ the counting of ordered partitions in Step 3 reproduces ordinary composition of power series. Passing to the limit coefficientwise, we obtain the bounds for $u(\theta)$. For the derivative in a fixed input θ_j, we mark this input in the same expansion. The branch containing it uses column sums and all other branches use row sums. By Step 3, the resulting scalar recursion is the derivative of the scalar equation, which is solved by the displayed formula for $Y'(t)$. By the reverse triangle inequality and $A|\varphi'| \le 12Ar$, its denominator has modulus at least $1 - \kappa - 12Ar \ge 5\delta/8$, and no further loss of the spatial rate occurs. All comparisons are made coefficient by coefficient, before summing over degrees.

Translation to a background of size r_1 in a smaller ball is handled by part (4): the coefficients of order s are bounded by $B(R-r_1)^{-s}$, and multiplying back by $s!$ and absorbing the prefactor for $s \ge 1$ gives $s!C_1^s$, with C_1 depending only on the majorants and radius ratios. For a parameter entering Φ with variation majorant $H(t,Y)$, differentiating the fixed-point equation, we obtain the coefficientwise inequality $Z \preceq H + (\partial_Y\Phi^+)Z$ between majorant series, and repeated substitution bounds Z by the Neumann series in $\partial_Y\Phi^+(t,Y(t))$. Evaluating at $0 \le t < t_0$ gives the value bound $Z(t) \le H(t,Y(t))/(1 - \partial_Y\Phi^+(t,Y(t)))$; it does not give $Z_n \le H_n/(1-q)$ for the individual coefficients. Since the only counting estimate in the proof was (5.5), all constants depend on the fixed J when the counting constant is D_J. This proves part (10). □

5.4 Concentration on products of balls

The conditional fluctuation kernels of (4.8) are measures of the form $Z^{-1}e^{-V}dw$ on a product of Euclidean balls, with a potential whose Hessian is bounded below. The next theorem gives the concentration inequalities for such measures used in later sections,

with constants depending only on the lower Hessian bound. The variance, entropy, and gradient arguments are those of Brascamp and Lieb [33], Gross [103], and Bakry and Émery [8]. The representation of covariances by a one-form operator is the method of Helffer and Sjöstrand [110], whose relation to the Brascamp–Lieb inequality is discussed by Helffer [109]. The passage from entropy to exponential moments is the Herbst argument [123, Section 2.3, Proposition 2.3, p. 149, and Corollary 2.4, p. 151]. We must check that these arguments survive the boundary of the product of balls, including the intersections of faces. They do because the balls are convex: in the Bochner identity for the Neumann Laplacian, the second fundamental form of each sphere contributes the nonnegative term $p_x^{-1}|(\nabla_x h)^{\tan}|^2$, and the faces of different factors meet transversally. We prove this realization explicitly rather than importing a statement on the whole space.

Theorem 5.4. *Let X be a finite set, and for $x \in X$ let $q_x \geq 1$ be integers and $p_x > 0$. Let*

$$\Omega = \prod_{x \in X} \{w_x \in \mathbb{R}^{q_x} : |w_x| \leq p_x\}, \qquad d\mu = Z^{-1} e^{-V(w)}\, dw \quad \text{on } \Omega,$$

where V is real and of class C^2 on a neighborhood of Ω, and $D^2 V \geq mI$ for some $m > 0$. Let $q = \sum_x q_x$ and $\xi = w - \mathbb{E}_\mu w$. Then the following statements hold.

1. *For every real $f \in H^1(\mu)$ and every real function F that is Lipschitz for the Euclidean norm,*

$$\operatorname{Ent}_\mu(f^2) \leq \frac{2}{m} \mathbb{E}_\mu |\nabla f|^2, \qquad \operatorname{Var}_\mu(f) \leq \frac{1}{m} \mathbb{E}_\mu |\nabla f|^2,$$

$$\log \mathbb{E}_\mu e^{t(F - \mathbb{E}_\mu F)} \leq \frac{t^2 \operatorname{Lip}(F)^2}{2m} \qquad (t \in \mathbb{R}),$$

   where $\operatorname{Ent}_\mu(h) = \mathbb{E}_\mu[h \log h] - \mathbb{E}_\mu h \log \mathbb{E}_\mu h$. These constants do not depend on $|X|$, on the q_x and p_x, or on upper bounds for the diagonal blocks of the Hessian.

2. *Let d be a metric on X and $b > 0$, and write $V_{xy} = D_{w_x} D_{w_y} V$. If*

$$\max\Big\{ \sup_x \sum_{y \neq x} (e^{bd(x,y)} - 1) \sup_\Omega \|V_{xy}\|,\ \sup_y \sum_{x \neq y} (e^{bd(x,y)} - 1) \sup_\Omega \|V_{xy}\| \Big\} \leq \frac{m}{2},$$

   then for all real or complex $F, G \in H^1(\mu)$,

$$|\operatorname{Cov}_\mu(F, G)| \leq \frac{2}{m} \sum_{x,y} e^{-bd(x,y)} \|\nabla_x F\|_{L^2(\mu)} \|\nabla_y G\|_{L^2(\mu)},$$

   where the covariance is bilinear for complex functions. In particular, if $V_{xy} = 0$ for $d(x,y) > r_0$ and the mixed blocks have row and column sums at most H_0, the hypothesis holds whenever $H_0(e^{br_0} - 1) \leq m/2$; exponentially decaying mixed Hessians are covered by the displayed condition.

3. *For every real symmetric $q \times q$ matrix A, the quadratic form $Q_A = \xi^{\mathsf{T}} A \xi$ satisfies*

$$\log \mathbb{E}_\mu e^{t(Q_A - \mathbb{E}_\mu Q_A)} \le \frac{8t^2}{m^2} \|A\|_{\mathrm{HS}}^2, \qquad |t| \le \frac{m}{4\|A\|_{\mathrm{op}}},$$

and for every $\zeta \in \mathbb{R}^q$,

$$\log \mathbb{E}_\mu e^{\zeta\cdot\xi + t(Q_A - \mathbb{E}_\mu Q_A)} \le \frac{|\zeta|^2}{m} + \frac{16t^2}{m^2} \|A\|_{\mathrm{HS}}^2, \qquad |t| \le \frac{m}{8\|A\|_{\mathrm{op}}},$$

where the range of t is all of $\mathbb{R}$ if $A = 0$.

4. *Suppose $q_x = 3$ for all x. Let $\mathcal{F}$ be a family of distinct pairs (e, f) of blocks such that every block belongs to at most D_0 pairs of $\mathcal{F}$, counting both orientations if both occur, and let $j_{ef} \in \mathbb{R}^3$. Then $\sum_{(e,f)\in\mathcal{F}} j_{ef} \cdot (\xi_e \times \xi_f) = \xi^{\mathsf{T}} A_j \xi$ for a real symmetric matrix A_j with*

$$\|A_j\|_{\mathrm{op}} \le \frac{D_0}{2} \|j\|_\infty, \qquad \|A_j\|_{\mathrm{HS}}^2 \le D_0 \sum_{(e,f)\in\mathcal{F}} |j_{ef}|^2.$$

If μ is invariant under the simultaneous rotation $w \mapsto (Rw_x)_x$ for every $R \in \mathrm{SO}(3)$, then this quadratic form has mean zero.

All statements concern the measure μ on the fixed convex set Ω, with its full potential V, and they are centered at the mean under μ. They give no convexity statement for marginals of μ or for measures on nonconvex sets.

Steps 1–6 construct the Neumann realization $\mathcal{L}$ of $-\Delta + \nabla V \cdot \nabla$ and a realization $\mathcal{A}_1$ of the corresponding operator on vector fields, whose form contains the Hessian of V and a nonnegative curvature term from the spheres. They also prove the commutation $\nabla \mathcal{L}^{-1} = \mathcal{A}_1^{-1} \nabla$, and establish the semigroup bound $|\nabla P_t h| \le e^{-mt} P_t |\nabla h|$. Steps 7 and 8 derive the entropy bound and, from $\mathrm{Cov}(F, G) = \langle \nabla F, \mathcal{A}_1^{-1} \nabla G \rangle$ and exponential conjugation, the covariance bound. Step 9 derives the quadratic moments by comparison with an auxiliary Gaussian vector and absorption of the relative entropy, without independent coordinates or a Hessian bound for the tilted measure, and Step 10 treats cross products. The construction of the operators in Steps 1 and 2 uses constants that may depend on the dimension, the radii, and the bounds of e^{-V} on the fixed compact set Ω; these constants do not enter the inequalities.

Proof of Theorem 5.4. All Hilbert spaces in this proof use the measure μ unless indicated otherwise. We write $B_x = \{|w_x| < p_x\}$, and n_x for the outer normal of the face $\partial B_x \times \prod_{z \neq x} B_z$.

Step 1: the scalar operator. The Sobolev space $H^1(\Omega)$ consists of the L^2 functions with first distributional derivatives in L^2; the weighted and unweighted norms are equivalent, since e^{-V} is bounded above and below on Ω. Smooth functions on $\overline{\Omega}$ are dense in $H^1(\Omega)$, and the embedding $H^1(\Omega) \to L^2(\Omega)$ is compact. For both facts we extend functions to a fixed ambient rectangle. On a ball of radius p, we reflect the radial coordinate $r \in (p, 3p/2)$ to $2p - r \in (p/2, p)$, multiply the reflected function by a smooth cutoff equal to one near $r = p$ and zero near $r = 3p/2$, and set it zero beyond. The Jacobians on the annulus are bounded above and below and the values match at $r = p$; differentiation in the radial and tangential directions shows that this extension is bounded on H^1. For an interval we reflect at each endpoint. Applying these extensions successively in the finitely many factors gives a bounded extension operator into H^1 of a rectangle, and convolution with smooth approximate identities proves density. For compactness, we replace an extended function u by its averages over a grid of cubes of side ε. Integrating $u(t) - u(s) = \int_s^t u'$ in each coordinate and using Cauchy–Schwarz, we bound the squared L^2 error by $C\varepsilon^2 \|\nabla u\|_2^2$. The averages lie in a fixed finite-dimensional space. From a bounded sequence in H^1 we may therefore extract, by a diagonal argument over $\varepsilon = 2^{-k}$, a subsequence converging in L^2.

The form $q_0(h,k) = \mathbb{E}_\mu \nabla h \cdot \nabla k$ on $H^1(\mu)$ is closed. For $f \in L^2(\mu)$, minimizing $q_0(h,h) + \|h\|_2^2 - 2\langle f, h\rangle$ gives a unique weak solution of $(I + \mathcal{L})h = f$. Indeed, a minimizing sequence is bounded, and the parallelogram identity shows that it is Cauchy in the form norm. Its limit lies in H^1 since distributional derivatives pass to L^2 limits, the first variation gives the weak equation, and strict positivity of the form gives uniqueness. The solution operator $T = (I + \mathcal{L})^{-1}$ is positive, self-adjoint, and compact by the compact embedding. It has a complete orthonormal eigenbasis. Indeed, we maximize $\langle Tu, u\rangle$ on the unit sphere. A maximizing sequence has a weakly convergent subsequence, and the compactness of T lets us pass to the limit in $\langle Tu, u\rangle$; positivity forces the limit to have norm one, and the first variation shows that it is an eigenvector. We repeat this in the orthogonal complement of the eigenvectors already found. The eigenvalues tend to zero, since otherwise the images under T of these orthonormal vectors would have no convergent subsequence. On the orthogonal complement of all the eigenvectors the supremum of $\langle Tu, u\rangle$ is zero. By polarization T vanishes there, and since T is injective this complement is trivial. Hence $\mathcal{L}$ has an orthonormal basis of eigenfunctions with eigenvalues $0 \le \lambda_\nu \to \infty$. Where its derivatives are defined, $\mathcal{L} = -\Delta + \nabla V \cdot \nabla$, with the weak Neumann condition. The kernel of $\mathcal{L}$ consists of the constants. Indeed, a function with zero energy has zero distributional gradient. It is therefore constant on each ball contained in Ω, and these constants agree since Ω is connected. There also exists a positive gap on functions of mean zero, since otherwise normalized functions of mean zero with gradients tending to zero would converge, by compactness, to a constant of mean zero and norm one. This preliminary gap is used only for the existence of solutions

of Poisson equations and for convergence to equilibrium.

Step 2: a core for the unweighted Laplacian. Let A_0 be the unweighted Neumann Laplacian on Ω, with respect to $L^2(dw)$. On a single ball, the construction of Step 1 gives a Neumann eigenbasis. Its eigenfunctions are smooth up to the boundary, and weak Neumann solutions are in H^2. In the interior this is the standard difference-quotient argument. Testing the weak equation with $-D_{-h,j}(\chi^2 D_{h,j}u)$, where χ is a cutoff and $D_{h,j}$ a difference quotient, gives

$$c\|\chi D_{h,j}\nabla u\|_2^2 \le \frac{c}{2}\|\chi D_{h,j}\nabla u\|_2^2 + C\big(\|f\|_2^2 + \|u\|_{H^1}^2\big)$$

for uniformly elliptic Lipschitz coefficients a. Here the leading term on the left is $\int \chi^2 a(\cdot + he_j)D_{h,j}\nabla u \cdot D_{h,j}\nabla u$, and all remaining terms contain either $D_{h,j}a$, which is bounded by the Lipschitz constant of a, or a derivative of χ. The right side $\int f[-D_{-h,j}(\chi^2 D_{h,j}u)]$ is bounded by $C\|f\|_2(\|\chi D_{h,j}\nabla u\|_2 + \|\nabla u\|_2)$, by the line-integral bound for a difference quotient, and the inequality $rs \le \epsilon r^2 + s^2/(4\epsilon)$ absorbs these terms. Uniformly bounded difference quotients yield weak second derivatives, since a subsequence converges weakly in L^2, and testing against smooth compactly supported functions identifies the limit as the distributional derivative. Near the boundary we use the inward normal distance $s \ge 0$ and coordinates y on the sphere; the metric has no mixed normal-tangential term and normal coefficient one, and its volume density J is smooth and positive on a thin collar. The weak Neumann equation reads $-\partial_s(J\partial_s u) - \partial_{y_\alpha}(Jg^{\alpha\beta}\partial_{y_\beta}u) = Jf$. Reflecting $u, J, g^{\alpha\beta}, f$ evenly in s gives Lipschitz, uniformly elliptic coefficients and a weak equation across $s = 0$, since adding its tests on the two half-collars gives exactly the Neumann weak equation. The interior estimate then gives H^2 up to the boundary, and integration by parts identifies the zero normal derivative. For an eigenfunction, $f = \lambda u$, we repeat the tangential difference-quotient argument in the half-collar; at each order the commutators differentiate only the smooth metric coefficients and lower derivatives already controlled, so all tangential derivatives gain one more H^1 derivative. The equation then solves for $\partial_s^2 u$, and differentiating it recovers successively the derivatives with two, three, and more normal indices; by induction $u \in H^k$ for every k. To deduce smoothness, we extend u from a half-chart by a finite linear combination $\sum_j c_j u(y, -js)$ of reflections, whose coefficients solve the invertible Vandermonde system $\sum_j c_j(-j)^l = 1$, $0 \le l < k$; this gives an H^k extension. We multiply it by an interior cutoff in an ambient rectangle with q coordinates. Repeated integration in the q coordinate directions and the Cauchy–Schwarz inequality bound the supremum of a derivative of order r of a smooth function by $C\|u\|_{H^{r+q}}$ on the rectangle. For example, the function itself is the iterated integral of $\partial_1 \cdots \partial_q u$ from each coordinate to the far side of the support. Applying this bound to smooth approximations of the extension and to their differences, we see that their derivatives through order r converge uniformly. It follows that the H^{r+q} function has continuous derivatives of order

r. Since k is arbitrary, u is smooth. For an interval the same conclusions follow from $-u'' = f$ and the Neumann conditions at the endpoints.

Finite products of these eigenfunctions are smooth, satisfy the Neumann condition on every face, and form an orthonormal basis of $L^2(dw)$ on Ω, as one sees by expanding successively in each factor using Fubini's theorem. Their eigenvalues for A_0 are sums of eigenvalues of the factors. They form a core for A_0. Indeed, the weak equation shows that every $h \in D(A_0)$ has coefficients with $\sum_\nu (1+\lambda_\nu^2)|h_\nu|^2 < \infty$; conversely, if this sum is finite, the partial sums solve the weak equation and converge in the graph norm, which shows that $h \in D(A_0)$. The same argument with $1+\lambda_\nu$ describes the form domain; in particular, a function orthogonal to all product eigenfunctions in the form norm has $(1+\lambda_\nu)h_\nu = 0$ for all ν and hence vanishes, which proves density in the form norm. Truncating the expansion therefore gives convergence in the graph norm and in the form norm.

Step 3: the boundary identity. For a function h in this core, two integrations by parts, one factor at a time, give

$$\|D^2 h\|^2_{L^2(dw)} + \sum_x \int_{\partial B_x \times \prod_{z\neq x} B_z} p_x^{-1} |(\nabla_x h)^{\tan}|^2 \, dS = \|A_0 h\|^2_{L^2(dw)}. \tag{5.9}$$

Indeed, the difference of the two bulk terms is the boundary integral of $(\Delta h)\partial_n h - D^2 h(n, \nabla h)$. The first term vanishes. Differentiating $\partial_{n_x} h = 0$ tangentially along the face of x, we find $D^2 h(n_x, \nabla h) = -p_x^{-1}|(\nabla_x h)^{\tan}|^2$, because $D_v n_x = p_x^{-1} v_x^{\tan}$. For an interval the curvature term is zero. By Fubini's theorem on the individual balls, the identity holds on the product. Since intersections of distinct faces have zero surface measure, there is no integral over a corner. Applied to differences of core functions, the identity shows that convergence in the graph norm of A_0 implies convergence in H^2 and in the boundary term.

Step 4: the operator on vector fields. Let $\mathcal{H}_1$ be the space of H^1 vector fields $u = (u_x)_{x\in X}$ with $u_x \cdot n_x = 0$ on the face of x, in the sense of traces. Traces are continuous on H^1: in the collar, $|u(y,0)|^2 \le C\int_0^\varepsilon (|u(y,s)|^2 + |u(y,s)||\partial_s u(y,s)|)\, ds$, and Cauchy–Schwarz applies. Smooth vector fields satisfying the face conditions are dense in $\mathcal{H}_1$. To see this, we reflect the normal component of u_x oddly and its tangential components evenly in the local normal frame of the face of x. The odd component has zero trace, and no jump occurs. Near an intersection of faces we do this separately in each active ball factor; the reflections commute, since the normal frames of different factors depend on different variables. Convolving with a kernel that is even in every reflected normal coordinate and restricting to the product half-chart preserves the zero normal components. A partition of unity, constant in the normal coordinate near each face, and ordinary convolution in the interior complete the approximation, including near all corners.

On $\mathcal{H}_1$ we define the symmetric form

$$q_1(u,v) = \mathbb{E}_\mu \sum_i \partial_i u \cdot \partial_i v + \mathbb{E}_\mu u^\mathsf{T}(D^2V)v \\ + \sum_x \int_{\partial B_x \times \prod_{z\neq x} B_z} p_x^{-1} u_x^{\tan} \cdot v_x^{\tan}\, Z^{-1} e^{-V}\, dS. \tag{5.10}$$

By the trace estimate, the boundedness of D^2V, and $D^2V \geq mI$, its norm is equivalent to the H^1 norm, and the form is therefore closed. The associated self-adjoint operator $\mathcal{A}_1$, obtained as in Step 1, satisfies

$$q_1(u,u) \geq m\|u\|_2^2, \qquad \|\mathcal{A}_1^{-1}\|_{2\to 2} \leq m^{-1}. \tag{5.11}$$

Only this lower bound enters the final constants. Formally $\mathcal{A}_1 = \mathcal{L}I + D^2V$; on the face of x the tangential part of the block u_x satisfies the Robin condition $\partial_{n_x} u_x^{\tan} + p_x^{-1} u_x^{\tan} = 0$, while the other blocks satisfy the Neumann condition. At intersections of faces, the closed form (5.10) is the definition.

Step 5: gradient commutation. Let $\mathcal{L}h = g$ weakly. Testing with e^V times an unweighted H^1 test function, we find that $A_0 h = g - \nabla V \cdot \nabla h$ weakly in $L^2(dw)$. Since the right side is in L^2, we have $h \in D(A_0)$, and there exist core functions h_j converging to h in the graph norm of A_0. By (5.9), $h_j \to h$ in H^2 and in the boundary term, and $\mathcal{L}h_j \to g$ in $L^2(\mu)$. For a smooth vector field v satisfying the face conditions, differentiation and integration by parts give

$$q_1(\nabla h_j, v) = \langle \mathcal{L}h_j, d_V^* v\rangle, \qquad d_V^* v = -\operatorname{div} v + \nabla V \cdot v. \tag{5.12}$$

Indeed, $\nabla \mathcal{L}h_j = \mathcal{L}\nabla h_j + D^2V \nabla h_j$, and on the face of x the normal derivative of the gradient, paired with v, equals $-p_x^{-1}(\nabla_x h_j)^{\tan} \cdot v_x^{\tan}$, while the other blocks have zero normal derivative there; these are exactly the boundary terms in (5.10). The scalar integration by parts produces no further term, since the normal traces of v vanish. By density, (5.12) extends to $v \in \mathcal{H}_1$. Passing to the limit $j \to \infty$, and taking $g \in H^1$, we obtain

$$\nabla h = \mathcal{A}_1^{-1} \nabla g. \tag{5.13}$$

This uses only the C^2 regularity of V: ∇V is bounded, and the differentiation in (5.12) uses only continuous second derivatives of V.

Step 6: semigroups and the gradient bound. Using the eigenbasis of Step 1, we define $P_t = e^{-t\mathcal{L}}$ by multiplying the coefficients by $e^{-t\lambda_\nu}$. It preserves constants, positivity, and the interval $[0,1]$. For the last two properties, we solve $(I + s\mathcal{L})h = f$ and test with h^- and $(h-1)^+$. If $0 \leq f \leq 1$, the first test gives $h^- = 0$ and the second $(h-1)^+ = 0$; since $P_t = \lim_k (I + (t/k)\mathcal{L})^{-k}$ in L^2, these properties pass to P_t. Symmetry and $P_t 1 = 1$ imply the invariance of μ, and the preliminary gap implies $P_t h \to \mathbb{E}_\mu h$ in L^2.

The variational construction applied to q_1 on vector-valued L^2, with form domain $\mathcal{H}_1$ (dense, since it contains the compactly supported smooth vector fields, and compactly embedded by the scalar argument), gives the semigroup $e^{-t\mathcal{A}_1}$. For $h \in H^1$ and $t > 0$, the spectral expansion puts $P_t h$ and $\mathcal{L} P_t h$ in the required domains, and (5.12) shows that $u_t = \nabla P_t h$ solves $\partial_t u_t = -\mathcal{A}_1 u_t$ weakly, with initial value ∇h. Uniqueness follows by differentiating the squared norm of the difference of two solutions and using (5.11). We conclude that $\nabla P_t h = e^{-t\mathcal{A}_1} \nabla h$.

We claim that

$$|e^{-t\mathcal{A}_1} u| \le e^{-mt} P_t |u|. \tag{5.14}$$

Let $u_t = e^{-t\mathcal{A}_1} u$ and $h_\varepsilon = (|u_t|^2 + \varepsilon^2)^{1/2}$. In the weak equation for u_t we use the test field $\psi u_t / h_\varepsilon$, with $\psi \in H^1$ bounded and nonnegative; it belongs to $\mathcal{H}_1$, since multiplication by a scalar preserves the face conditions. The kinetic term equals

$$\nabla h_\varepsilon \cdot \nabla \psi + \psi \Big(\frac{|\nabla u_t|^2}{h_\varepsilon} - \frac{|\nabla h_\varepsilon|^2}{h_\varepsilon} \Big),$$

whose second summand is nonnegative by Cauchy–Schwarz. The Hessian term is at least $m\psi |u_t|^2 / h_\varepsilon \ge m\psi (h_\varepsilon - \varepsilon)$, and every boundary curvature term is nonnegative. Hence $(\partial_t + \mathcal{L} + m)(h_\varepsilon - \varepsilon) \le 0$ in the weak scalar sense. We compare with $e^{-mt} P_t |u|$ and test the difference with its positive part; the squared L^2 norm of this positive part does not increase from zero. This comparison is justified first on intervals $[\delta, T]$, where the spectral solutions have time derivatives in L^2 and lie in the form domains, and then by continuity in L^2 as $\delta \downarrow 0$; truncation of the tests and approximation in the form norm justify the chain rule, whose derivatives are bounded for fixed ε. Letting $\varepsilon \downarrow 0$ proves (5.14). Combined with the previous paragraph, this gives

$$|\nabla P_t h| \le e^{-mt} P_t |\nabla h|.$$

Step 7: entropy, variance, and exponential moments. Let h be smooth, positive, and bounded above and below. Applying the positive operator P_t to $(f - ch)^2 / h \ge 0$ for every rational c and minimizing over c, we obtain the pointwise inequality $(P_t f)^2 \le P_t(f^2/h)\, P_t h$. With $f = |\nabla h|$ and the gradient bound of Step 6, we obtain

$$\frac{|\nabla P_t h|^2}{P_t h} \le e^{-2mt} P_t \Big(\frac{|\nabla h|^2}{h} \Big). \tag{5.15}$$

By the weak equation and the chain rule for $\log P_t h$, we have

$$-\frac{d}{dt} \mathbb{E}_\mu [(P_t h) \log P_t h] = \mathbb{E}_\mu \frac{|\nabla P_t h|^2}{P_t h}.$$

Since the bounds on h persist under P_t, convergence of $P_t h$ to its mean in L^2 implies convergence of the entropy integral to $(\mathbb{E} h) \log \mathbb{E} h$. Integrating in time and using (5.15)

and the invariance of μ, we find $\mathrm{Ent}_\mu(h) \le (2m)^{-1}\mathbb{E}_\mu|\nabla h|^2/h$. For bounded smooth f, substituting $h = f^2 + \varepsilon$ and letting $\varepsilon \downarrow 0$, we obtain $\mathrm{Ent}_\mu(f^2) \le (2/m)\mathbb{E}_\mu|\nabla f|^2$. For general $f \in H^1$, we truncate, approximate by smooth functions, and use that the entropy is lower semicontinuous under convergence in L^2. Indeed, $s \log s$ is bounded below, and Fatou's lemma applies along an almost everywhere convergent subsequence, while the mean term converges in L^1. This proves the logarithmic Sobolev inequality.

Expanding at $f = 1 + \varepsilon g$ with g bounded, we find $\mathrm{Ent}((1+\varepsilon g)^2) = 2\varepsilon^2 \operatorname{Var}(g) + o(\varepsilon^2)$. Then the logarithmic Sobolev inequality implies the Poincaré inequality with constant $1/m$; truncation and density extend it to H^1. For a real Lipschitz F let $\varphi(t) = \log \mathbb{E}_\mu e^{tF}$. Applying the logarithmic Sobolev inequality to $e^{tF/2}$, we find $t\varphi'(t) - \varphi(t) \le t^2 \operatorname{Lip}(F)^2/(2m)$. Integrating $(\varphi(t)/t)'$ from zero proves the exponential moment bound for $t > 0$, and applying it to $-F$ gives $t < 0$. To justify the chain rule, we extend F to a neighborhood by $\inf_{y\in\Omega}(F(y) + \operatorname{Lip}(F)|x-y|)$ and smooth; this preserves the Lipschitz constant and converges uniformly on Ω; no differentiability of F at the boundary is needed. This proves part (1).

Step 8: covariances. For real $G \in H^1$, we solve $\mathcal{L}h = G - \mathbb{E}G$ with $\mathbb{E}h = 0$, using the preliminary gap. By weak integration by parts and (5.13), we have

$$\operatorname{Cov}_\mu(F, G) = \langle \nabla F, \mathcal{A}_1^{-1} \nabla G \rangle_{L^2(\mu)}, \tag{5.16}$$

first for smooth F and then for $F \in H^1$ by density. Complexifying gives the bilinear identity for complex F, G, with neither function conjugated; its absolute value is bounded by the Cauchy–Schwarz inequality in the complex Hilbert space.

Fix $y_0 \in X$ and set $W_x = e^{bd(x,y_0)} I_{q_x}$ on the components of the block x. This weight does not depend on w; it preserves the face conditions and commutes with the kinetic and boundary forms and with every diagonal block of the Hessian. In the closed-form realization, we obtain

$$W\mathcal{A}_1 W^{-1} = \mathcal{A}_1 + B, \qquad B_{xz} = \big(e^{b(d(x,y_0)-d(z,y_0))} - 1\big) V_{xz}(w).$$

Each block multiplier has norm at most $(e^{bd(x,z)} - 1)\sup_\Omega \|V_{xz}\|$. By the row-column bound of Step 5 in the proof of Lemma 5.3 and the hypothesis of part (2), we have $\|B\|_{2\to 2} \le m/2$ on the direct sum of the block spaces $L^2(\mu)$. By (5.11) and a Neumann series, $\|(W\mathcal{A}_1 W^{-1})^{-1}\| \le 2/m$, and the (x, y_0) block satisfies

$$\|(\mathcal{A}_1^{-1})_{xy_0}\|_{L^2\to L^2} \le \frac{2}{m} e^{-bd(x,y_0)}.$$

Inserting this bound into (5.16) and applying Cauchy–Schwarz to each block pairing, we obtain the covariance bound of part (2), for real and complex functions. For an interaction of range r_0, every off-diagonal weight is at most $e^{br_0} - 1$, which gives the stated criterion. Neither the individual p_x, q_x nor an upper bound on the diagonal Hessian blocks entered.

Step 9: quadratic moments. The classical Hanson–Wright inequality concerns independent coordinates [108], and extensions based on concentration allow dependent vectors [1, Theorem 2.5, p. 4]; here we derive the required bounds directly from the logarithmic Sobolev inequality for μ. Applying part (1) to the linear function $v \cdot w$, we obtain

$$\mathbb{E}_\mu e^{v\cdot\xi} \le e^{|v|^2/(2m)}. \tag{5.17}$$

If $A = 0$, all quadratic statements follow from this. Let $A \neq 0$, and let Z_0 be a standard Gaussian vector in $\mathbb{R}^q$, independent of w. Since $e^{\alpha|y|^2} = \mathbb{E}e^{\sqrt{2\alpha}Z_0\cdot y}$ (completion of the square, as in Lemma 5.2) and all integrands are positive, we have for $\alpha \ge 0$

$$\mathbb{E}_\mu e^{\alpha|A\xi|^2} = \mathbb{E}_{Z_0}\mathbb{E}_\mu e^{\sqrt{2\alpha}(AZ_0)\cdot\xi} \le \mathbb{E}_{Z_0} e^{(\alpha/m)|AZ_0|^2} = \det\bigl(I - (2\alpha/m)A^2\bigr)^{-1/2},$$

provided $2\alpha\|A\|_{\mathrm{op}}^2 < m$. At $\alpha = m/(4\|A\|_{\mathrm{op}}^2)$ all eigenvalues of $(2\alpha/m)A^2$ are at most $1/2$, and since $-\log(1-s) \le 2s$ on $[0,1/2]$,

$$\log \mathbb{E}_\mu e^{\alpha|A\xi|^2} \le \frac{2\alpha}{m}\|A\|_{\mathrm{HS}}^2. \tag{5.18}$$

Now let $Q = \xi^{\mathsf{T}} A\xi$, $\psi(t) = \log \mathbb{E}_\mu e^{tQ}$, and $d\mu_t = e^{tQ-\psi(t)}d\mu$. All these quantities are finite and smooth in t, since the domain is compact. The relative entropy of μ_t with respect to μ is $D_t = t\psi'(t) - \psi(t)$; with $r = d\mu_t/d\mu$, integrating $r\log r \ge r - 1$ against μ, we find $D_t \ge 0$. Applying the logarithmic Sobolev inequality to $e^{tQ/2}$ and using $\nabla Q = 2A\xi$, we find $D_t \le (2t^2/m)\mathbb{E}_{\mu_t}|A\xi|^2$. For any real random variable Y, the entropy inequality $\alpha\mathbb{E}_{\mu_t}Y \le D_t + \log \mathbb{E}_\mu e^{\alpha Y}$ holds (Jensen's inequality for the logarithm, applied to $e^{\alpha Y}d\mu/d\mu_t$ under μ_t). With $Y = |A\xi|^2$ and (5.18), we obtain

$$D_t \le \frac{8t^2\|A\|_{\mathrm{op}}^2}{m^2}D_t + \frac{4t^2}{m^2}\|A\|_{\mathrm{HS}}^2.$$

For $|t| \le m/(4\|A\|_{\mathrm{op}})$ the first coefficient is at most $1/2$, which implies $D_t \le 8t^2\|A\|_{\mathrm{HS}}^2/m^2$. For $t > 0$, integrating $(\psi(t)/t)' = D_t/t^2$ from zero, where $\psi(t)/t \to \mathbb{E}_\mu Q$, proves the first bound of part (3); replacing A by $-A$ gives $t < 0$. For the joint bound, by the Cauchy–Schwarz inequality and (5.17), we have

$$\log \mathbb{E}_\mu e^{\zeta\cdot\xi + t(Q-\mathbb{E}Q)} \le \frac{1}{2}\log \mathbb{E}_\mu e^{2\zeta\cdot\xi} + \frac{1}{2}\log \mathbb{E}_\mu e^{2t(Q-\mathbb{E}Q)} \le \frac{|\zeta|^2}{m} + \frac{16t^2}{m^2}\|A\|_{\mathrm{HS}}^2,$$

for $|t| \le m/(8\|A\|_{\mathrm{op}})$. This proves part (3).

Step 10: cross products. We write $J(j)v = j \times v$. A pair (e,f) contributes the symmetric matrix with blocks $A_{ef} = -J(j_{ef})/2$ and $A_{fe} = A_{ef}^{\mathsf{T}}$, because $\xi_e^{\mathsf{T}}[-J(j_{ef})]\xi_f = j_{ef}\cdot(\xi_e \times \xi_f)$. Since $\|J(j)\|_{\mathrm{op}} = |j|$ and $\|J(j)\|_{\mathrm{HS}}^2 = 2|j|^2$, a single pair has block row sums

$|j_{ef}|/2$ and squared Hilbert–Schmidt norm $|j_{ef}|^2$. Since at most D_0 pairs meet a block, the row-column bound implies $\|A_j\|_{\mathrm{op}} \le D_0\|j\|_\infty/2$; using $|\sum_{k=1}^r b_k|^2 \le r\sum_k |b_k|^2$ with $r \le D_0$ in each repeated matrix entry, we obtain $\|A_j\|_{\mathrm{HS}}^2 \le D_0 \sum |j_{ef}|^2$. Pairs with $e = f$ contribute zero. If μ is invariant under simultaneous rotations, then $\mathbb{E}_\mu w$ is invariant and ξ transforms as a vector. The law of ξ therefore has the same invariance. The vector $\mathbb{E}(\xi_e \times \xi_f)$ is then fixed by every rotation, hence zero (a rotation by π about an axis perpendicular to a nonzero vector reverses it). This proves part (4). □

5.5 Conditioning, exponential moments, and gauge identities

The next lemma gives conditioning bounds and identities for parameter derivatives and gauge transformations; the bound on large fields enters the proof through the comparison of a measure with its conditioning (see (3.1)). For a link e and $a \in \{1,2,3\}$ we write L_e^a and R_e^a for the derivatives of a function of U along $s \mapsto e^{s\tau_a}U_e$ and $s \mapsto U_e e^{s\tau_a}$ at $s = 0$, all other link variables being fixed.

Lemma 5.5. *Let μ be a probability measure on a measurable space, and let S be a measurable event with $e = \mu(S^c) < 1$. Put $\nu = \mu(\cdot \mid S)$. Then the following statements hold.*

1. *With $\|\mu - \nu\|_{\mathrm{TV}} = \sup_A |\mu(A) - \nu(A)|$, we have $\|\mu - \nu\|_{\mathrm{TV}} = e$, and*

$$|\mathbb{E}_\mu F - \mathbb{E}_\nu F| \le 2e\|F\|_\infty$$

   for every bounded complex measurable F; if $0 \le F \le A$, the bound is eA. The image measures of μ and ν under a common measurable map satisfy the same bound on the total variation distance. If $d\mu = Z^{-1} f\, d\omega$ with $f \ge 0$, then the restricted partition function $Z_S = \int_S f\, d\omega$ satisfies $Z_S/Z = 1 - e$, and $|\log(Z_S/Z)| \le 2e$ if $e \le 1/2$.

2. *For nested events $S_0 \supset S_1 \supset \cdots \supset S_k$ of positive probability and $0 \le i \le k$,*

$$\mu(S_k) = \mu(S_i) \prod_{j=i}^{k-1} \mu(S_{j+1} \mid S_j).$$

   With $r_j = \mu(S_j \setminus S_{j+1} \mid S_j)$, it follows that $1 - \mu(S_k) \le 1 - \mu(S_i) + \sum_{j=i}^{k-1} r_j$; the successive conditional failure probabilities are added without dividing by $\mu(S_i)$.

3. *For a real function J with $|J| \le R$, the tilted probability measure $\mu_J = e^J \mu / \mathbb{E}_\mu e^J$ satisfies $\mu_J(A) \le e^{2R}\mu(A)$ for every event A.*

4. *Let $O_1, \dots, O_r$ be real measurable functions with $|O_i| \le 1$, and set $M_\mu(z) = \mathbb{E}_\mu e^{\sum_i z_i O_i}$ and $M_\nu(z) = \mathbb{E}_\nu e^{\sum_i z_i O_i}$ for $z \in \mathbb{C}^r$. If $\sum_i |z_i| \le R$, then*

$$|M_\mu(z) - M_\nu(z)| \le 2e^R e.$$

If moreover $R < \log 2$, the branches of $\log M_\mu$ and $\log M_\nu$ vanishing at $z = 0$ satisfy

$$|\log M_\mu(z) - \log M_\nu(z)| \le \frac{2e^R}{2 - e^R}\, e,$$

and their derivatives satisfy the corresponding Cauchy bounds on every smaller polydisc, with constants depending only on the two polydiscs and the order of the derivative.

5. *Let ω be a measure on a fixed domain, let $V(\theta, w)$ be real with $0 < Z(\theta) = \int e^{-V(\theta,w)}\, d\omega(w) < \infty$, and let $F(\theta, w)$ be a function such that both e^{-V} and Fe^{-V} can be differentiated in θ under the integral. A sufficient condition is pointwise differentiability in θ together with an ω-integrable envelope, uniform for θ near the given parameter, for*

$$e^{-V}\big(1 + |\partial_\theta V| + |F| + |\partial_\theta F| + |F\partial_\theta V|\big);$$

joint C^1 regularity of V and F on a fixed compact domain and a neighborhood of the parameter suffices. Then, with $p_\theta = Z(\theta)^{-1} e^{-V(\theta,\cdot)}$,

$$\partial_\theta \log Z = -\mathbb{E}_\theta \partial_\theta V, \qquad \partial_\theta \log p_\theta = -\partial_\theta V + \mathbb{E}_\theta \partial_\theta V,$$

$$\partial_\theta \mathbb{E}_\theta F = \mathbb{E}_\theta \partial_\theta F - \mathrm{Cov}_\theta(F, \partial_\theta V).$$

These are identities for the full normalized density, and the covariance is bilinear for complex F.

6. *Let μ be the Wilson measure on a periodic lattice, or more generally a probability measure of the form in Lemma 5.1(1), and let $\mathscr{G}_v^a = \sum_{e \text{ starts at } v} L_e^a - \sum_{e \text{ ends at } v} R_e^a$ be the gauge generator at the vertex v. Then for all C^1 functions F and J, possibly complex,*

$$\mathbb{E}_\mu\big[e^J(\mathscr{G}_v^a F + F\mathscr{G}_v^a J)\big] = 0.$$

In a spanning-tree gauge, only the corresponding identity for the simultaneous conjugation at the root remains. If S is invariant under the gauge transformations, the same identity holds under $\mu(\cdot \mid S)$, without any regularity of the boundary of S. The same conclusion holds in any finite joint coordinate representation whose full normalized measure is invariant. In particular, a triangular change of variables $w_i' = O_i(\theta, w_{i+1}, \dots, w_r) w_i$ by orthogonal matrices O_i, independent of w_i, has Jacobian of absolute value one, preserves every product of balls centered at the origin, and its infinitesimal generator has zero flux through every face; the parameter-dependent normalizing factors remain in the joint derivative of the log-density.

7. *If F is integrable but possibly unbounded and $e > 0$, there is only the exact identity*

$$\mathbb{E}_\mu F - \mathbb{E}_\nu F = e\big(\mathbb{E}_{\mu(\cdot|S^c)} F - \mathbb{E}_\nu F\big);$$

an error tending to zero requires additional control of these integrals.

All constants are explicit as displayed.

Proof. Parts (1)–(3). If $e = 0$, then $\mu = \nu$ and there is nothing to prove. For $e > 0$ let $\nu^c = \mu(\cdot \mid S^c)$. Splitting every integral over S and S^c, we obtain

$$\mu = (1 - e)\nu + e\nu^c. \tag{5.19}$$

For an event A, we have $\mu(A) - \nu(A) = e(\nu^c(A) - \nu(A))$, where both $\nu(A)$ and $\nu^c(A)$ lie in $[0, 1]$. This bounds the total variation distance by e, and $A = S$ attains it. For complex F, the two conditional expectations have absolute value at most $\|F\|_\infty$, which gives $2e\|F\|_\infty$; if $0 \le F \le A$, their difference is at most A. A common measurable map replaces each test event by its preimage and therefore does not increase the total variation distance. In the density notation, $Z_S = \int_S f \, d\omega = Z\mu(S)$, and for $0 \le e \le 1/2$ we have $-\log(1 - e) = \int_0^e (1 - t)^{-1} dt \le 2e$.

For nested events, consecutive conditional probabilities cancel:

$$\prod_{j=i}^{k-1} \mu(S_{j+1} \mid S_j) = \prod_{j=i}^{k-1} \frac{\mu(S_{j+1})}{\mu(S_j)} = \frac{\mu(S_k)}{\mu(S_i)}.$$

Induction on the number of factors gives $1 - \prod_j (1 - r_j) \le \sum_j r_j$, the induction step being $1 - (1 - a)(1 - b) = a + b - ab \le a + b$. Since $\mu(S_k) = \mu(S_i) \prod_j (1 - r_j) \ge \mu(S_i) - (1 - \prod_j (1 - r_j))$, we obtain $1 - \mu(S_k) \le 1 - \mu(S_i) + \sum_j r_j$. For $|J| \le R$, the density of μ_J with respect to μ is at most $e^R / e^{-R} = e^{2R}$.

Part (4). Let $T(z) = \sum_i z_i O_i$; on the ball $\sum_i |z_i| \le R$ we have $|T(z)| \le R$ and $|e^{T(z)}| \le e^R$. Applying part (1) to $e^{T(z)}$, we obtain $|M_\mu - M_\nu| \le 2e^R e$. By the exponential series, we have $|M_\mu(z) - 1| \le e^R - 1$ and $|M_\nu(z) - 1| \le e^R - 1$. If $R < \log 2$, these values lie in the open disc of center 1 and radius $e^R - 1 < 1$, where the series of $\log(1 + w)$ defines the branch vanishing at the origin. Integrating its derivative $1/u$ along the segment between the two values, on which $|u| \ge 2 - e^R$, we find

$$|\log M_\mu(z) - \log M_\nu(z)| \le (2 - e^R)^{-1} |M_\mu(z) - M_\nu(z)|.$$

The functions are holomorphic, since bounded observables allow termwise integration of the exponential series. If a smaller polydisc has coordinate distances $\delta_i > 0$ to a larger one inside the ball, the Cauchy formula gives

$$|\partial^\alpha (\log M_\mu - \log M_\nu)| \le \alpha! \prod_i \delta_i^{-\alpha_i} \frac{2e^R}{2 - e^R} \, e$$

at every point of the smaller polydisc.

Part (5). Fix θ_0 and a neighborhood on which the integrable envelope $B(w)$ is valid. We write $g_\theta = e^{-V(\theta, \cdot)}$ and $h_\theta = F(\theta, \cdot) e^{-V(\theta, \cdot)}$. Their pointwise derivatives are $\partial_\theta g_\theta = -(\partial_\theta V) e^{-V}$ and $\partial_\theta h_\theta = (\partial_\theta F - F \partial_\theta V) e^{-V}$. The envelope bounds $|g_\theta|$, $|h_\theta|$,

and both derivatives by B, and the mean value theorem, applied to real and imaginary parts, bounds the difference quotients by $2B$. By dominated convergence, with $N(\theta) = \int F(\theta, w) e^{-V(\theta,w)}\, d\omega(w)$, we have

$$\partial_\theta Z = -\int (\partial_\theta V) e^{-V}\, d\omega, \qquad \partial_\theta N = \int (\partial_\theta F - F \partial_\theta V) e^{-V}\, d\omega. \tag{5.20}$$

For a vector parameter the argument applies to each coordinate derivative. Since $0 < Z < \infty$, dividing by Z gives the first identity, and differentiating $\log p_\theta = -V - \log Z$ gives the second. The quotient rule for $\mathbb{E}_\theta F = N/Z$ yields the third; the covariance is finite because the envelope also controls $|F \partial_\theta V| e^{-V}$. For the sufficient condition on a compact domain Ω, choose a compact neighborhood of the parameter inside the domain of C^1 regularity. Joint continuity bounds $|V|$, $|F|$, $|\partial_\theta V|$, and $|\partial_\theta F|$ by some $C \geq 1$ there. Moreover $e^{-V(\theta_0,w)} \geq e^{-C}$ and $Z(\theta_0) < \infty$ imply $\omega(\Omega) \leq e^C Z(\theta_0) < \infty$. Then the constant $e^C(1 + 3C + C^2)$ is an integrable envelope, uniformly on this neighborhood. No boundary term occurs, since the domain is fixed. In particular, a term of V that depends only on θ cancels in the derivative of $\log p_\theta$ only together with its contribution to $\log Z$; it cannot be deleted from a joint density.

Part (6). Let $k(s)$ equal $e^{s\tau_a}$ at v and I at all other vertices. By Lemma 5.1, μ is invariant under $U \mapsto U^{k(s)}$, which gives

$$\int (F e^J)(U^{k(s)})\, d\mu(U) = \int F e^J\, d\mu.$$

Differentiation at $s = 0$ is valid for C^1 functions on the compact manifold of configurations. On a link starting at v the derivative is L_e^a, and on a link ending at v it is $-R_e^a$; their sum is $\mathscr{G}_v^a$, and the product rule gives the identity, for real or complex J. In a spanning-tree gauge, the conjugation at the root described in Lemma 5.1 acts on every remaining link by $U_e \mapsto k U_e k^{-1}$; its derivative is $\sum_{e \notin T} (L_e^a - R_e^a)$, and the same change of variables gives the remaining identity. No generator at a vertex other than the root is used on the gauge-fixed configurations. If S is invariant, we insert $\mathbf{1}_S$ into the integral before the change of variables and divide by $\mu(S) > 0$. Neither the regularity of ∂S nor a derivative of $\mathbf{1}_S$ is needed, since the indicator is unchanged for every s.

For the triangular change of variables, given the transformed variables of higher index, we solve for w_i using O_i^{-1}, proceeding downward. This shows that the map is invertible, and it preserves the product of balls. Its Jacobian matrix is block triangular with orthogonal diagonal blocks O_i, and its determinant therefore has absolute value one. For a differentiable one-parameter family of such maps, the generator is $Y_i = B_i(\theta, w_{>i}) w_i$ with $B_i^{\mathsf{T}} = -B_i$. Hence

$$\operatorname{div}_{w_i} Y_i = \operatorname{tr} B_i = 0, \qquad w_i \cdot Y_i = 0 \quad \text{on } |w_i| = p_i,$$

and the flux through every face vanishes; intersections of faces carry no additional flux, since the map preserves each radius $|w_i|$. Under the assumed invariance of the full

joint probability measure, we obtain the gauge-invariance identity by differentiating the change-of-variables identity. If this measure is written with conditional factors $Z(\theta)^{-1}e^{-V(\theta,w)}$, their parameter derivatives are the derivatives of the normalized log-densities computed in part (5); a derivative of an unnormalized conditional density is never substituted into a joint identity.

Part (7). The identity (5.19) applies to an integrable F when $e > 0$, and both conditional integrals are finite since both events have positive probability. Without further control there is no small error: on a two-point space, give S^c probability e and take $F = e^{-2}\mathbf{1}_{S^c}$; then $\mathbb{E}_\nu F = 0$ and $\mathbb{E}_\mu F = e^{-1}$. □

5.6 Invariant functions of three holonomies

The weak-coupling results concern continuous functions of the three holonomies H_1, H_2, H_3 around the coordinate cycles of the torus, with a common basepoint, that are invariant under simultaneous conjugation. The next lemma shows that such functions are exactly the continuous functions of seven traces. If we write $H_i = a_i I + v_i \cdot t$, the traces of H_i and H_iH_j determine the scalar parts a_i and the Gram matrix of the vectors v_i. The trace of $H_1H_2H_3$ determines in addition the orientation $\det(v_1, v_2, v_3)$, and a triple of vectors is determined up to rotation by its Gram matrix and its orientation. These seven coordinates are the case of three generators in the classical theory of trace coordinates of Horowitz [111]; the argument below proves the separation and the continuous factorization for all triples in $\mathrm{SU}(2)$, including those of deficient rank.

Lemma 5.6. *Define* $\mathfrak{p} : \mathrm{SU}(2)^3 \to [-1,1]^7$ *by the normalized traces of* $H_1, H_2, H_3, H_1H_2, H_1H_3, H_2H_3, H_1H_2H_3$, *in this order. For all* $H, H' \in \mathrm{SU}(2)^3$,

$$\mathfrak{p}(H) = \mathfrak{p}(H') \quad \Longleftrightarrow \quad \text{there exists } k \in \mathrm{SU}(2) \text{ with } H_i' = kH_ik^{-1} \text{ for } i = 1,2,3.$$

This includes all triples of deficient rank and the central triples. Explicitly, if $H_i = a_i I + 2v_i^a \tau_a$ *with* $a_i^2 + |v_i|^2 = 1$, *the normalized trace of* H_iH_j *is* $a_ia_j - v_i \cdot v_j$, *and that of* $H_1H_2H_3$ *is*

$$a_1a_2a_3 - a_3 v_1 \cdot v_2 - a_1 v_2 \cdot v_3 - a_2 v_1 \cdot v_3 - \det(v_1, v_2, v_3).$$

The map induced by $\mathfrak{p}$ *from the quotient of* $\mathrm{SU}(2)^3$ *by simultaneous conjugation onto* $\mathfrak{p}(\mathrm{SU}(2)^3)$ *is a homeomorphism. Every continuous function* $F : \mathrm{SU}(2)^3 \to \mathbb{C}$ *invariant under simultaneous conjugation has the form* $F = f \circ \mathfrak{p}$, *where* f *is continuous on* $\mathfrak{p}(\mathrm{SU}(2)^3)$ *and extends to a continuous function on* $[-1,1]^7$ *with* $\|f\|_\infty \le \|F\|_\infty$. *In particular, if the trace vectors* $\mathfrak{p}(H^{(k)})$ *of random triples* $H^{(k)}$ *converge jointly in distribution, then for every such* F *the expectations* $\mathbb{E}F(H^{(k)})$ *converge, to the expectation of* f *under the limiting law, which is supported on* $\mathfrak{p}(\mathrm{SU}(2)^3)$.

The lemma concerns one triple of matrices and its seven traces; it does not by itself relate lattice holonomies to continuum observables.

Proof. By (5.1), $H_i = a_i I + v_i \cdot t$ with $t_a = 2\tau_a$; the scalar part a_i is the normalized trace, and $a_i^2 + |v_i|^2 = 1$. The scalar part of $H_i H_j$ is $a_i a_j - v_i \cdot v_j$. Multiplying once more, we find that the scalar part of $H_1 H_2 H_3$ is

$$(a_1 a_2 - v_1 \cdot v_2) a_3 - (a_1 v_2 + a_2 v_1 + v_1 \times v_2) \cdot v_3,$$

which expands to the stated formula, with the minus sign in front of $\det(v_1, v_2, v_3) = (v_1 \times v_2) \cdot v_3$ for our choice of τ_a.

Suppose $\mathfrak{p}(H) = \mathfrak{p}(H')$. Then $a_i = a_i'$, the Gram matrices $(v_i \cdot v_j)$ and $(v_i' \cdot v_j')$ agree (including the diagonal entries $1 - a_i^2$), and $\det(v_1, v_2, v_3) = \det(v_1', v_2', v_3')$. We define a map between the spans by $T(\sum_i c_i v_i) = \sum_i c_i v_i'$. Equality of the Gram matrices shows that T is well defined, since if $\sum_i c_i v_i = 0$ then $|\sum_i c_i v_i'|^2$ is the same quadratic form in c and vanishes, and that T is an isometry onto the span of the v_i'. Completing orthonormal bases of the two spans to bases of $\mathbb{R}^3$, we extend T to an orthogonal map R. If the common rank is three, equality of the nonzero determinants implies $\det R = 1$. If the rank is at most two and $\det R = -1$, we compose R with the reflection in a direction perpendicular to the span of the v_i'; this fixes every v_i' and changes the determinant to $+1$. Rank zero covers the central triples. In every case some $R \in \mathrm{SO}(3)$ maps each v_i to v_i'. By the surjectivity of Ad (Lemma 5.1) there exists $k \in \mathrm{SU}(2)$ with $\mathrm{Ad}(k) = R$. Since conjugation does not change the scalar parts, we have $H_i' = k H_i k^{-1}$. Conversely, simultaneous conjugation preserves the trace of every product, by cyclicity of the trace.

Let Q_0 be the quotient of $\mathrm{SU}(2)^3$ by simultaneous conjugation, with the quotient topology, and let $A = \mathfrak{p}(\mathrm{SU}(2)^3)$. Then Q_0 is compact, as a continuous image of a compact space, and so is A. Since the polynomial map $\mathfrak{p}$ is continuous and constant on equivalence classes, it induces a continuous map $Q_0 \to A$, which is bijective by what we just proved. A closed subset of Q_0 is compact, and its image is compact and hence closed in the metric space A. Thus the inverse map is continuous, and the induced map is a homeomorphism.

A continuous invariant function F descends to a continuous function on Q_0, which defines a continuous function f_A on A with $\|f_A\|_\infty = \|F\|_\infty$. We construct a continuous extension to the cube. For a real continuous function g on the compact set A with $|g| \le B$, set $g_T(x) = \inf_{y \in A}\{g(y) + T|x - y|\}$ for $x \in [-1, 1]^7$. By the triangle inequality g_T is T-Lipschitz, and $g_T \le g$ on A. Given $\varepsilon > 0$, choose $\delta > 0$ from the uniform continuity of g, and T with $T\delta \ge 2B$. For $x \in A$, the terms with $|x - y| \le \delta$ are at least $g(x) - \varepsilon$, and the remaining terms are at least $-B + T\delta \ge B \ge g(x)$. Thus $g - \varepsilon \le g_T \le g$ on A, and clipping g_T to $[-B, B]$ preserves its continuity and this approximation, and it bounds the result by B on the cube. Let $M = \|f_A\|_\infty$. If $M = 0$, extend by zero. Otherwise let $r_0 = f_A$. If $\|r_k\|_\infty \le B_k = 2^{-k} M$, apply this construction to the real and imaginary parts of r_k, with errors at most $B_k/(2\sqrt{2})$; this gives a continuous complex function h_k on the cube with $\|h_k\|_\infty \le \sqrt{2} B_k$ and $\|r_k - h_k|_A\|_\infty \le B_k/2$, and we set $r_{k+1} = r_k - h_k|_A$.

Since $\sum_k \sqrt{2}B_k < \infty$, the series $h = \sum_k h_k$ converges uniformly on the cube. Then h is continuous, and $h = f_A$ on A since the residuals tend to zero uniformly. Composing h with the radial retraction of $\mathbb{C}$ onto the closed disc of radius M,

$$z \longmapsto \begin{cases} z, & |z| \leq M, \\ Mz/|z|, & |z| > M, \end{cases}$$

which is continuous and fixes the values of f_A, gives a continuous extension f with $\|f\|_\infty \leq M$. Finally, $\mathbb{E}F(H^{(k)}) = \mathbb{E}f(\mathfrak{p}(H^{(k)}))$. Since f is bounded and continuous on the cube, convergence in distribution of the traces implies convergence of the expectations. The limiting law, a probability measure on the cube, is supported on the closed set A, since the nonnegative continuous function $\operatorname{dist}(\cdot, A)$ has expectation zero under every approximating law and hence under the limit. The limit of the expectations is therefore the integral of the intrinsically defined function f_A. □

SECTION 6

Block averaging and chessboard estimates

In this section, we prove the finite-dimensional properties of the block averaging map T_M of Definition 4.3 that are used throughout the renormalization group analysis, and the reflection positivity estimates for the Wilson measure on which the bound on large fields rests. Section 6.1 shows that T_M is Borel, gauge covariant, and covariant under the translations and reflections preserving the coarse lattice, also where its logarithm is not defined, and that its iterates have nested local dependence sets (Proposition 6.2). Section 6.2 constructs local constraint coordinates near the coarse-field lift $U_0(b)$ for every coarse configuration b, restores the block gauge variables, and computes Haar measure on the resulting coordinate domain exactly (Lemma 6.3); this formula is the starting point of every fluctuation integral in Parts IV and VI. Section 6.3 proves that the curl bounds the ℓ^2 norm on the linearized constrained fluctuation space, uniformly in the volume (Lemma 6.5); this is an input of Section 8. Section 6.4 contains reflection positivity and chessboard estimates for the Wilson measure and its images under T_M^ℓ, and exponential moment bounds for plaquette energies on the finest lattice (Theorem 6.6); these are used in Sections 7, 22, and 23. The inputs are the conventions of Definitions 4.1 and 4.3, the Haar measure, tree gauge, and finite-word estimates of Lemma 5.1, and the coefficient calculus of Lemma 5.3. No later result is used.

Throughout this section, we measure distances and dependence sets in fine lattice units; physical rescaling multiplies every spatial coordinate by the fine mesh. Unless a more specific dependence is stated, constants depend only on M, on the stated coordinate radii, and, for derivative estimates, on the prescribed finite derivative order. They are independent of L, the lattice side, the coupling, and the number of preceding averaging steps; this is the dependence described in item (1) of Definition 4.14.

6.1 The block averaging map

The block averaging map is an instance of Bałaban's averaging operation for lattice gauge fields [12, eq. (15)]: the fine link variables of a block are transported to a common reference path, their logarithms are averaged, and the average is exponentiated. It is defined in Definition 4.3; we fix the additional notation used in this section and the next.

Definition 6.1. Let $M = 2R_M + 1 \geq 3$ be odd, let the fine periodic lattice have side Mm with $m \geq 4$, work in fine lattice units, and let T_M be the block averaging map of Definition 4.3, with the centered blocks $\mathsf{B}_M(v)$, $v \in M\mathbb{Z}^3$, the root paths $\sigma_{v,x}$, the reference paths C_c, and the paths

$$F_{c,x} = \sigma_{v,x}\,[x, x + Me_i]\,\sigma^{-1}_{v+Me_i,x+Me_i}, \qquad c = (v, v + Me_i),\ x \in \mathsf{B}_M(v),$$

defined there; we call the $F_{c,x}$ translated paths with endpoint connectors. The logarithm in the first clause of (4.3) is the principal logarithm on $\mathrm{SU}(2) \setminus \{-I\}$, with $|\mathrm{Log}\, V| < 2\pi$, and we call the second clause, $(T_M U)_c = U(C_c)$ when some based loop holonomy $U(F_{c,x})U(C_c)^{-1}$ equals $-I$, the Borel extension of T_M. For odd $s \geq 1$ and a vertex v set

$$\mathsf{B}_s(v) = v + \{-(s-1)/2, \dots, (s-1)/2\}^3,$$

so that $\mathsf{B}_1(v) = \{v\}$. The links of the paths $\sigma_{v,x}$, $x \in \mathsf{B}_M(v)$, form a spanning tree of the block (Proposition 6.2), which we call the block tree, with root v. For $\ell \geq 1$, T_M^ℓ denotes the ℓ-fold composition of T_M; one renormalization group step is the composition T_M^J, not an average over blocks of side M^J. For a configuration b on the coarse lattice, the coarse-field lift $U_0(b)$ is the fine configuration that equals I on every link with both endpoints in one block, and equals b_c on every link from $\mathsf{B}_M(v)$ to $\mathsf{B}_M(v + Me_i)$, where $c = (v, v + Me_i)$.

Figure 6.1 shows these paths for two neighboring blocks.

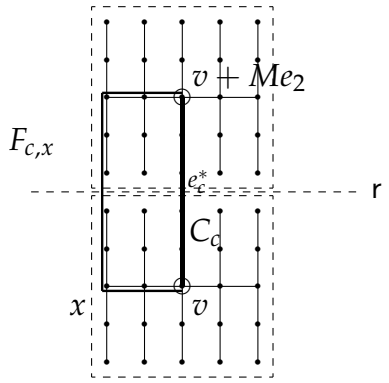

Figure 6.1. Two neighboring centered blocks for $M = 5$, in the plane spanned by e_1 and e_2, with $c = (v, v + Me_2)$. Dashed squares: the blocks $\mathsf{B}_M(v)$ and $\mathsf{B}_M(v + Me_2)$. Thin lines: the block trees. Thick line: the reference path C_c; it contains the eliminated edge e_c^* of Section 6.2. Medium line: the translated path with endpoint connectors $F_{c,x}$ for $x = v - 2e_1$. Dotted line: the plane of a reflection r bisecting the links between the two blocks; each block lies on one side of it.

Proposition 6.2. *Let M and m be as in Definition 6.1. Then the following statements hold.*

1. *The centered blocks partition the fine vertices. In each block the links of the paths $\sigma_{v,x}$ form a spanning tree with $M^3 - 1$ links, and the paths from the root v in this tree are the $\sigma_{v,x}$.*
2. *T_M is a Borel map on the whole configuration space $\mathcal{U}_{Mm}$.*
3. *For every periodic gauge transformation k, $T_M(U^k) = (T_M U)^{k|_{M\mathbb{Z}^3}}$.*
4. *T_M commutes with the translations by vectors of $M\mathbb{Z}^3$ and with every coordinate reflection $x_j \mapsto a_j - x_j$ with $a_j \in M\mathbb{Z}$, in particular with the spatial inversion $x \mapsto -x$. This includes the configurations at which the Borel extension is used. These reflections map block trees onto block trees; no invariance under permutations of the coordinates is needed or claimed.*
5. *For every coarse configuration b, without any restriction on its holonomies, $T_M \mathcal{U}_0(b) = b$.*
6. *Let $\ell \geq 0$, $m_\ell = M^\ell$, and let the fine side be $N = m_\ell n$ with $n \geq 4$. The value of $T_M^\ell U$ on the coarse link $(v, v + m_\ell e_i)$ depends only on the fine links with both endpoints in*

$$\mathsf{B}_{m_\ell}(v) \cup \mathsf{B}_{m_\ell}(v + m_\ell e_i).$$

For $\ell \geq 1$ the blocks are nested:

$$\bigcup_{\delta \in \{-R_M, \dots, R_M\}^3} \mathsf{B}_{M^{\ell-1}}\big(v + M^{\ell-1}\delta\big) = \mathsf{B}_{M^\ell}(v). \tag{6.1}$$

All statements are deterministic. The sets in (6) do not depend on L, the coupling, the number of preceding averaging steps, or the fields outside them.

Proof. Blocks and trees. In one coordinate, the intervals $Mk + \{-R_M, \dots, R_M\}$, $k \in \mathbb{Z}$, consist of M consecutive integers and have centers at distance M. They therefore partition $\mathbb{Z}$, and also $\mathbb{Z}/Mm\mathbb{Z}$. Taking products, we see that the blocks partition the vertices, including across the periodic identifications. For a vertex $x \neq v$ of $\mathsf{B}_M(v)$, we define the parent of x by decreasing the absolute value of the last nonzero component of $x - v$ by one. Since the ℓ^1 distance to v decreases strictly along parents and every vertex reaches v, the links from vertices to their parents form a tree with $M^3 - 1$ links. Read from v, the path to x in this tree changes first the first coordinate, then the second, then the third; it is $\sigma_{v,x}$. This proves (1).

Measurability and gauge covariance. Every transport along a translated path with endpoint connectors or a reference path is a finite product of link matrices and their inverses. The set of configurations at which none of the finitely many based loop holonomies equals $-I$ is open. Since the principal logarithm is continuous on $\mathrm{SU}(2) \setminus \{-I\}$, the first clause of (4.3) defines a continuous map on this open set. On its closed complement, $(T_M U)_c = U(C_c)$ is continuous. This proves (2); no value of $\mathrm{Log}(-I)$ is used. Let k be a periodic gauge transformation. The paths $F_{c,x}$ and C_c both start at v and end at $v + Me_i$, so each based loop holonomy $U(F_{c,x})U(C_c)^{-1}$ is conjugated by k_v. On $\mathrm{SU}(2) \setminus \{-I\}$ the principal logarithm satisfies $\mathrm{Log}(kVk^{-1}) = \mathrm{Ad}(k)\,\mathrm{Log}\,V$, since both sides exponentiate to kVk^{-1} and lie in the ball of radius 2π on which the exponential

map is injective. The condition that some based loop holonomy equals $-I$ is invariant under conjugation. Multiplying by the reference transport $k_v U(C_c) k_{v+Me_i}^{-1}$ gives (3), in both cases of the definition.

Translations and reflections. A translation by a vector of $M\mathbb{Z}^3$ maps blocks, root paths, translated paths with endpoint connectors, and reference paths to the corresponding objects. For reflections we use the following identity. Let F_x, $x \in \mathsf{B}_M(v)$, and C be elements of $\mathrm{SU}(2)$ with $F_x C^{-1} \neq -I$ for all x, and let $A = M^{-3} \sum_x \operatorname{Log}(F_x C^{-1})$. Then

$$\begin{aligned} \operatorname{Log}(F_x^{-1} C) &= -\operatorname{Ad}(C^{-1}) \operatorname{Log}(F_x C^{-1}), \\ \exp\Big(M^{-3} \sum_x \operatorname{Log}(F_x^{-1} C)\Big) C^{-1} &= C^{-1} e^{-A} = (e^A C)^{-1}. \end{aligned} \tag{6.2}$$

The first line follows from $F_x^{-1} C = C^{-1} (F_x C^{-1})^{-1} C$, the conjugation property of Log just used, and $\operatorname{Log}(V^{-1}) = -\operatorname{Log} V$; the second follows from the first. If one of the elements $F_x C^{-1}$ equals $-I$, then its conjugated inverse $F_x^{-1} C$ also equals $-I$, and the two values given by the Borel extension are C and C^{-1}, which are again inverse to each other.

We write a coordinate reflection preserving $M\mathbb{Z}^3$ as $x_j \mapsto a_j - x_j$ with $a_j \in M\mathbb{Z}$. It maps blocks to blocks and centers to centers, and it changes the signs of the steps of a path without changing the order in which the coordinates are changed. In particular, it maps each block tree and each root path $\sigma_{v,x}$ to the corresponding block tree and root path. If $j \neq i$, it maps $F_{c,x}$ and C_c to the corresponding paths of the reflected positive link. If $j = i$, let s denote the reflection, let $c' = (s(v + Me_i), s(v))$ be the positive link associated with the image of c, and let $y = s(x + Me_i)$, which lies in the initial block of c'. Substituting the reflected endpoint paths, we find

$$s F_{c,x} = F_{c',y}^{-1}, \qquad s C_c = C_{c'}^{-1},$$

and $x \mapsto y$ is a bijection between the two initial blocks. Then (6.2), including its exceptional case, implies reflection covariance. Products of the three coordinate reflections give the spatial inversion. This proves (4).

Right inverse. Each straight segment $[x, x + Me_i]$ passes from the initial block of c into the final block exactly once; its transverse coordinates stay in the common transverse range of the two blocks, and both root paths stay in their blocks. The same holds for the reference path. For $U_0(b)$, every link inside a block has transport I and the single interface link crossed has transport b_c. This gives $U_0(b)(F_{c,x}) = U_0(b)(C_c) = b_c$ for every x. Every based loop holonomy then equals I, and $(T_M U_0(b))_c = b_c$. This proves (5).

Nesting and dependence sets. Let $s = M^{\ell-1}$. In one coordinate, the intervals $s\delta + \{-(s-1)/2, \dots, (s-1)/2\}$, $-R_M \leq \delta \leq R_M$, are consecutive disjoint integer intervals, with extreme endpoints $\pm(sR_M + (s-1)/2) = \pm(Ms - 1)/2$. Taking products in three coordinates yields (6.1), including the case $s = 1$. For $\ell = 1$, the dependence statement in (6) follows from the description of the three pieces of each translated path with endpoint

connectors in the previous paragraph, and from the fact that the reference path lies in the two blocks. Suppose that it holds for $\ell - 1$. The last averaging step reads only intermediate links with both endpoints in the two centered blocks of intermediate vertices around the final endpoints. By the induction hypothesis, each of these intermediate links depends only on fine links in the blocks of side $M^{\ell-1}$ around its endpoints. By (6.1) the union of these blocks lies in the two claimed blocks of side M^ℓ. The decision whether the Borel extension is used reads the same based loop holonomies and does not enlarge the dependence set. By induction, this proves (6) for the composition T_M^ℓ. Since $n \geq 4$, the union of two blocks of side M^ℓ has extent $2M^\ell < M^\ell n$ in each coordinate, and all these sets lift to boxes in the covering lattice $\mathbb{Z}^3$, also across the periodic identifications. □

6.2 Local constraint coordinates and Haar measure

We now parametrize the configurations near a level set $\{T_M U = b\}$. In each block we fix the gauge by the block tree, with gauge transformations equal to I at the block centers; we call this the block axial gauge. For each positive coarse link $c = (v, v + Me_i)$ we then eliminate one link variable, on the central interface link

$$e_c^* = \big(v + R_M e_i,\, v + (R_M + 1)e_i\big),$$

by solving the equation $(T_M U)_c = b_c$. This edge, which we call the eliminated edge, lies on the reference path C_c (Figure 6.1), and C_c consists of e_c^* and of links of the two block trees.

The equation can be solved with radii independent of b. To see this, write $U = e^X U_0(b)$ on the links not in the block trees, and suppose that only $X_{e_c^*} = \omega$ is nonzero. Exactly M of the M^3 paths $F_{c,x}$ cross e_c^*, namely those with $x - v \in \mathbb{Z}e_i$, while the reference path always crosses it. Then $M^3 - M$ of the based loop holonomies equal $e^{-\omega}$, the others equal I, and

$$(T_M U)_c = e^{-(1-M^{-2})\omega} e^{\omega} b_c = e^{M^{-2}\omega} b_c.$$

The derivative of the constraint in the eliminated variable is therefore $M^{-2} I_3$ at every real coarse field b, including coarse fields with large holonomies. We construct the local inverse in a neighborhood of $U_0(b)$ rather than of the identity configuration.

The variables are counted as follows; here f denotes the number of remaining SU(2) variables.

fine links	$3(Mm)^3$
links of the block trees	$(Mm)^3 - m^3$
links not in the block trees	$2(Mm)^3 + m^3$
eliminated edges e_c^*, one for each positive coarse link	$3m^3$
remaining SU(2) variables	$f = 2((Mm)^3 - m^3)$
real dimension of the free logarithmic coordinates z	$3f$

We obtain the Haar formula in Lemma 6.3 by two successive changes of variables. First, with the free link matrices fixed, we replace the eliminated link matrices by the coarse output $T_M U$. Then we translate the free link matrices on the right by $U_0(b)^{-1}$ and pass to their logarithms. In the first change, the constant c_{Haar} of the output chart cancels that of the eliminated edges, but their Haar density j_H remains. For this reason the numerator of the Haar disintegration density $\mathscr{J}_b$ below contains j_H for every link not in the block trees. Recall from Lemma 5.1 that $dH(e^X) = c_{\mathrm{Haar}}\, j_H(X)\, d^3X$ for $|X| < 2\pi$, with $c_{\mathrm{Haar}} = (16\pi^2)^{-1}$ and $j_H(X) = \mathrm{sinc}^2(|X|/2)$.

Lemma 6.3. *Let M, m, and the block trees be as in Definition 6.1, and fix the block axial gauge. For a coarse configuration b write $U_e = e^{X_e} U_{0,e}(b)$ on the links e not in the block trees, and $U_e = I$ on the links of the block trees. For each positive coarse link c define*

$$\mathsf{C}_{b,c}(X) = \mathrm{Log}\big((T_M(e^X U_0(b)))_c\, b_c^{-1}\big).$$

Call the variables X_e with e not in the block trees and not an eliminated edge the free logarithmic coordinates, and denote their vector by z.

1. *Among the eliminated variables $X_{e^*_{c'}}$, the function $\mathsf{C}_{b,c}$ depends only on $X_{e^*_c}$. It depends on at most $6M^3$ links, all with both endpoints in the two blocks of c, and each link enters at most six of the functions $\mathsf{C}_{b,c}$. For every real b,*

$$\mathsf{C}_{b,c}(0) = 0, \qquad D_{X_{e^*_c}} \mathsf{C}_{b,c}(0) = M^{-2} I_3.$$

2. *There exist $r_M, \widetilde{r}_M > 0$, depending only on M, with the following property. For every real b and every vector z of free logarithmic coordinates with $\max_e |z_e| < r_M$, there exists a unique X whose free entries equal z, whose eliminated entries have norm less than $\widetilde{r}_M$, and which satisfies $\mathsf{C}_{b,c}(X) = 0$ for all c. Writing $X = \Gamma_b(z)$, we have*

$$\Gamma_b(0) = 0, \qquad (\Gamma_b(z))_{\mathrm{free}} = z, \qquad T_M\big(e^{\Gamma_b(z)} U_0(b)\big) = b.$$

   The map Γ_b is real analytic and has a holomorphic extension, jointly in the free logarithmic coordinates and in local complex coordinates of the target around every real b. The eliminated entry of Γ_b at e^*_c depends only on the free logarithmic coordinates in the two blocks of c. For each order $s \geq 1$, the derivatives of order s of Γ_b on a fixed smaller complex polydisc have absolute row and column sums bounded in terms of M, s, and the ratio of the radii of the two polydiscs. These bounds do not depend on m, on b, or on the number of preceding averaging steps. All determinants $\det D_{X_{e^*_c}} \mathsf{C}_{b,c}(\Gamma_b(z))$ are positive.

3. *Let $f = 2((Mm)^3 - m^3)$ be the number of free $\mathrm{SU}(2)$ variables, and set*

$$\mathscr{J}_b(z) = c_{\mathrm{Haar}}^f \, \frac{\prod_{e \notin \text{block trees}} j_H\big((\Gamma_b(z))_e\big)}{\prod_c \det D_{X_{e^*_c}} \mathsf{C}_{b,c}(\Gamma_b(z))}.$$

For a Borel set $\mathcal{Z} \subset \{\max_e |z_e| < r_M\}$, let $\mathcal{D}_{\mathcal{Z}}$ be the set of configurations $(e^{\Gamma_b(z)} U_0(b))^k$ with b a coarse configuration, $z \in \mathcal{Z}$, and k a gauge transformation equal to I at every block center. Then for every nonnegative Borel function F on $\mathcal{U}_{Mm}$,

$$\int_{\mathcal{D}_{\mathcal{Z}}} F(U)\, dH_{Mm}(U) = \int dH_m(b) \int_{\mathcal{Z}} \mathscr{J}_b(z)\, dz \int F\big((e^{\Gamma_b(z)} U_0(b))^k\big)\, dH_{\mathrm{for}}(k),$$

where dz is Lebesgue measure on $\mathbb{R}^{3f}$ and H_{for} is the product Haar probability measure on the values of k at the vertices other than block centers. For gauge-invariant F the inner integral equals $F(e^{\Gamma_b(z)} U_0(b))$. The numerator of $\mathscr{J}_b$ contains the Haar density of every eliminated edge, and no further factor (no density in a coarse logarithm, no Gram determinant, and no volume of a gauge orbit) occurs.

4. *Let $g > 0$. The substitution $z = g\eta$ turns $\mathscr{J}_b(z)\, dz$ into $g^{3f}\, \mathscr{J}_b(g\eta)\, d\eta$. If F is the Wilson weight $\exp[-4g^{-2} \sum_p q(U_p)]$ times the indicator of an event, the integrand in η is $g^{3f}\, \mathscr{J}_b(g\eta) \exp[-4g^{-2} \sum_p q((e^{\Gamma_b(g\eta)} U_0(b))_p)]$ times that indicator and the indicator of $\{g\eta \in \mathcal{Z}\}$. After integrating over η and normalizing, one obtains the image under T_M of the restricted measure; in general it differs from the image of the unrestricted Wilson measure, since the mass of the restriction depends on the target.*
5. *At fixed real b, a coarse gauge transformation h, extended to be constant on each block, acts on the free logarithms by $X_e \mapsto \mathrm{Ad}(h_v) X_e$, where v is the center of the block containing the initial vertex of e. The spatial inversion acts, together with the induced permutation of links, by*

$$X'_{e'} = -\,\mathrm{Ad}\big(U_{0,e}(b)^{-1}\big) X_e.$$

These orthogonal maps commute with Γ and preserve the Wilson action and $\mathscr{J}$ exactly. They map products of three-dimensional Euclidean balls to the products with permuted radii; products of balls with a common radius are invariant. Although the maps depend on b, the joint change of variables (b, z) has a block-triangular derivative whose diagonal block in z has absolute determinant one.

All constants depend only on M, the stated coordinate radii, and, where applicable, the prescribed derivative order. The only restriction involving g is that $g\eta$ lies in the coordinate domain of (2).

The uniqueness in (2) holds in the stated neighborhood of $U_0(b)$, not on the whole level set $\{T_M U = b\}$, and the formula in (3) concerns only the set $\mathcal{D}_{\mathcal{Z}}$. We construct Γ_b by a contraction argument in one coarse link at a time; this is why the radii do not depend on the number of blocks.

Proof. We proceed in six steps.

Step 1: locality of the constraints. We apply the block version of the tree identity of Lemma 5.1, with every block center fixed; the block trees have $(Mm)^3 - m^3$ links. In this gauge every reference path has exactly one link not in a block tree, namely its eliminated

edge. Since a straight segment crosses only the interface of c and a root path never crosses an interface, no constraint contains the eliminated variable of another constraint. The remaining variables of $\mathsf{C}_{b,c}$ are links in the two blocks of c and on their common interface, at most $6M^3$ positive links. A free link inside a block can affect only the constraints of the six coarse links incident to the center of that block, and a free interface link affects only its own constraint. In particular, every variable enters at most six constraints.

Step 2: the linear coefficient. If all free variables vanish and only $X_{e_c^*} = \omega$ is varied, then exactly M of the M^3 straight segments cross e_c^*: their two transverse offsets vanish and their longitudinal offset has M possible values. The translated paths with endpoint connectors that contain them, and the reference path, have transport $e^{\omega} b_c$; all other such paths have transport b_c. For ω small every based loop holonomy different from I equals $e^{-\omega}$. Hence

$$(T_M(e^X U_0(b)))_c = e^{-(1-M^{-2})\omega} e^{\omega} b_c = e^{M^{-2}\omega} b_c, \qquad \mathsf{C}_{b,c}(\omega, 0) = M^{-2}\omega. \tag{6.3}$$

This gives the value and the derivative in (1) at every real b, including coarse fields whose holonomies do not commute.

Step 3: analytic neighborhoods. In local target coordinates we write $b'_c = e^{\theta_c} b_c$ with b_c real. The word $F_{c,x} C_c^{-1}$ has at most $5M - 3$ fine factors, and at $X = 0$ it equals I, also for the complex target b', since the identity $U_0(b)(F_{c,x}) = U_0(b)(C_c)$ is algebraic. There exists $\epsilon_M > 0$, depending only on M, such that for $\max_e |X_e| < \epsilon_M$ and $\max_c |\theta_c| < \epsilon_M$ all these words and the outer transport $T_M(e^X U_0(b'))_c b_c'^{-1}$ have matrix distance less than $1/4$ from I. Indeed, we insert the factors e^{X_e} one at a time into the fixed word: real compact factors have operator norm one, the complex target factors and their inverses have norm at most $e^{|\theta_c|}$, and $\|e^Y - I\| \le e^{|Y|} - 1$. The resulting bound tends to zero uniformly in the real background. The outer transport tends to I by the same bound applied to the finite sum of inner logarithms. On this domain every logarithm is given by the convergent series $\sum_{k \ge 1} (-1)^{k+1} (V - I)^k / k$. By the finite-word estimates of Lemma 5.1, we have first and second derivative bounds there, uniform in the real background.

Step 4: construction of the inverse. We solve one constraint at a time. In one constraint let $\omega = X_{e_c^*}$ and let z denote its free logarithmic coordinates, with $\|z\|_\infty$ the maximum of their norms. After decreasing ϵ_M, we fix $A_M^{\mathrm{an}}, K_M^{\mathrm{an}} \ge 1$ such that, for all local targets with $\max|\theta| < \epsilon_M/2$ and $|\omega|, \|z\|_\infty < \epsilon_M/2$,

$$\begin{aligned} |\mathsf{C}_{b',c}(0, z)| &\le A_M^{\mathrm{an}} \|z\|_\infty, \\ \|D_\omega \mathsf{C}_{b',c}(\omega, z) - M^{-2} I\| &\le K_M^{\mathrm{an}} \big(|\omega| + \|z\|_\infty\big). \end{aligned} \tag{6.4}$$

The first line follows from the first derivative bound and $\mathsf{C}_{b',c}(0, 0) = 0$. The identity (6.3) continues to the complex target coordinates, so $D_\omega \mathsf{C}_{b',c}(0, 0) = M^{-2} I$, and the second line

follows from the second derivative bound. All these norms concern at most $6M^3$ links, independently of m. Fix

$$\delta_M \le \min\{\epsilon_M/4,\ (8M^2K_M^{\mathrm{an}})^{-1},\ 1/4\}, \qquad \widetilde{r}_M = \delta_M, \qquad r_M = \frac{\delta_M}{4M^2A_M^{\mathrm{an}}}.$$

For $\|z\|_\infty < r_M$, the second line of (6.4) implies that the map $\Psi(\omega) = \omega - M^2\mathsf{C}_{b',c}(\omega, z)$ has Lipschitz constant at most $1/4$ on $\{|\omega| \le \delta_M\}$, and by the first line we have $|\Psi(0)| \le \delta_M/4$. Then Ψ maps this closed ball into the ball of radius $\delta_M/2$. Starting from $\omega_0 = 0$, the iterates satisfy $|\omega_{j+1} - \omega_j| \le 4^{-j}\delta_M/4$ and converge uniformly to a solution of $\mathsf{C}_{b',c}(\omega, z) = 0$. Two solutions in the ball of radius δ_M differ by at most a quarter of their distance, so they coincide. We define Γ_b by solving these independent equations, one for each c, and keeping the free entries z.

Each iterate is holomorphic. On every strictly smaller polydisc in the free logarithmic coordinates and the target variables the uniform limit is holomorphic, since the one-variable Cauchy formula in each coordinate passes to the uniform limit. Iterated Cauchy formulas give the derivative bounds. If the margins between the two polydiscs are $d_z, d_\theta > 0$, a coefficient of order s in one constraint is bounded by $\delta_M s!\,(C_M/\min(d_z, d_\theta))^s$, after enlarging C_M to account for the at most $3(6M^3+1)$ scalar variables of the constraint. The free entries of Γ_b are coordinate functions. Each eliminated entry uses only the variables of its own constraint, and each variable belongs to at most six constraints, by Step 1. This proves the row and column bounds of every fixed order in (2); it is also the finite-range case of Lemma 5.3. Real coefficients and uniqueness imply real analyticity in real variables. The same construction applies in target coordinates centered at every real b, with the radii just chosen. On the solution, $\|M^2 D_\omega \mathsf{C} - I\| \le 1/4$, so the determinant does not vanish; by continuity from $X = 0$ it is positive for real data, and it lies between $M^{-6}(3/4)^3$ and $M^{-6}(5/4)^3$. This proves (2).

Step 5: the Haar formula. There are $d_{\mathrm{nf}} = 3(Mm)^3 - ((Mm)^3 - m^3) = 2(Mm)^3 + m^3$ links not in the block trees, of which $3m^3$ are eliminated edges, so $f = d_{\mathrm{nf}} - 3m^3 = 2((Mm)^3 - m^3)$ and dz is Lebesgue measure in dimension $3f$.

We first keep the untranslated free link matrices V_e fixed and replace the matrices on the eliminated edges by the output $T_M V$. At a configuration with output b we use the output chart $y_c = \mathrm{Log}((T_M V)_c b_c^{-1})$. Since $y_c = 0$ at that point, the coarse Haar measure has density $c_{\mathrm{Haar}}\, d^3 y_c$ there. In the input chart $V_{e_c^*} = e^{X_{e_c^*}} b_c$ the Haar measure of the eliminated edge has density $c_{\mathrm{Haar}}\, j_H(X_{e_c^*})\, d^3 X_{e_c^*}$. With the free matrices fixed, the derivative $D_{X_{e^*}} y$ is block diagonal with blocks $D_{X_{e_c^*}} \mathsf{C}_{b,c}$, by Step 1, and its determinant is positive. This gives the density factor

$$\prod_c \frac{j_H(X_{e_c^*})}{\det D_{X_{e_c^*}} \mathsf{C}_{b,c}(X)} \tag{6.5}$$

relative to the coarse Haar probability measure and the Haar measure of the untranslated free matrices. The constants c_{Haar} of the eliminated edges cancel against those of the output chart, not against the factors j_H.

At fixed b we next write $V_e U_{0,e}(b)^{-1} = e^{z_e}$ for the free links. Right translation preserves Haar measure. Made jointly with b, this change of variables is triangular, so the derivatives of z in b do not affect its determinant. Passing to logarithms gives the factor $c_{\mathrm{Haar}}^{f} \prod_{e \text{ free}} j_H(z_e)\, dz$. Combining this with (6.5), we obtain $\mathscr{J}_b$, with the factor j_H of every link not in the block trees in its numerator. Since no coarse logarithm has been integrated against Lebesgue measure, there is no additional coarse factor j_H. Since we used independent coordinates throughout, no surface measure or Gram determinant occurs.

The parametrization is injective: the target is recovered by applying T_M, and then the free logarithms are recovered from the free links. The image of a Borel set $\mathcal{Z}$ is Borel. Indeed, with $b = T_M V$, a configuration in the block axial gauge belongs to the image if and only if its logarithms relative to $U_0(b)$ on the links not in the block trees exist in the neighborhoods above, its free logarithms belong to $\mathcal{Z}$, and its eliminated logarithms have norm less than $\widetilde{r}_M$. The constraint then holds, and uniqueness identifies these logarithms with Γ_b; each condition is Borel. The pointwise Jacobian computation therefore gives the integral formula, first on coordinate neighborhoods and then on a disjoint measurable refinement of countably many of them. Countably many suffice, since a finite product of matrix groups has a countable base of coordinate neighborhoods. By monotone approximation, the formula holds for all nonnegative Borel F. Finally we restore the block-tree links by the tree identity of Lemma 5.1; they contribute the integral over k against H_{for}. For a gauge-invariant integrand this integral equals the value at $k = I$. Since the tree gauge and its inverse are finite products of transports, restoring it preserves the Borel description. This proves (3).

The substitution $z = g\eta$ multiplies Lebesgue measure in dimension $3f$ by g^{3f}, and multiplication by the Wilson weight gives the stated factor together with every indicator. Integrating out η and normalizing gives the image of the restricted measure. This proves (4).

Step 6: symmetries. We extend a coarse gauge transformation h to be constant on each block. The coarse-field lift transforms into the lift of b^h, the block-tree links remain equal to I, and the relative logarithm on a link whose initial vertex lies in the block of v becomes $\mathrm{Ad}(h_v) X_e$. This is an orthogonal map of $\mathbb{R}^3$ with determinant one. It acts in the same way on an eliminated input and on the output of its constraint, so $D_{X_{e_c^*}} \mathsf{C}_{b,c}$ is conjugated and its determinant is unchanged; uniqueness implies the equivariance of Γ.

Under the spatial inversion, let e' be the positive link representing the reversed image of e. The lift is covariant under inversion, and

$$\big(e^{X_e} U_{0,e}\big)^{-1} = e^{-\operatorname{Ad}(U_{0,e}^{-1})X_e}\, U_{0,e}^{-1},$$

which gives the formula in (5). At fixed real b this is an orthogonal signed permutation of the free and the eliminated variables. The reflected constraint for the reversed coarse link is

$$\operatorname{Log}\big((T_M V)_c^{-1} b_c\big) = -\operatorname{Ad}(b_c^{-1})\, \mathsf{C}_{b,c}(X),$$

and its eliminated input is transformed by the same orthogonal map, because $U_{0,e_c^*} = b_c$. Its derivative is therefore conjugated, and its determinant is unchanged. Norms and the Haar factors j_H are unchanged, and so is the Wilson action, since a reflection changes a plaquette transport only by conjugation and possibly inversion, both of which preserve q. Uniqueness implies the intertwining of Γ. A product of three-dimensional balls is mapped to the product with relabeled radii, and a product with a common radius is invariant. Although these orthogonal matrices depend on the target, the joint transformation of (b, z) has a triangular derivative, and its diagonal block in z has absolute determinant one. This proves (5). □

6.3 Coercivity on the constrained fluctuation space

At the identity configuration the constraint $T_M U = I$ linearizes to $DT_M(I)a = 0$, where a is a real one-cochain with values in $\mathfrak{su}(2) \simeq \mathbb{R}^3$. On this space, after the block axial gauge fixing, the curl controls the ℓ^2 norm with a constant depending only on M, for a local reason. The value of a gauge-fixed cochain on a link e not in a block tree is the circulation of a around the short loop formed by e and two root paths. On interface links, the loop has to be closed through the reference path C_c and therefore also involves the eliminated edge e_c^*. The constraint $DT_M(I)a = 0$ expresses $a_{e_c^*}$ as an average of circulations around the short loops $F_{c,x} C_c^{-1}$. Each circulation around a short loop is bounded by the curl in a small box, by an explicit filling (Lemma 6.4). The tree gauge and the constraint remove the directions in which the curl vanishes; the coarse field itself is not controlled.

Lemma 6.4. *Let P be a box in $\mathbb{Z}^3$ with side lengths d_1, d_2, d_3, measured in links. Every closed lattice path ξ of length h in P is the boundary of an integer combination $\sum_p n_p p$ of oriented elementary plaquettes of P with*

$$\sum_p |n_p| \le h(d_1 + d_2 + d_3).$$

In particular, every real $\mathfrak{su}(2)$-valued one-cochain a satisfies

$$|a(\xi)| \le h(d_1 + d_2 + d_3) \Big(\sum_{p \subset P} |(\mathrm{d}a)_p|^2 \Big)^{1/2},$$

where $a(\xi)$ is the signed sum of a along ξ and $(\mathrm{d}a)_p$ is the signed sum of a around p.

Proof. Let o be the lower corner of P and let τ_x be the path from o to x that changes the coordinates in the order $1, 2, 3$. For a positive link $e = (x, y)$ in direction i, we move the final step of $\tau_x e$ backwards through the steps of τ_x in the directions $j > i$. Each interchange crosses one elementary ij plaquette inside P; the result is τ_y, and the number of plaquettes crossed is $\sum_{j>i}(x_j - o_j) \le d_1 + d_2 + d_3$. This gives an integer filling of the closed chain $\tau_x + e - \tau_y$ with that mass bound. For a negatively oriented step we use the negative of the filling of the reversed positive link. When we sum over all steps of a closed path, the terms τ_x cancel and the oriented edge chain of ξ remains. Adding the mass bounds, we obtain the first assertion, also for paths that retrace links or repeat plaquettes. Pairing the chain identity with a gives $a(\xi) = \sum_p n_p (\mathrm{d}a)_p$, and the second assertion follows from the triangle inequality and $\max_p |(\mathrm{d}a)_p| \le (\sum_{p \subset P} |(\mathrm{d}a)_p|^2)^{1/2}$. The constant does not depend on the components of a. □

Lemma 6.5. *Fix an odd $M \ge 3$. There exist $0 < c_M \le C_M < \infty$, depending only on M, with the following properties. Let $m \ge 4$, and let a be a real $\mathfrak{su}(2)$-valued one-cochain on the periodic fine lattice of side Mm that vanishes on the block trees and satisfies $DT_M(I)a = 0$. Then*

$$\sum_e |a_e|^2 \le C_M \sum_p |(\mathrm{d}a)_p|^2,$$

where $\mathrm{d}a$ is the signed elementary curl in fine lattice units. Further, let Γ_I be the map of Lemma 6.3(2) at the coarse configuration all of whose links equal I, and let $E_0 = D_z \Gamma_I(0)$ be the induced linear embedding of the free logarithmic coordinates. Then

$$c_M I \le E_0^{\mathsf{T}} \mathrm{d}^{\mathsf{T}} \mathrm{d} E_0 \le C_M I.$$

The rows and columns of E_0 have finite range and absolute sums bounded in terms of M. These estimates include all periodic identifications and all three components of $\mathfrak{su}(2)$, and the constants do not depend on m or on the number of preceding averaging steps.

Proof. The linearized constraint. We differentiate (4.3) at I. The contribution of the reference path to the mean of the logarithms of the based loop holonomies cancels the derivative of the final reference factor, and we find

$$(DT_M(I)a)_c = M^{-3} \sum_{x \in \mathsf{B}_M(v)} a(F_{c,x}). \tag{6.6}$$

Since a vanishes on the block trees, $a(C_c) = a_{e_c^*}$, and the constraint gives

$$a_{e_c^*} = -M^{-3} \sum_x \big(a(F_{c,x}) - a(C_c) \big). \tag{6.7}$$

Local bounds. The closed path $F_{c,x}C_c^{-1}$ lies in the box P_c formed by the two blocks of c, and its length is at most $5M-3$: each root path has at most $3R_M$ links, the straight segment has M links, and C_c has M links. The side lengths of P_c, in links, sum to $(2M-1)+2(M-1)=4M-3$. By Lemma 6.4 and (6.7), with the common constant $A_M^{\mathrm{fill}}=20M^2\geq(5M-3)(4M-3)$, we have

$$|a_{e_c^*}|\leq A_M^{\mathrm{fill}}\Big(\sum_{p\subset P_c}|(\mathrm{d}a)_p|^2\Big)^{1/2}. \tag{6.8}$$

A link $e=(x,y)$ not in the block tree with both endpoints in the block of v has the closed path $\sigma_{v,x}e\sigma_{v,y}^{-1}$, of length at most $3M-2$. Its circulation is a_e, since a vanishes on the tree. The side lengths of the block sum to $3M-3$, and $(3M-2)(3M-3)\leq A_M^{\mathrm{fill}}$, so the same filling bound controls $|a_e|$ by the curl in this single block. For an interface link $e=(x,y)$ from the block of v to the block of $v+Me_i$, the closed path $\sigma_{v,x}e\sigma_{v+Me_i,y}^{-1}C_c^{-1}$ has length at most $4M-2$ and circulation $a_e-a_{e_c^*}$, and $(4M-2)(4M-3)\leq A_M^{\mathrm{fill}}$. Combining these bounds with (6.8), we find, for every fine link e,

$$|a_e|^2\leq 4\big(A_M^{\mathrm{fill}}\big)^2\sum_{p\subset P_e}|(\mathrm{d}a)_p|^2, \tag{6.9}$$

where P_e is the block containing e or, for an interface link, the box of the two blocks. Links of the block trees satisfy the same inequality, since a vanishes on them.

Summation. A plaquette has its vertices in at most four blocks. A box of one or two blocks containing the plaquette contains one of these blocks, and for each block there are at most seven such boxes: the block itself, or its union with one of its six neighbors. Each such box has at most $2M^3$ vertices and hence at most $6M^3$ positive links to which it is assigned. When (6.9) is summed over e, a fixed plaquette is counted at most $D_M^{\mathrm{ov}}=4\cdot 7\cdot 6M^3=168M^3$ times, and

$$\sum_e|a_e|^2\leq C_M^{\mathrm{gap}}\sum_p|(\mathrm{d}a)_p|^2,\qquad C_M^{\mathrm{gap}}=4\big(A_M^{\mathrm{fill}}\big)^2D_M^{\mathrm{ov}}. \tag{6.10}$$

Since a box of two blocks has longest side $2M-1<Mm/2$ for $m\geq 4$, it lifts to a box in the covering lattice even when it meets the periodic identifications. The fillings above are therefore valid with the same bounds. All arguments are identities for chains, applied to each of the three components of a, with the Euclidean norm on $\mathfrak{su}(2)$.

The embedding. In the block axial gauge we write (6.6) as

$$M^{-2}a_{e_c^*}+\sum_{e\ \mathrm{free}}q_{ce}a_e=0.$$

The coefficient of $a_{e_c^*}$ is M^{-2}, since e_c^* occurs in exactly M of the paths $F_{c,x}$. The sum of the absolute values of the other coefficients is at most $M^{-3}\sum_x\mathrm{length}(F_{c,x})\leq 4M$.

Differentiating the identity $\mathsf{C}_{I,c}(\Gamma_I(z)) = 0$ of Lemma 6.3 at $z = 0$, we find that the free rows of E_0 are the identity and that the eliminated rows are

$$(E_0 z)_{e_c^*} = -M^2 \sum_e q_{ce} z_e,$$

with absolute row sums at most $4M^3$; in particular each entry of an eliminated row is at most $4M^3$ in absolute value. A free link inside a block occurs only in the six constraints incident to its block, and a free interface link only in its own constraint. Hence the absolute row and column sums of E_0 are at most $1 + 4M^3$ and $1 + 24M^3$, respectively, and its rows and columns have finite range. For any matrix A, by the weighted Cauchy–Schwarz inequality, we have

$$\sum_x \Big| \sum_y A_{xy} z_y \Big|^2 \le \Big(\sup_x \sum_y |A_{xy}| \Big) \Big(\sup_y \sum_x |A_{xy}| \Big) \sum_y |z_y|^2,$$

and this also applies to scalar coefficients tensored with the identity on $\mathbb{R}^3$. In particular, $\|E_0\|_2^2 \le (1 + 4M^3)(1 + 24M^3)$. Since the curl matrix has four signed entries in each row and each link lies in four plaquettes, we have $\|\mathrm{d}\|_2 \le 4$. This proves the upper bound with the constant $16(1 + 4M^3)(1 + 24M^3)$.

For the lower bound, note that the free entries of $E_0 z$ are the entries of z, and that $E_0 z$ vanishes on the block trees and satisfies the linearized constraints. Applying (6.10) to $a = E_0 z$, we obtain

$$\|\mathrm{d} E_0 z\|_2^2 \ge \big(C_M^{\mathrm{gap}}\big)^{-1} \|E_0 z\|_2^2 \ge \big(C_M^{\mathrm{gap}}\big)^{-1} \|z\|_2^2.$$

We take $c_M = (C_M^{\mathrm{gap}})^{-1}$ and let C_M be the larger of C_M^{gap} and $16(1 + 4M^3)(1 + 24M^3)$. Both depend only on M. □

6.4 Reflection positivity and chessboard estimates

Osterwalder and Seiler proved in [134] that the Wilson measure is reflection positive. The chessboard estimate is the consequence of reflection positivity developed by Fröhlich, Israel, Lieb, and Simon in [92, 93]; we follow the formulation and proof of Biskup in [29, Theorem 5.8 and (5.34)–(5.35)]. We need these results for the images of the Wilson measure under T_M^ℓ, for gauge-invariant observables, for reflections through planes bisecting links, and for disjoint cells of two sites in each direction. The treatment in [29] concerns spin systems with blocks that share boundary sites. We therefore verify reflection positivity directly for the observables we need, show that it survives the block averaging map because the blocks are centered and nested, and give the chessboard argument in full. At the end of the section, we prove exponential moment bounds for plaquette energies under the Wilson measure by combining the chessboard estimate with elementary bounds on partition functions.

Reflections and observables. Let $n \in 4\mathbb{N}$ and consider the periodic lattice of side n, in its own lattice units. A bond reflection is a map r of the vertices of the form $x_j \mapsto 2b + 1 - x_j$ for one coordinate j and some $b \in \mathbb{Z}$, with the other coordinates unchanged. It fixes the two planes $x_j = b + 1/2$ and $x_j = b + 1/2 + n/2$, which bisect links, and these planes divide the vertices into two open halves of width $n/2$ that are exchanged by r. It acts on configurations by $(\mathsf{r}U)_{(x,y)} = U_{(\mathsf{r}x,\mathsf{r}y)}$, with the convention $U_{(y,x)} = U_{(x,y)}^{-1}$, and on functions by $(F \circ \mathsf{r})(U) = F(\mathsf{r}U)$. All observables below are bounded complex-valued Borel functions of the link variables. An observable supported in a reflection half of r is such a function that is invariant under all periodic gauge transformations and depends only on links with both endpoints in one of the two open halves of r. In particular, it does not depend on the links crossing the two planes.

We tile the vertices by the cells $Q_t = 2t + \{0,1\}^3$, $t \in (\mathbb{Z}/(n/2)\mathbb{Z})^3$. There are $\mathfrak{m} = n^3/8$ cells, and the cell indices form a torus of side $n/2$, which is even. An observable supported in Q_t is a bounded Borel function, invariant under all periodic gauge transformations, of the links with both endpoints in Q_t. For a cell index t, let g_t be the map of the vertices with coordinate maps

$$g_{t,j}(x_j) = x_j + 2t_j \quad \text{if } t_j \text{ is even}, \qquad g_{t,j}(x_j) = 2t_j + 1 - x_j \quad \text{if } t_j \text{ is odd},$$

modulo n. It maps Q_0 onto Q_t, and in each coordinate j it is the composition of the t_j reflections $x_j \mapsto 4k + 3 - x_j$, $0 \le k < t_j$, through the planes $x_j = 2k + 3/2$ between consecutive cells; since $n/2$ is even, g_t depends only on t modulo $n/2$. For an observable f supported in Q_0, the reflected translate $\vartheta_t f$ is the observable supported in Q_t defined by $\vartheta_t f(U) = f(U \circ g_t)$, where $(U \circ g_t)_{(x,y)} = U_{(g_t x, g_t y)}$ for the links (x,y) of Q_0. If r is the reflection through the planes between two consecutive cells and t' is the image of the cell index t under r, a direct computation gives $\mathsf{r} \circ g_t = g_{t'}$, and hence $(\vartheta_t f) \circ \mathsf{r} = \vartheta_{t'} f$. For a shift $\eta \in \{0,1\}^3$ we use in the same way the shifted tiling by the cells $\eta + 2t + \{0,1\}^3$, with $g_{t,j}(x_j) = x_j + 2t_j$ if t_j is even and $g_{t,j}(x_j) = 2\eta_j + 2t_j + 1 - x_j$ if t_j is odd.

For $\beta \ge 0$ and an even side $N \ge 4$, let

$$Z_N(\beta) = \int e^{-\beta \sum_{p \in \mathcal{P}_N} q(U_p)} \, dH_N(U), \qquad d\mu_N^\beta = Z_N(\beta)^{-1} e^{-\beta \sum_{p \in \mathcal{P}_N} q(U_p)} \, dH_N.$$

The Wilson measure of Definition 4.1 is $\mu_{N,\gamma} = \mu_N^\beta$ with $\beta = 4N/\gamma$.

Theorem 6.6. *Let $M \ge 3$ be odd, $\ell \ge 0$, $n \in 4\mathbb{N}$, and $N = M^\ell n$. For $\beta \ge 0$ let $\mu^{(\ell)} = (T_M^\ell)_* \mu_N^\beta$ be the image of μ_N^β on the coarse lattice of side n; for $\ell = 0$ this is μ_n^β.*

1. Reflection positivity. *For every bond reflection r of the coarse lattice and every observable F supported in a reflection half of r,*

$$\mathbb{E}_{\mu^{(\ell)}}\left[F \, \overline{F \circ \mathsf{r}}\right] \ge 0.$$

The same holds under μ_N^β for every bounded Borel function on $\mathcal{U}_N$ that is invariant under all periodic gauge transformations and depends only on fine links with both endpoints in the union of the blocks $\mathsf{B}_{M^\ell}(v)$ over the coarse vertices v of one open half; this class contains $F \circ T_M^\ell$ for every observable F supported in a reflection half of r. The configurations at which the Borel extension of T_M is used are included.

2. Chessboard estimates. *For nonnegative observables $f_1, \dots, f_k$ supported in Q_0 and distinct cell indices $t_1, \dots, t_k$,*

$$\mathbb{E}_{\mu^{(\ell)}} \prod_{j=1}^{k} \vartheta_{t_j} f_j \le \prod_{j=1}^{k} \Big[\mathbb{E}_{\mu^{(\ell)}} \prod_{t} \vartheta_t f_j \Big]^{1/\mathfrak{m}}.$$

The same holds for each of the eight shifted tilings, and every coarse plaquette lies in a cell of at least one of them. In particular, writing $V = T_M^\ell U$ and $D_t(u) = \{\max_{p \subset Q_t} \rho_G(V_p) > u\}$ for $u \ge 0$, where the maximum is over the plaquettes with all vertices in Q_t, we have for every set T of cell indices

$$\mu^{(\ell)}\Big(\bigcap_{t \in T} D_t(u) \Big) \le \mu^{(\ell)}\Big(\bigcap_{t} D_t(u) \Big)^{|T|/\mathfrak{m}},$$

and

$$\mu_N^\beta \Big\{ \max_p \rho_G\big((T_M^\ell U)_p\big) > u \Big\} \le n^3 \Big[\frac{1}{Z_N(\beta)} \int e^{-\beta \sum_p q(U_p)} \mathbf{1}_{\cap_t D_t(u)}(T_M^\ell U)\, dH_N(U) \Big]^{8/n^3}.$$

More generally, the chessboard inequality holds under μ_N^β for the cells $C_t^\eta = \bigcup_{\zeta \in \{0,1\}^3} \mathsf{B}_{M^\ell}(M^\ell(\eta + 2t + \zeta))$ of the fine lattice, for every shift η, and for nonnegative observables supported in C_0^η, with the reflected translates defined in Section 6.4. The inequality for $\mu^{(\ell)}$ is the special case of the functions $f \circ T_M^\ell$.

3. Plaquette energies under the Wilson measure. *Let $\ell = 0$ and $C_0 = 48 + 24 \log(1/c_{\mathrm{ball}})$, where $c_{\mathrm{ball}} = \operatorname{sinc}^2(1/2)/(12\pi)$ is the constant of Lemma 5.1. For $\beta \ge 2$ and $0 < s \le 1/2$ set*

$$A_s(n, \beta) = C_0 + 24 \log \frac{1}{1 - s} + \frac{36 \log \beta}{n}.$$

Then for every deterministic set S of plaquettes,

$$\mathbb{E}_{\mu_n^\beta} \exp\Big(\frac{s}{8} \sum_{p \in S} \beta q(U_p) \Big) \le e^{A_s(n,\beta)|S|/8}.$$

For $K \ge 0$ and a cell Q let $D_Q(K) = \{\max_{p \subset Q} \beta q(U_p) \ge K\}$. For distinct cells $Q_{t_1}, \dots, Q_{t_k}$ of one tiling,

$$\mu_n^\beta\Big(\bigcap_{j=1}^{k} D_{Q_{t_j}}(K) \Big) \le \big[6 e^{A_s(n,\beta) - sK} \big]^k$$

and

$$\mu_n^\beta\Big\{\max_p \beta q(U_p) \ge K\Big\} \le \min\big\{1, 6n^3 e^{A_s(n,\beta)-sK}\big\}.$$

If $\beta \le b_+ n$ for some $b_+ > 0$, then $36\log\beta/n \le 36b_+/\mathrm{e}$.

4. Conditioning. *If D is an event with $\mu_n^\beta(D) \ge 1 - \varepsilon_D > 0$, then $\mathbb{E}_{\mu_n^\beta}[X \mid D] \le (1-\varepsilon_D)^{-1}\mathbb{E}_{\mu_n^\beta} X$ for every nonnegative random variable X.*

The constant C_0 is absolute; no constant in (1)–(4) depends on L, β, n, N, or ℓ.

Remark 6.7. Reflection positivity is asserted here for the Wilson measure and its images. For $\ell > 0$, the integral in part (2) is estimated in Sections 22 and 23. The term $36\log\beta/n$ in A_s comes from the comparison of the periodic lattice with the open cube in Lemma 6.11. After tree gauge fixing, the periodic lattice has $r_P = 2n^3 + 1$ independent link variables and the open cube with n vertices per side has $r_O = 2n^3 - 3n^2 + 1$. Each variable contributes a factor of order $\beta^{-3/2}$, and the chessboard exponent is $1/\mathfrak{m} = 8/n^3$, so that

$$\frac{8}{n^3}\cdot\frac{3}{2}\,(r_P - r_O)\log\beta = \frac{36\log\beta}{n}.$$

This term cannot be absorbed into C_0 when n and β vary independently, so we keep it.

We prove part (1) in Section 6.4, part (2) in Section 6.4, and parts (3) and (4) in Section 6.4.

Reflection positivity

Lemma 6.8. *Let $N \ge 4$ be even, $\beta \ge 0$, and let r be a bond reflection of the periodic lattice of side N. Then μ_N^β is invariant under r, and $\mathbb{E}_{\mu_N^\beta}[F\,\overline{F\circ\mathsf{r}}] \ge 0$ for every observable F supported in a reflection half of r.*

Proof. Since the two planes of r divide the vertices into halves of width $N/2 \ge 2$, a vertex is an endpoint of at most one link crossing the planes, and the crossing links form a matching. We write the integral of the gauge-invariant function $G(U) = F(U)\overline{F(\mathsf{r}U)}e^{-\beta\sum_p q(U_p)}$ against H_N as an iterated integral, first over the links not crossing the planes and then over the crossing links. For fixed values of the crossing links, let k be the gauge transformation with $k_y = U_e$ at the endpoint y in the plus half of each crossing link e, oriented from the minus half to the plus half, and $k = I$ at all other vertices. It is well defined because the crossing links form a matching. Then $(U^k)_e = I$ on every crossing link, while every other link undergoes a left or right translation by a matrix depending only on the crossing links. These translations preserve the product Haar measure of the noncrossing links, and $G(U^k) = G(U)$. Hence the integral equals the integral of G with all crossing links set to I, against the Haar measure of the noncrossing links. The integrals over the crossing links give one. No cycle around the torus is removed by this gauge fixing.

A plaquette either has all its vertices in one half or crosses one of the planes. After the crossing links are set to I, the transport around a crossing plaquette is, up to conjugation and inversion, UV^{-1}, where U is a link of the plus half parallel to the plane and adjacent to it, and V is the reflected link of the minus half. We identify $\mathrm{SU}(2)$ with the unit quaternions, $U \leftrightarrow u \in S^3 \subset \mathbb{R}^4$ and $V \leftrightarrow v$. Then $\mathrm{tr}(UV^{-1})/2 = u \cdot v$, so

$$e^{-\beta q(UV^{-1})} = e^{-\beta} \sum_{r=0}^{\infty} \frac{\beta^r}{r!} \sum_{a_1,\dots,a_r=1}^{4} u_{a_1} \cdots u_{a_r} v_{a_1} \cdots v_{a_r}. \tag{6.11}$$

For each r the sum of the absolute values of the terms is at most $(\sum_a |u_a v_a|)^r \le 1$. The series and its finite products over the crossing plaquettes therefore converge absolutely and uniformly, and every coefficient is nonnegative for $\beta \ge 0$. The plaquettes inside the minus half and the Haar measure of its links are the reflected copies of those of the plus half. Integrating $F\overline{F \circ \mathsf{r}}$ against the expanded weight, we obtain

$$Z_N(\beta)\, \mathbb{E}_{\mu_N^\beta}\left[F\, \overline{F \circ \mathsf{r}}\right] = e^{-\beta |\mathcal{P}_{\mathrm{cross}}|} \sum_{\alpha} c_\alpha \left| \int F(U_+) e^{-\beta A_+(U_+)} \phi_\alpha(U_+)\, dH_+(U_+) \right|^2 \ge 0. \tag{6.12}$$

Here $\mathcal{P}_{\mathrm{cross}}$ is the set of crossing plaquettes, α runs over the degrees and component indices in (6.11) for all crossing plaquettes, c_α is the product of the corresponding coefficients $\beta^r/r!$, U_+ denotes the links with both endpoints in the plus half, H_+ their product Haar measure, A_+ the sum of $q(U_p)$ over the plaquettes in the plus half, and ϕ_α the product of the corresponding real quaternion components of the plus links adjacent to the planes. Absolute convergence justifies the interchange of sum and integral for bounded Borel F. The partition function $Z_N(\beta)$ is positive by Lemma 5.1, and the term $r = 0$ covers $\beta = 0$. Finally, μ_N^β is invariant under r, since Haar measure is preserved by permutations of links and by inversion, and q is preserved by conjugation and inversion. □

Proof of Theorem 6.6(1). For $\ell = 0$ this is Lemma 6.8. Let $\ell \ge 1$ and $a = M^\ell$, so that $N = an$. In fine units, a bond reflection of the coarse lattice acts in the reflected coordinate by $x \mapsto (2b+1)a - x$ for some $b \in \mathbb{Z}$. Since a is odd, both planes are bond planes of the fine lattice. For $0 \le k < \ell$, the intercept divided by the mesh M^k of the lattice after k averaging steps is $(2b+1)M^{\ell-k}$, an odd multiple of M. By Proposition 6.2(4), each averaging step therefore commutes with this reflection, including at the configurations where the Borel extension is used, and so does T_M^ℓ. By Proposition 6.2(6), a coarse link with both endpoints in one open half depends only on fine links in the union of the blocks of side a of that half. Since the block nearest a plane ends half a fine lattice spacing before it, these fine links do not cross the fine planes. Since T_M^ℓ is Borel, the composition with T_M^ℓ of an observable supported in a reflection half is bounded and Borel. By gauge covariance (Proposition 6.2(3)), it is invariant under all periodic gauge transformations of the fine lattice. Applying Lemma 6.8 to $F \circ T_M^\ell$ and to the other functions in the stated class

proves (1). By the same covariance, $\mu^{(\ell)}$ is invariant under the translations of the coarse lattice and under its bond reflections, since μ_N^β is invariant under the corresponding fine maps. □

The chessboard estimate

For an odd integer $a \geq 1$, $n \in 4\mathbb{N}$, and a shift $\eta \in \{0,1\}^3$, consider the periodic lattice of side an and the cells

$$C_t^\eta = \bigcup_{\zeta \in \{0,1\}^3} \mathsf{B}_a\big(a(\eta + 2t + \zeta)\big), \qquad t \in (\mathbb{Z}/(n/2)\mathbb{Z})^3.$$

They are cubes with $2a$ vertices in each direction, and they partition the vertices, since the blocks $\mathsf{B}_a(av)$, $v \in \mathbb{Z}^3$, do; for $a = 1$ they are the cells $\eta + 2t + \{0,1\}^3$ above. In the coordinate j, the plane between the cells with indices k and $k+1$ is $x_j = (2\eta_j + 4k + 3)a/2$. It bisects links, since a is odd, and the reflection through it, $x_j \mapsto (2\eta_j + 4k + 3)a - x_j$, maps each cell onto a cell. The second fixed plane of this reflection lies at distance $an/2 = 2a \cdot (n/4)$ from the first, which is a multiple of the side $2a$ of the cells. It is also a plane between consecutive cells, and every cell lies in one open half of the reflection. Observables supported in C_t^η are defined as for $a = 1$; they depend only on the links with both endpoints in C_t^η. The maps g_t now have the coordinate maps $g_{t,j}(x_j) = x_j + 2at_j$ if t_j is even and $g_{t,j}(x_j) = (2\eta_j + 2t_j + 1)a - x_j$ if t_j is odd, modulo an; they map C_0^η onto C_t^η and are compositions of t_j reflections through planes between consecutive cells in each coordinate j. Reflected translates are defined by $\vartheta_t f(U) = f(U \circ g_t)$ for observables f supported in C_0^η. If r is the reflection through the plane between the cells with indices k and $k+1$ in the coordinate j, it maps the index t to the index t' with $t'_j = 2k + 1 - t_j$ and the other components unchanged. Further, $\mathsf{r} \circ g_t = g_{t'}$, since for even t_j, $(2\eta_j + 4k + 3)a - (x_j + 2at_j) = (2\eta_j + 2t'_j + 1)a - x_j$, and for odd t_j, $(2\eta_j + 4k + 3)a - ((2\eta_j + 2t_j + 1)a - x_j) = x_j + 2at'_j$. This implies $(\vartheta_t f) \circ \mathsf{r} = \vartheta_{t'} f$.

Lemma 6.9. *Let $a \geq 1$ be odd, $n \in 4\mathbb{N}$, and $\eta \in \{0,1\}^3$. Let ν be a probability measure on $\mathcal{U}_{an}$ such that, for every bond reflection r through the planes between consecutive cells C_t^η, ν is invariant under r and $\mathbb{E}_\nu[F\,\overline{F \circ \mathsf{r}}] \geq 0$ for every observable F supported in a reflection half of r. Then for nonnegative observables $f_1, \dots, f_k$ supported in C_0^η and distinct cell indices $t_1, \dots, t_k$,*

$$\mathbb{E}_\nu \prod_{j=1}^k \vartheta_{t_j} f_j \leq \prod_{j=1}^k \Big[\mathbb{E}_\nu \prod_t \vartheta_t f_j\Big]^{1/\mathfrak{m}}, \qquad \mathfrak{m} = n^3/8.$$

The hypotheses concern only the reflections between the cells of the given tiling. In the applications below, all bond reflections are available.

Proof. The Schwarz inequality. Let r be a reflection through planes between consecutive cells, and call one of its open halves the plus half. For observables G, H supported in

the plus half, let $B_{\mathsf{r}}(G,H) = \mathbb{E}_\nu[G\,\overline{H\circ\mathsf{r}}]$. Since ν is invariant under the involution r, we have $B_{\mathsf{r}}(H,G) = \mathbb{E}_\nu[(H\circ\mathsf{r})\,\overline{G}] = \overline{B_{\mathsf{r}}(G,H)}$, so B_{r} is Hermitian, and by assumption it is positive semidefinite. Expanding $B_{\mathsf{r}}(G+zH, G+zH) \geq 0$ for complex z, we find $|B_{\mathsf{r}}(G,H)|^2 \leq B_{\mathsf{r}}(G,G)B_{\mathsf{r}}(H,H)$. If a diagonal entry vanishes, varying the real and imaginary parts of z shows that the mixed entry vanishes as well, so no nondegeneracy is needed. For an assignment $\boldsymbol{f} = (f_t)_t$ of nonnegative observables supported in C_0^η to the cell indices, we set

$$\mathcal{F}(\boldsymbol{f}) = \mathbb{E}_\nu \prod_t \vartheta_t f_t, \qquad \mathcal{F}(\boldsymbol{f})^2 \leq \mathcal{F}(R_+\boldsymbol{f})\,\mathcal{F}(R_-\boldsymbol{f}), \tag{6.13}$$

where $R_+\boldsymbol{f}$ assigns f_t both to each index t of the plus half and to its image t' under r, and $R_-\boldsymbol{f}$ is defined in the same way from the minus half. To prove the inequality, let $G = \prod_t \vartheta_t f_t$ and $H = \prod_t \vartheta_t f_{t'}$, both products over the indices t of the plus half. Since every cell lies in one open half of r, the functions G and H are observables supported in the plus half: they are bounded, Borel, gauge invariant, and depend only on links with both endpoints in that half. Since $(\vartheta_t f_{t'})\circ\mathsf{r} = \vartheta_{t'} f_{t'}$, the product $H\circ\mathsf{r}$ is the product over the minus half, so that $\mathcal{F}(\boldsymbol{f}) = B_{\mathsf{r}}(G,H)$, $\mathcal{F}(R_+\boldsymbol{f}) = B_{\mathsf{r}}(G,G)$, and $\mathcal{F}(R_-\boldsymbol{f}) = B_{\mathsf{r}}(H,H)$. These identities show that (6.13) is the Schwarz inequality.

One direction. Consider first a cyclic array of q positions, q even, in which the object at each position may be an entire product over a transverse slab of cells, and reflections through the planes between positions act as above. Fix a finite collection of strictly positive bounded functions, and for its assignments $(f_0,\dots,f_{q-1})$ set

$$\mathcal{G}(f_0,\dots,f_{q-1}) = \frac{\mathcal{F}(f_0,\dots,f_{q-1})}{\prod_{j=0}^{q-1}\mathcal{F}(f_j,\dots,f_j)^{1/q}},$$

where $\mathcal{F}(f_j,\dots,f_j)$ is the value at the assignment that places f_j at every position. The denominator is positive. Under each of the two copies in (6.13) every function of one half appears twice. The product of the two new denominators therefore equals the square of the old one, and $\mathcal{G}$ satisfies (6.13). Let $\mathcal{G}_*$ be the maximum of $\mathcal{G}$ over the finite set of assignments; $\mathcal{G}_* \geq 1$, since a constant assignment gives the value one. Among the maximizers we choose one with a longest cyclic run of one function, of length k. If $k < q$, we cut just before this run and at the opposite position; these two planes are the two fixed planes of one reflection through planes between cells. We copy the half that begins with the run to the other half. If $k < q/2$, the new array has a run of length at least $2k$; if $k \geq q/2$, that half is constant and the new array is constant. The two copied arrays have values at most $\mathcal{G}_*$, and (6.13) at the maximizer forces both values to equal $\mathcal{G}_* > 0$. This contradicts the maximality of the run unless $k = q$. Hence a constant assignment is a maximizer, and $\mathcal{G}_* = 1$. This proves the one-dimensional inequality $\mathcal{F}(f_0,\dots,f_{q-1}) \leq \prod_j \mathcal{F}(f_j,\dots,f_j)^{1/q}$ for every even q, without assuming that q is a power of two.

Three directions. Let $q = n/2$. We group the cell functions into the q products over the transverse slabs with fixed first cell index and apply the one-dimensional inequality. Each resulting expectation repeats one slab, by reflected translates, in the first direction, and carries the exponent $1/q$. We apply the inequality in the second direction to each of these expectations, grouping over the first and third indices. Now the first two directions are homogeneous, and each exponent is $1/q^2$. Applying it in the third direction, grouping over the first two, leaves the products over all reflected translates of single cell functions, with exponent $1/q^3 = 1/\mathfrak{m}$. Every slab product used is bounded, nonnegative, gauge invariant, and supported in a reflection half of the reflections in question. To allow functions with zeros, we replace each f by $f + \varepsilon$ and let $\varepsilon \downarrow 0$; the finite products converge boundedly. For partial assignments, we place the constant function one in the unused cells. This proves the inequality for the tiling with shift η. □

Proof of Theorem 6.6(2). We apply Lemma 6.9 in two ways.

Coarse cells. For every shift η, the reflections through the planes between consecutive cells $\eta + 2t + \{0,1\}^3$ are bond reflections of the coarse lattice. By part (1) and the invariance proved with it, $\nu = \mu^{(\ell)}$ is invariant under every bond reflection of the coarse lattice and reflection positive for observables supported in its reflection halves. Then the lemma with $a = 1$ implies the functional inequality for $\mu^{(\ell)}$ and every shifted tiling.

Fine cells. Let $a = M^\ell$. For every shift η, the planes between consecutive cells C_t^η are $x_j = (2\eta_j + 4k + 3)M^\ell/2$, and the reflections through them are bond reflections of the fine lattice, since $(2\eta_j + 4k + 3)M^\ell$ is odd. An observable supported in a reflection half of such a reflection is a bounded Borel gauge-invariant function of the fine links with both endpoints in one open half. Since the blocks partition the vertices and the planes run between blocks, these are the fine links with both endpoints in the union of the blocks $\mathsf{B}_{M^\ell}(v)$ over the coarse vertices v of that half. By Lemma 6.8, $\nu = \mu_N^\beta$ is invariant under every bond reflection of the fine lattice and reflection positive for these observables. By the lemma with $a = M^\ell$, the inequality holds for nonnegative observables supported in C_0^η, for every shift η.

The coarse inequality as a special case. Let f be an observable supported in the coarse cell $\eta + \{0,1\}^3$. By Proposition 6.2(2), (3), and (6), $f \circ T_M^\ell$ is bounded, Borel, invariant under all periodic gauge transformations of the fine lattice, and depends only on fine links with both endpoints in the union of the blocks $\mathsf{B}_{M^\ell}(M^\ell v)$ over the vertices v of the coarse cell, that is, in C_0^η. Written in fine units, the coarse map g_t is the fine map g_t with $a = M^\ell$: in each coordinate it is a translation by $2M^\ell t_j$ or a reflection $x_j \mapsto (2\eta_j + 2t_j + 1)M^\ell - x_j$. After $k < \ell$ averaging steps these are, in the units of that lattice, a translation by a multiple of M or a reflection with intercept $(2\eta_j + 2t_j + 1)M^{\ell-k} \in M\mathbb{Z}$. By Proposition 6.2(4), each averaging step commutes with them, and so does T_M^ℓ. We conclude that $(\vartheta_t f) \circ T_M^\ell =$

$\vartheta_t(f \circ T_M^\ell)$ and

$$\mathbb{E}_{\mu^{(\ell)}} \prod_j \vartheta_{t_j} f_j = \mathbb{E}_{\mu_N^\beta} \prod_j \vartheta_{t_j}(f_j \circ T_M^\ell),$$

so the inequality for $\mu^{(\ell)}$ is the special case of the functions $f \circ T_M^\ell$ of the fine inequality.

Bad cells. The reflections permute the six plaquettes of a cell and conjugate or invert their transports, which preserves ρ_G; hence the reflected translate of $\mathbf{1}_{D_0(u)}$ is $\mathbf{1}_{D_t(u)}$. As a function of V, this indicator is a nonnegative observable supported in Q_0, since ρ_G is continuous and invariant under conjugation. Its composition with T_M^ℓ is Borel and gauge invariant by Proposition 6.2(2) and (3). Taking $f_j = \mathbf{1}_{D_0(u)}$ for the cells of T gives the bound for $\bigcap_{t\in T} D_t(u)$. A coarse ij plaquette is contained in a cell of the tiling whose shift matches the parities of its starting vertex in the directions i and j, with either shift in the third direction. The eight tilings therefore cover all plaquettes, with $8\mathfrak{m} = n^3$ cells in total. The event that all cells of a shifted tiling are bad is a translate of the corresponding event for $\eta = 0$, and $\mu^{(\ell)}$ is invariant under translations of the coarse lattice. The bound for a single cell and a union bound over the n^3 cells give the maximum inequality, since

$$\mu^{(\ell)}\Big(\bigcap_t D_t(u)\Big) = \frac{1}{Z_N(\beta)} \int e^{-\beta \sum_p q(U_p)} \mathbf{1}_{\cap_t D_t(u)}(T_M^\ell U)\, dH_N(U).$$

□

Partition functions and plaquette energy moments

We now derive the moment bounds of part (3). We combine the chessboard estimate with bounds on partition functions obtained by tree gauge fixing, by integrating independent plaquette variables, and by dropping nonnegative plaquette terms. Elementary bounds of this kind are in the tradition of the stability estimates of Faria da Veiga and O'Carroll in [64, 65]; we derive the precise periodic correction needed here.

Lemma 6.10. *For every $\beta > 0$,*

$$z_1(\beta) = \int_{\mathrm{SU}(2)} e^{-\beta q(U)}\, dH(U) = \frac{2}{\pi} \int_0^\pi e^{-\beta(1-\cos t)} \sin^2 t\, dt$$
$$= \frac{2e^{-\beta} I_1(\beta)}{\beta} \le c_G \beta^{-3/2}, \qquad c_G = \sqrt{2/\pi},$$

where $I_1(\beta) = \sum_{k\ge 0} (\beta/2)^{2k+1}/(k!(k+1)!)$, and $z_1(0) = 1$ by continuous extension. If S is a random variable with density $s^{1/2}e^{-s}/\Gamma(3/2)$ on $s > 0$, then

$$\frac{z_1(\beta)}{c_G \beta^{-3/2}} = \mathbb{E}\sqrt{(1 - S/(2\beta))_+}.$$

For an integer $n \ge 1$ let O_n be the open cube with vertices $\{0, \dots, n\}^3$, all links and plaquettes between them, and no prescribed boundary links, and let $Z_{O_n}(\beta)$ be its partition function with

respect to the product Haar probability measure. Let $r_n = 2n^3 + 3n^2$ *be the number of links of* O_n *not in a spanning tree, and let* $P_n = 3n^2(n+1)$ *be the number of its plaquettes. Then for every* $\beta \geq 1$,

$$-\tfrac{3}{2} r_n \log \beta + r_n \log c_{\mathrm{ball}} - 2P_n \leq \log Z_{O_n}(\beta) \leq r_n \log z_1(\beta) \leq -\tfrac{3}{2} r_n \log \beta + r_n \log c_G,$$

where $c_{\mathrm{ball}} = \mathrm{sinc}^2(1/2)/(12\pi)$. *The constants are absolute and the inequalities hold uniformly in* n *and* β; *the bound* $Z_{O_n}(\beta) \leq z_1(\beta)^{r_n}$ *holds for every* $\beta > 0$. *For an open cube with* n *vertices in each direction the number of links not in a spanning tree is* $2n^3 - 3n^2 + 1$. *Finally, the partition function of the periodic lattice of side* $n+1$ *at any* $\beta > 0$ *is at most* $Z_{O_n}(\beta)$.

The last statement compares unnormalized integrals. It bounds a periodic partition function from above, but it does not replace that partition function in the denominator of a normalized expectation.

Proof. One plaquette. By the radial form of Haar measure in Lemma 5.1, with $t = |X|/2$, we have $z_1(\beta) = (2/\pi) \int_0^\pi e^{-\beta(1-\cos t)} \sin^2 t \, dt$. To compute the series, let $J_k = \int_0^\pi \sin^2 t \cos^{2k} t \, dt$, so $J_0 = \pi/2$. For $k \geq 1$, integrating the derivative of $\sin^3 t \cos^{2k-1} t$, whose boundary values vanish, gives $(2k+2)J_k = (2k-1)J_{k-1}$, and therefore $J_k = \pi(2k)!/(2 \cdot 4^k k!(k+1)!)$. Odd powers of $\cos t$ integrate to zero against $\sin^2 t$, by the substitution $t \mapsto \pi - t$. Since the exponential series converges uniformly on $[0, \pi]$, integrating termwise, we find

$$z_1(\beta) = e^{-\beta} \sum_{k \geq 0} \frac{(\beta/2)^{2k}}{k!(k+1)!} = \frac{2e^{-\beta} I_1(\beta)}{\beta}.$$

The integral is at most one and tends to one as $\beta \downarrow 0$, which gives the continuous extension. For $\beta > 0$, we substitute $s = \beta(1 - \cos t)$. Since $\sin t = (2s/\beta)^{1/2}(1 - s/(2\beta))^{1/2}$ and $ds = \beta \sin t \, dt$, we obtain

$$z_1(\beta) = \frac{2\sqrt{2}}{\pi} \beta^{-3/2} \int_0^{2\beta} s^{1/2} e^{-s} \sqrt{1 - \frac{s}{2\beta}} \, ds. \tag{6.14}$$

Dividing by $c_G \beta^{-3/2}$ and using $\Gamma(3/2) = \sqrt{\pi}/2$ gives the identity with the Gamma variable S. The integrand $\sqrt{(1 - S/(2\beta))_+}$ lies between zero and one, which proves $z_1(\beta) \leq c_G \beta^{-3/2}$ for every $\beta > 0$.

Counting. The open cube has $(n+1)^3$ vertices, $3n(n+1)^2$ links, and $P_n = 3n^2(n+1)$ plaquettes, and $3n(n+1)^2 - (n+1)^3 + 1 = r_n$. The following links form a spanning tree: all links in direction 1, the links in direction 2 in the plane $x_1 = 0$, and the links in direction 3 on the line $x_1 = x_2 = 0$. Indeed every vertex reaches $(0,0,0)$ by decreasing first x_1, then x_2, then x_3, and there are $n(n+1)^2 + n(n+1) + n = (n+1)^3 - 1$ such links. By Lemma 5.1, integrating out the gauge in this tree gives the factor one. In this gauge

we write $Y_{x,y,z}$ and $Z_{x,y,z}$ for the links in directions 2 and 3 at the vertex (x, y, z); then $Y_{0,y,z} = I$ and $Z_{0,0,z} = I$.

Upper bound. Consider the set of plaquettes consisting of all 12 plaquettes, all 13 plaquettes, and the 23 plaquettes in the plane $x_1 = 0$. With positive orientations, their transports are

$$A_{x,y,z} = Y_{x+1,y,z} Y_{x,y,z}^{-1}, \qquad B_{x,y,z} = Z_{x+1,y,z} Z_{x,y,z}^{-1}, \qquad D_{y,z} = Z_{0,y+1,z} Z_{0,y,z}^{-1}.$$

For A and B the coordinate x runs from 0 to $n-1$ and the other coordinates over their full ranges, so there are $n^2(n+1)$ plaquettes of each of these two kinds, and there are n^2 plaquettes D; in total r_n. From the D variables we reconstruct the links $Z_{0,y,z}$ successively in y, starting from $Z_{0,0,z} = I$. From the A variables we reconstruct every Y successively in x, starting from $Y_{0,y,z} = I$. From the B variables, with $Z_{0,y,z}$ already known, we reconstruct the remaining Z successively in x. In each step a new link equals a new plaquette variable times a link already fixed. By invariance of Haar measure and iterated integration, these plaquette variables are independent and Haar distributed. The plaquettes not in this set contribute factors at most one, since $q \geq 0$. Dropping them, we find $Z_{O_n}(\beta) \leq z_1(\beta)^{r_n}$ for every $\beta > 0$.

Lower bound. Let $\beta \geq 1$. We restrict each of the r_n links not in the tree to $\{\rho_G(U_e) < \beta^{-1/2}\}$, where $\beta^{-1/2} \leq 1$. By Lemma 5.1 each such ball has Haar measure at least $c_{\mathrm{ball}} \beta^{-3/2}$. A plaquette contains at most four links not in the tree, so by the triangle inequality for ρ_G we have $\rho_G(U_p) \leq 4\beta^{-1/2}$, and $q(U_p) \leq \rho_G(U_p)^2/8 \leq 2/\beta$; the first inequality is an inequality between group distances and holds even if its right side exceeds the radius of the logarithm chart. Hence the Boltzmann factor is at least e^{-2P_n} on this set, whose product Haar measure is at least $(c_{\mathrm{ball}} \beta^{-3/2})^{r_n}$. Taking logarithms gives the lower bound, and the bound of the previous paragraph together with $z_1(\beta) \leq c_G \beta^{-3/2}$ gives the remaining inequality. Since the boundary spheres of the balls have Haar measure zero, open and closed balls give the same estimate.

Replacing n by $n-1$, we find that the number of links not in a spanning tree of an open cube with n vertices in each direction is $2(n-1)^3 + 3(n-1)^2 = 2n^3 - 3n^2 + 1$. Finally, deleting from the periodic lattice of side $n+1$ the plaquettes that contain a link joining the vertex layers $x_j = n$ and $x_j = 0$, for some j, leaves the open cube O_n and the links joining those layers, which no remaining plaquette uses. The integrals of the latter against Haar probability measure equal one, and deleting plaquettes with nonnegative cost can only increase the integral. This proves the last statement. □

Lemma 6.11. *Let $n \in 4\mathbb{N}$, put $V = n^3$ and $\mathfrak{m} = V/8$, and let $Z_P(n, \beta) = Z_n(\beta)$ be the partition function of the periodic lattice of side n. Put $r_P = 2V + 1$ and $r_O = 2V - 3n^2 + 1$. Then*

$$\log Z_P(n, \beta) \geq -\tfrac{3}{2} r_P \log \beta + r_P \log c_{\mathrm{ball}} - 6V, \qquad \beta \geq 1, \tag{6.15}$$

$$Z_P(n, \beta') \leq Z_{O_{n-1}}(\beta') \leq \left(c_G (\beta')^{-3/2}\right)^{r_O}, \qquad \beta' > 0. \tag{6.16}$$

As a consequence, for $\beta \geq 2$ *and* $0 < s \leq 1/2$,

$$\begin{aligned} \frac{1}{\mathfrak{m}} \log \frac{Z_P(n,(1-s)\beta)}{Z_P(n,\beta)} &\leq \frac{12(r_P - r_O)}{V} \log \beta + \frac{12 r_O}{V} \log \frac{1}{1-s} \\ &\quad + \frac{8}{V}\left(r_O \log c_G - r_P \log c_{\mathrm{ball}} + 6V\right) \\ &\leq \frac{36 \log \beta}{n} + 24 \log \frac{1}{1-s} + C_0 = A_s(n,\beta), \end{aligned} \tag{6.17}$$

with

$$C_0 = 48 + 24 \log(1/c_{\mathrm{ball}}). \tag{6.18}$$

Proof. A spanning tree of the periodic lattice has $V - 1$ links, so $3V - (V-1) = r_P$ links are not in it; by Lemma 5.1 the gauge in the tree integrates to one. We restrict all links not in the tree, including those carrying the holonomies around the torus, to balls $\{\rho_G(U_e) < \beta^{-1/2}\}$ with $\beta^{-1/2} \leq 1$. As in the proof of Lemma 6.10, each ball has Haar measure at least $c_{\mathrm{ball}} \beta^{-3/2}$ and each plaquette costs at most $q(U_p) \leq 2/\beta$. There are $3V$ plaquettes, which gives (6.15). By the last statement of Lemma 6.10, applied with side $n = (n-1)+1$, the periodic partition function is at most that of the open cube with n vertices in each direction, which has r_O links not in a spanning tree. The upper bound of Lemma 6.10 then implies (6.16). This upper bound needs only $\beta' > 0$; below we use it with $\beta' = (1-s)\beta \geq 1$, where every inequality of the lemma applies.

Subtracting (6.15) from the logarithm of (6.16) with $\beta' = (1-s)\beta$ and multiplying by $1/\mathfrak{m} = 8/V$, we obtain the first inequality in (6.17). For the second we use $r_P - r_O = 3n^2$, $r_O/V \leq 2$, $r_P/V \leq 3$, $\log \beta \geq 0$, and $\log c_G < 0$: the first term equals $36 \log \beta / n$, the second is at most $24 \log(1/(1-s))$, and the third is at most $(8/V)(3V \log(1/c_{\mathrm{ball}}) + 6V) = C_0$. We keep the surface term $36 \log \beta / n$ in this form, before any relation between n and β is imposed. □

Proof of Theorem 6.6(3) and (4). We write $Y_p = \beta q(U_p) \geq 0$ and $\mathfrak{m} = n^3/8$. For a cell Q_0 let $f = \exp(s \sum_{p \subset Q_0} Y_p)$, the sum running over the six plaquettes of the cell. This is a nonnegative bounded observable supported in Q_0. The product of its reflected translates over all cells uses each plaquette inside a cell exactly once, so its exponent is at most $s \sum_p Y_p$, the sum over all plaquettes. By Lemma 6.11, we have

$$\mathbb{E}_{\mu_n^\beta} \prod_t \vartheta_t f \leq \frac{Z_P(n,(1-s)\beta)}{Z_P(n,\beta)} \leq e^{A_s(n,\beta)\mathfrak{m}}.$$

By part (2), the product of f over h distinct cells of one tiling has expectation at most $e^{A_s(n,\beta)h}$. Now let S be a deterministic set of plaquettes. We assign each $p \in S$, by a fixed rule, to a cell containing it in one of the eight shifted tilings. Let S_a be the plaquettes assigned to the tiling a, and let h_a be the number of cells of that tiling to which some

plaquette is assigned. Enlarging each assigned sum to all six plaquettes of the cell, we find $\mathbb{E}\exp(s\sum_{p\in S_a} Y_p) \le e^{A_s(n,\beta)h_a}$. By Hölder's inequality with eight exponents equal to eight, we have

$$\mathbb{E}e^{(s/8)\sum_{p\in S} Y_p} \le \prod_{a=1}^{8}\Big[\mathbb{E}e^{s\sum_{p\in S_a} Y_p}\Big]^{1/8} \le e^{A_s(n,\beta)\sum_a h_a/8} \le e^{A_s(n,\beta)|S|/8}.$$

In the last inequality we used $\sum_a h_a \le |S|$ and $A_s(n,\beta) \ge 0$.

For the bad cells, note the pointwise bound $\mathbf{1}_{D_Q(K)} \le \sum_{p\subset Q} e^{s(Y_p-K)}$. Multiplying over the $\mathfrak{m}$ cells of a tiling and expanding, we obtain $6^{\mathfrak{m}}$ terms, one for each choice of a plaquette in every cell. The chosen plaquettes are distinct, and the sum of their energies is at most the sum over all plaquettes. Therefore

$$\mu_n^\beta\Big(\bigcap_t D_{Q_t}(K)\Big) \le 6^{\mathfrak{m}} e^{-sK\mathfrak{m}}\,\frac{Z_P(n,(1-s)\beta)}{Z_P(n,\beta)} \le \big[6e^{A_s(n,\beta)-sK}\big]^{\mathfrak{m}}.$$

Applying part (2) to the indicator of $D_{Q_0}(K)$ in k distinct cells, we obtain the joint bound. A union bound over the n^3 cells of the eight tilings, together with the trivial bound by one, gives the bound for the maximum. All constants in these bounds are absolute.

If $\beta \le b_+ n$, then

$$\frac{\log\beta}{n} = \frac{\beta}{n}\cdot\frac{\log\beta}{\beta} \le \frac{b_+}{\mathrm{e}},$$

since $(\log x)/x$ attains its maximum at $x = \mathrm{e}$; this simplification uses the additional relation between β and n. Finally, for a nonnegative X and an event D with $\mu_n^\beta(D) \ge 1-\varepsilon_D > 0$,

$$\mathbb{E}[X \mid D] = \frac{\mathbb{E}[X\mathbf{1}_D]}{\mu_n^\beta(D)} \le (1-\varepsilon_D)^{-1}\mathbb{E}X.$$

This bound does not depend on the number of factors in X, and it does not use reflection positivity of the conditioned measure. This completes the proof of Theorem 6.6. □

SECTION 7

Periodic gauge fixing and energy estimates

In this section, we prove deterministic estimates for the block averaging map and for gauge fixing, and one probability bound. Together they show that configurations with small curvature at every scale lie in the domains where the renormalization group analysis applies. The two main estimates are the following. We write $\delta(U) = \max_p \rho_G(U_p)$ for the maximal curvature and $\mathscr{E}(U) = \sum_p q(U_p)$ for the Wilson energy of a configuration U. If $\delta(U)$ is small, then

$$\mathscr{E}(T_M U) \le M\big(1 + C_M \delta(U)\big)\mathscr{E}(U), \qquad \delta(T_M U) \le M^2 \delta(U) + c_M \delta(U)^2$$

(Theorem 7.3). Since the squared coupling grows by the factor M in each averaging step, the first inequality bounds the output Wilson action divided by the squared coupling by $1 + C_M\delta(U)$ times its input value. The product of these upper-bound factors is bounded under the squared-mesh curvature hypothesis of part (5) of that theorem. Second, on a periodic cubic lattice of side $n \ge 4$, every configuration with $\delta(U) \le \delta \le \delta_{\mathrm{SG}}$ has a periodic gauge transform U^k with

$$\max_e \rho_G(U^k_e) \le C_{\mathrm{SG}}\big(\sqrt{\delta} + n^{-1}\big)$$

(Theorem 7.7). In particular, $\delta(U) \le \delta_r$ and $n \ge 4C_{\mathrm{SG}}/r$ imply that U lies in the gauge-invariant small-field domain D_r, with δ_r defined in that theorem, and the plaquette moments of Theorem 6.6 bound the probability of the complement of D_r under the Wilson measure.

Section 7.1 gives sufficient conditions, small links or small plaquettes, under which the logarithms of a configuration relative to the coarse-field lift are the local constraint coordinates of Lemma 6.3 (Lemma 7.2), and Section 7.2 proves the energy estimate; these results are used in the classical analysis of Sections 8, 9, and 11 and in Sections 14, 22, and 23. Section 7.3 describes the dependence sets of iterated averages and the eight shifted tilings by which the chessboard estimates are applied to blocked plaquettes (Lemma 7.4). Section 7.4 constructs periodic gauges by gluing local axial gauges (Lemmas 7.5 and 7.6), and Section 7.5 proves the small-curvature gauge estimate and the probability bound; these results are used in the large-field analysis of Sections 18 and 21 to 23. The inputs are the block averaging map, its local constraint coordinates, and the chessboard estimates of Section 6, together with the metric, word, and conditioning estimates of Lemmas 5.1 and 5.5. No result on conditional constrained minimizers or on normalized fluctuation variables is used.

Conventions. The distance between group elements is $\operatorname{dist}(g,h) = \rho_G(gh^{-1})$. We work in lattice units until a physical mesh is displayed. A rectangular patch contains all its vertices, all links with both endpoints among those vertices, and all plaquettes with their four vertices among them; in particular its boundary links are included. A plaquette is counted once in every sum of energies, and a maximum over an empty set of plaquettes is zero. When an estimate concerns only the norm of a logarithm of a group element V, it refers to a shortest logarithm, whose norm is $\rho_G(V)$; every logarithm that is later used as an analytic coordinate lies in a fixed ball strictly inside the domain of the principal logarithm. Constants depend only on M and on such fixed radii, with additional dependencies stated explicitly; this is the dependence described in item (1) of Definition 4.14.

7.1 Local inverse coordinates for block averaging

We begin with the elementary discrete form of the non-Abelian Stokes theorem in a box: in an axial gauge, every link is a product of transported plaquette variables along strips of width one.

Lemma 7.1. *Let $Q = \prod_{i=1}^{3}\{0,\dots,b_i\}$ with integers $b_i \geq 0$, assign arbitrary values in $\mathrm{SU}(2)$ to its links, and put $b = b_1 + b_2 + b_3$. Let $q_Q(x)$ be the transport from the lower corner of Q to x along the path that changes the coordinates in the order $1,2,3$. After the gauge transformation q_Q, every link of Q is a product of at most b conjugates of plaquette variables of Q or their inverses. In particular, writing $d_p = \rho_G(U_p)$,*

$$\max_{e\subset Q} \rho_G\big(U_e^{q_Q}\big) \leq b \max_{p\subset Q} d_p, \qquad \Big(\sum_{e\subset Q} \rho_G\big(U_e^{q_Q}\big)^2\Big)^{1/2} \leq b\sqrt{3|Q|}\Big(\sum_{p\subset Q} d_p^2\Big)^{1/2}.$$

If the first bound is smaller than a fixed radius below 2π, these are bounds for the principal logarithms of the links. Every closed path of s links in Q has a transport that is a product of at most sb conjugated plaquette variables. These statements also hold in a periodic lattice for a box that lifts injectively to the covering lattice.

Proof. For two successive orthogonal positive steps we have the identity

$$U_i(x)U_k(x+e_i) = U_{p_{ik}(x)}U_k(x)U_i(x+e_k), \qquad i<k.$$

Changing an orientation replaces the plaquette factor by a conjugate of its inverse, and in a longer path the transport of the preceding subpath conjugates the plaquette factor. Each interchange of two adjacent orthogonal steps therefore introduces exactly one transported plaquette and leaves the other factors unchanged. Repeating it gives the corresponding identity for a strip of width one, including its boundary links.

The path from the corner to x first runs in direction 1, then 2, then 3. For a link in direction 3, the path to its endpoint is the path to its initial point followed by the link,

and its transformed value is I. For a link in direction 2, we move it backwards through the direction-3 part of the path, of length x_3. This uses the x_3 plaquettes of a 23 strip of width one, and the remaining path is the path to the endpoint, which cancels. For a link in direction 1, we move it first through the direction-3 part, using x_3 plaquettes of a 13 strip, and then through the direction-2 part in the lower plane, using x_2 plaquettes of a 12 strip. The direction-1 parts then cancel. These moves stay in the closed box and use at most b plaquettes. Reversing a link inverts its word. Using the bi-invariance of ρ_G, the triangle inequality $\rho_G(UV) \le \rho_G(U) + \rho_G(V)$ of Lemma 5.1, and invariance under inversion, we obtain the bound on the maximum.

Since each d_p is at most $(\sum_{p \subset Q} d_p^2)^{1/2}$, each transformed link is bounded by b times this quantity, and there are at most $3|Q|$ links. This gives the second bound. In a closed path the gauge factors cancel except for a conjugation at the starting vertex, and substituting the words just obtained for its links gives at most sb factors. In an injective periodic lift every interchange uses a lifted plaquette, and the same proof applies. If Q has no plaquettes, all words are empty. □

For a coarse link $c = (v, v + Me_i)$, its two blocks form a rectangular patch with $2M$ vertices in direction i and M vertices in the other directions. For a coarse ik plaquette, the four blocks at its corners form a rectangular patch with $2M$, $2M$, and M vertices in the directions i, k, and the third direction. Their diameters in the lattice path metric are at most $4M$ and $5M$. Since on a coarse lattice of side $m \ge 4$ every coordinate extent of these patches is smaller than the period Mm, each patch lifts injectively to a box of the covering lattice, also when it meets the periodic identifications. Every translated path with endpoint connectors, every reference path, and every strip used below lies in such a lift. Figure 7.1 shows these patches.

We now recall the setting of Lemma 6.3. Let h be the block axial gauge transformation, $h_x = U(\sigma_{v,x})$ for $x \in \mathsf{B}_M(v)$, so that $h_v = I$ at every block center and $U^h = I$ on the block trees. By gauge covariance, $b = T_M U^h = T_M U$. On the links not in the block trees we write

$$U_e^h = e^{X_e} U_{0,e}(b), \qquad z = X_{\text{free}}.$$

Lemma 6.3 provides radii r_M and $\widetilde{r}_M$ for the free and the eliminated coordinates, independent of the coarse configuration b, within which the constraint has the unique solution $X = \Gamma_b(z)$. The next lemma identifies the logarithms X of the given configuration with $\Gamma_b(z)$. The existence of a solution of the constraint near $U_0(b)$ would not suffice, since later sections integrate functions of the given configuration in these coordinates. We distinguish three normalizations: the relative logarithms X and their free part z, which are controlled here; the coupling-rescaled coordinates z/g; and the normalized fluctuation variables w of Lemma 12.3, defined by $z_i = z_i^* + g_i K_i^{-1/2} w_i$ after the conditional constrained minimizer has been subtracted, which do not appear in this section.

Lemma 7.2. *Fix an odd $M \geq 3$ and a fine side Mm with $m \geq 4$, and let T_M, the block trees, and Γ_b be as in Definition 6.1 and Lemma 6.3. There exist $u_M, \delta_M > 0$ and $C_M < \infty$, depending only on M and on fixed radii strictly inside the coordinate domain of Lemma 6.3 and the domain of the principal logarithm, with the following properties.*

1. *If $\max_e \rho_G(U_e) \leq u$ and $(5M-3)u < 2\pi$, then no based loop holonomy $U(F_{c,x})U(C_c)^{-1}$ in one application of T_M equals $-I$, and*

$$\max_c \rho_G\big((T_M U)_c\big) \leq (6M-3)u \leq 10Mu.$$

   In the block axial gauge, the logarithms relative to $U_0(b)$, $b = T_M U$, of the links not in the block trees satisfy $\max_e |X_e| \leq C_M u$, where shortest logarithms are meant. If moreover $u \leq u_M$, then all these logarithms, including those on the eliminated edges, are principal logarithms in the coordinate domain of Lemma 6.3, and $X = \Gamma_b(X_{\text{free}})$.
2. *Let $J \geq 1$ be fixed, and let the fine side be $M^J m_{\text{out}}$ with an integer $m_{\text{out}} \geq 4$. Suppose that $\max_e \rho_G(U_e) \leq u$ and $(10M)^J u \leq u_M$. Then the conclusions of (1) with $u \leq u_M$ hold for each of the J averaging steps, with u replaced by $(10M)^s u$ at the step from $T_M^s U$ to $T_M^{s+1} U$, and*

$$\max_e \rho_G\big((T_M^s U)_e\big) \leq (10M)^s u, \qquad 0 \leq s \leq J.$$

3. *Suppose only that $\max_p \rho_G(U_p) \leq \delta \leq \delta_M$; no bound on the links is assumed. Then all based loop holonomies in one application of T_M lie in a fixed ball strictly inside the domain of the principal logarithm, and in the block axial gauge*

$$\max_e |X_e| \leq C_M \delta, \qquad X = \Gamma_{T_M U}(X_{\text{free}}), \qquad \max_P \rho_G\big((T_M U)_P\big) \leq C_M \delta,$$

   where P runs over the coarse plaquettes. For every $g > 0$ the coupling-rescaled coordinate $\eta = z/g$ satisfies $\|\eta\|_\infty \leq C_M \delta / g$.
4. *Each statement is local: it holds for a given coarse link or plaquette if its hypothesis is imposed only on the patch formed by the two blocks of the link, or by the four blocks at the corners of the plaquette, with all their links and plaquettes. Links outside these patches and the holonomies around the noncontractible cycles of the torus do not affect the estimates.*

All constants are independent of m, of the physical scale, of the coupling, and of the number of preceding averaging steps.

Proof. Small links. Recall that $R_M = (M-1)/2$. Since each root path has at most $3R_M$ links, the path $F_{c,x}$ has at most $M + 6R_M = 4M - 3$ links and $F_{c,x} C_c^{-1}$ at most $5M - 3$. By the triangle inequality, a product of s links of distance at most u from I has distance at most su. If $(5M-3)u < 2\pi$, every based loop holonomy therefore differs from $-I$. With

$$A_c = M^{-3} \sum_{x \in \mathsf{B}_M(v)} \operatorname{Log}\big(U(F_{c,x})U(C_c)^{-1}\big), \qquad b_c = e^{A_c} U(C_c),$$

we have $|A_c| \le (5M-3)u$ and hence $\rho_G(b_c) \le (6M-3)u \le 10Mu$.

In the block axial gauge every transformed link not in a block tree is a product of at most $1 + 6R_M = 3M - 2$ links, and its distance from I is at most $(3M-2)u$. Since its value under the coarse-field lift is I or one of the b_c, every relative element $U_e^h U_{0,e}(b)^{-1}$ has distance at most $(9M-5)u$ from I. Taking shortest logarithms gives the first bound in (1) with any $C_M \ge 9M$.

Let $r_M, \widetilde{r}_M$ be the radii of Lemma 6.3 for the free and the eliminated coordinates. Fix smaller positive radii inside them and inside a fixed ball strictly within the domain of the principal logarithm, and choose $u_M > 0$ with

$$(5M-3)u_M < 2\pi, \qquad C_M u_M < \tfrac{1}{2}\min\{r_M, \widetilde{r}_M, 1\},$$

decreasing u_M further if the fixed ball requires it. For $u \le u_M$ all relative logarithms are unique principal logarithms. By gauge covariance, and since $h = I$ at the block centers, $T_M U^h = b$. Hence the vector X solves the constraint at the target b, and both its free and its eliminated entries lie in the uniqueness neighborhood of Lemma 6.3. Uniqueness implies $X = \Gamma_b(X_{\text{free}})$; this identifies every eliminated entry, not only the free ones. This proves (1).

Several averaging steps. Let the initial side be $M^J m_{\text{out}}$, and define

$$n_s = M^{J-s} m_{\text{out}} \quad (0 \le s \le J), \qquad n_s = M n_{s+1}, \quad n_{s+1} \ge m_{\text{out}} \ge 4 \quad (0 \le s < J). \tag{7.1}$$

At each step, the input side is a multiple of M and the output side is at least four, so the hypotheses of Definition 6.1 and Lemma 6.3 hold and every patch used above lifts injectively. Let $u_s = (10M)^s u$. The assumed bound $\max_e \rho_G(U_e) \le u$ gives the link bound for $s = 0$, and the hypothesis $(10M)^J u \le u_M$ implies $u_s \le u_M$, and hence $(5M-3)u_s < 2\pi$, for $0 \le s \le J$. We apply (1) to $T_M^s U$ on the lattice of side n_s, for $s = 0, 1, \dots, J-1$ in turn. This identifies the relative coordinates of each step with the solution Γ at its target and gives the link bound $10Mu_s = u_{s+1}$ for the next step. The constants are the same at every step, since they do not depend on n_s. This proves (2).

Small plaquettes. We now assume only a bound on the plaquettes, and let $K_M^{(0)} = 100M^2$. Every based loop holonomy is the transport around a closed path of at most $5M-3$ links in a patch of two blocks, whose side lengths sum to at most $4M$. By Lemma 7.1, it is a product of at most $20M^2 \le K_M^{(0)}$ conjugated plaquette variables, so

$$\rho_G\big(U(F_{c,x})U(C_c)^{-1}\big) \le K_M^{(0)}\delta, \qquad |A_c| \le K_M^{(0)}\delta. \tag{7.2}$$

Here and below, δ need only bound the plaquettes of the indicated patch. It is chosen so small that the first bound lies in a fixed ball strictly inside the domain of the principal logarithm.

Consider a link not in the block tree with both endpoints in one block. Its gauge-transformed value is the transport around the closed path formed by the link and two

root paths, of length at most $6R_M + 1$ in one block. The same argument bounds its distance from I by $K_M^{(0)}\delta$. For an interface link $e = (x, y)$ between the blocks of c, we write

$$W_e = U(\sigma_{v,x})\, U_e\, U(\sigma_{v+Me_i,y})^{-1} = U_e^h.$$

The closed path for $W_e U(C_c)^{-1}$ lies in the patch of the two blocks and has length at most $6R_M + 1 + M$. As before, we have $\rho_G(W_e U(C_c)^{-1}) \le K_M^{(0)}\delta$. Since $b_c = e^{A_c} U(C_c)$,

$$\rho_G\big(W_e b_c^{-1}\big) \le \rho_G\big(W_e U(C_c)^{-1}\big) + |A_c| \le 2K_M^{(0)}\delta. \tag{7.3}$$

This includes the eliminated edge. The coarse plaquette formed by the four reference paths has distance at most $M^2\delta$ from I, since its M by M square can be reduced by successive interchanges of steps that use each of its M^2 plaquettes once. Replacing its four reference transports by the values b_c changes this distance by at most $4K_M^{(0)}\delta$. Here we used that the bi-invariant metric satisfies $\operatorname{dist}(\prod_i a_i, \prod_i b_i) \le \sum_i \operatorname{dist}(a_i, b_i)$, as one sees by replacing one factor at a time, and that inverting both elements preserves each term. We obtain

$$\rho_G\big((T_M U)_P\big) \le \big(M^2 + 4K_M^{(0)}\big)\delta. \tag{7.4}$$

We increase C_M so that it dominates the three constants in (7.2), (7.3), and (7.4), and choose $\delta_M > 0$ with $C_M\delta_M < \min\{r_M, \widetilde{r}_M, 1\}/2$, also respecting the fixed logarithm radius. Then the relative vector lies in the uniqueness neighborhood of Lemma 6.3, and, as in the proof of (1), we obtain $X = \Gamma_{T_M U}(X_{\mathrm{free}})$. Its free part satisfies $\|z\|_\infty \le C_M\delta$, and dividing by $g > 0$ gives the bound for η. This proves (3).

Locality. All paths and all fillings used above lie in the patches of two or four blocks. A gauge transformation on such a patch can be extended arbitrarily to the other vertices of the torus, and by covariance of T_M no link outside the patch enters these computations; the block axial gauge uses only the paths in its own block. The local statements therefore do not constrain any holonomy around a noncontractible cycle. For a local statement on the inverse coordinates, the equality with Γ_b refers to the coordinates in question: we extend the local free data by zero to a free vector in the coordinate domain. Each eliminated coordinate is determined by its own constraint, which involves only its two blocks. By the locality and uniqueness statements of Lemma 6.3, the corresponding entry of Γ_b does not depend on the extension. The local eliminated value solves the same constraint in the same uniqueness neighborhood; by uniqueness, the two agree. This proves (4). All radii and constants were chosen from fixed finite patches and from the radii of Lemma 6.3; they depend only on M and the fixed radii. □

7.2 Energy estimates and physical curvature

The leading factor M in the energy estimate has a simple origin. At the linear level, the curvature of a coarse plaquette is an average over M^3 translates of the sum of the M^2

fine curvatures in an M by M square ((7.5) below). A coarse curvature is therefore about M^2 times a typical fine curvature, while the number of plaquettes decreases by the factor M^3. The sum of the squared curvatures, and with it the Wilson energy, is multiplied by $M^4/M^3 = M$. Since the squared coupling satisfies $g_{j+1}^2 = Mg_j^2$, this factor cancels in the action $4\mathscr{E}/g^2$. Part (3) bounds the nonlinear error by the maximal curvature times the local ℓ^2 norm of the curvature, which keeps the estimate uniform in the volume. The bound on the maximal curvature in part (1) and its iteration in parts (5) and (6) adapt the estimates of Bałaban for his averaging operation in [12, Section B, Propositions 1 and 2], which also use the four blocks at the corners of a coarse plaquette. We give the proofs for the paths and the metric used here. The estimate for the Wilson energy with leading factor M requires in addition the exact column sums of the linearized kernel and the local form of the remainder.

Theorem 7.3. *For each odd $M \geq 3$ there exist $\delta_*(M) > 0$ and $C_M, c_M < \infty$ with the following properties, for every $m \geq 4$ and every configuration U on the fine lattice of side Mm. Write $\delta(U) = \max_p \rho_G(U_p)$ and $\mathscr{E}(U) = \sum_p q(U_p)$.*

1. *If $\delta(U) \leq \delta_*$, then*

$$\mathscr{E}(T_M U) \leq M\big(1 + C_M\delta(U)\big)\mathscr{E}(U), \qquad \delta(T_M U) \leq M^2\delta(U) + c_M\delta(U)^2.$$

2. *The derivative of T_M at the identity acts on curvatures by the nonnegative kernel*

$$(\mathsf{L}_M f)_{ik}(v) = M^{-3} \sum_{r \in \{-R_M,\dots,R_M\}^3} \sum_{s,t=0}^{M-1} f_{ik}(v + r + se_i + te_k),$$

that is, $\mathrm{d}\, DT_M(I) = \mathsf{L}_M \mathrm{d}$ on one-cochains. Its row sums equal M^2 and its column sums equal M^{-1}, and $\|\mathsf{L}_M f\|_2^2 \leq M\|f\|_2^2$ for every array f indexed by plaquettes with values in a Euclidean space.

3. *For a set $\mathcal{A}$ of positive coarse plaquettes, let $\mathrm{Pa}(\mathcal{A})$ be the union, counted once, of the fine plaquettes in the patches of four blocks of the plaquettes in $\mathcal{A}$. If $\delta = \max_{p \in \mathrm{Pa}(\mathcal{A})} \rho_G(U_p) \leq \delta_*$, then*

$$\sum_{P \in \mathcal{A}} q\big((T_M U)_P\big) \leq M(1 + C_M\delta) \sum_{p \in \mathrm{Pa}(\mathcal{A})} q(U_p).$$

For each $P \in \mathcal{A}$ there is a rooted axial gauge on its patch $Q(P)$ of four blocks in which

$$\mathrm{Log}\big((T_M U)_P\big)^{(P)} = \sum_p \mathsf{L}_M(P,p)\,\mathrm{Log}(U_p)^{(P)} + e_P,$$

with

$$|e_P| \leq C_M\delta\Big(\sum_{p \subset Q(P)} \rho_G(U_p)^2\Big)^{1/2},$$

where the superscript (P) refers to this gauge; the gauges for different P need not agree. Each fine plaquette lies in at most 48 of the patches $Q(P)$, and the restriction of L_M to output plaquettes in $\mathcal{A}$ has row sums at most M^2 and column sums at most M^{-1}.

4. *Let $U^{j+1} = T_M U^j$, $0 \le j < d$, be configurations on lattices all of whose coarse sides are at least four, and let $g_j > 0$ satisfy $g_{j+1}^2 = M g_j^2$. If $\delta_j = \delta(U^j) \le \delta_*$ for $j < d$, then*

$$\frac{4\mathscr{E}(U^d)}{g_d^2} \le \prod_{j<d}(1 + C_M\delta_j)\,\frac{4\mathscr{E}(U^0)}{g_0^2} \le e^{C_M \sum_{j<d}\delta_j}\,\frac{4\mathscr{E}(U^0)}{g_0^2}.$$

5. *Measure lengths in units of the mesh of the coarsest lattice, so that U^j lives on a lattice of mesh $\epsilon_j = M^{j-d}$. Let*

$$0 < \varepsilon \le \varepsilon_M, \qquad \varepsilon_M \le \min\bigl\{\delta_*/2,\ M^2(M^2-1)/(4c_M)\bigr\}.$$

If $\delta(U^0) \le \varepsilon\epsilon_0^2$, then each of $U^0, \dots, U^{d-1}$ satisfies the hypothesis of Lemma 7.2(3), and

$$\delta(U^j) \le 2\varepsilon\epsilon_j^2 \quad (0 \le j \le d), \qquad \sum_{j<d}\delta(U^j) \le \frac{2\varepsilon}{M^2-1},$$

and

$$\frac{4\mathscr{E}(U^d)}{g_d^2} \le e^{2C_M\varepsilon/(M^2-1)}\,\frac{4\mathscr{E}(U^0)}{g_0^2}.$$

6. *Let U^0 be obtained by sampling a fixed smooth periodic connection, with $\delta(U^0) \le C_A a_0^2$, where a_j denotes the physical mesh of U^j and $a_* = a_d$, so that $a_j = a_*\epsilon_j$. If $\varepsilon = C_A a_*^2 \le \varepsilon_M$, the conclusions of (5) hold, and the free logarithmic coordinates z_j of U^j in Lemma 7.2(3) satisfy*

$$\|z_j/g_j\|_\infty \le C_{A,M}\,a_j^{3/2}/g_3, \qquad g_j = g_3\sqrt{a_j}, \qquad 0 \le j < d,$$

with $C_{A,M} = 2C_M C_A$.

All constants are independent of d, of the volume, of the physical side, and of the coupling, except for the constant C_A of the smooth connection. The iterated bound in (4) is uniform under a bound on the sum of the curvatures, not merely under a bound on each curvature separately.

In the proof, we first compute the derivative of T_M at the identity and the row and column sums of its kernel on curvatures. Then, in an axial gauge on the patch of each coarse plaquette, we compare $\operatorname{Log}((T_M U)_P)$ with its linearization by Taylor's formula. The remainder is quadratic in the logarithms of the links, and the axial gauge bounds these by the curvatures in the patch. Summing over P with the bounded overlap of the patches gives the energy estimate, and a single row gives the curvature recursion. The iteration in (4)–(6) is then elementary.

Proof. The linearized kernel. Let a be a real $\mathfrak{su}(2)$-valued one-cochain and let $U_e(t) = e^{ta_e}$. For a coarse vertex v define

$$r(v) = M^{-3} \sum_{x \in \mathsf{B}_M(v)} \sum_{e \in \sigma_{v,x}} a_e, \qquad k_i(v) = M^{-3} \sum_{r \in \{-R_M, \dots, R_M\}^3} \sum_{s=0}^{M-1} a_i(v + r + se_i),$$

where the sum along a path takes orientations into account. We differentiate the formula for T_M. The derivative of the reference transport cancels its negative occurrence in the logarithm of every based loop holonomy, and we find

$$(DT_M(I)a)_i(v) = r(v) + k_i(v) - r(v + Me_i).$$

Around a coarse plaquette the four terms involving r cancel. For each r, the four segment sums in k form the boundary of the translated M by M square, and summing the signed curls of its plaquettes cancels every interior link. With d the signed curl in the respective lattice units, this gives

$$\big(\mathrm{d}\, DT_M(I)a\big)_{ik}(v) = M^{-3} \sum_{r \in \{-R_M, \dots, R_M\}^3} \sum_{s,t=0}^{M-1} (\mathrm{d}a)_{ik}(v + r + se_i + te_k). \tag{7.5}$$

This proves the kernel identity in (2); repeated occurrences of a fine plaquette are added in its entry. Since each row has $M^3 M^2$ terms of weight M^{-3}, the row sums equal M^2. Fix a fine plaquette at x with orientation ik. For each $(s,t) \in \{0, \dots, M-1\}^2$ the vertex $x - se_i - te_k$ has exactly one representation $v + r$ with v a coarse vertex and $r \in \{-R_M, \dots, R_M\}^3$. This gives exactly M^2 contributions in the column, and its sum is M^{-1}; this count includes contributions across the periodic identifications. For an array f with values in a Euclidean space, by the weighted Cauchy–Schwarz inequality, we have

$$\sum_P \Big| \sum_p \mathsf{L}_M(P,p) f_p \Big|^2 \le M^2 \sum_{P,p} \mathsf{L}_M(P,p) |f_p|^2 = M \sum_p |f_p|^2. \tag{7.6}$$

Restricting to output plaquettes in $\mathcal{A}$ keeps the row sums equal to M^2 and decreases the column sums, so the restricted kernel satisfies the stated bounds and the same inequality.

The local Taylor estimate. Fix an output plaquette P. We use the rooted axial gauge of Lemma 7.1 on its patch $Q(P)$ of four blocks and set $A_e = \operatorname{Log}(U_e^{q_{Q(P)}})$. The patch has at most $12M^3$ links and at most $12M^3$ plaquettes, and the sum of its side lengths is at most $5M$. By Lemma 7.1, with constants depending only on M,

$$\|A\|_\infty \le C_M \delta, \qquad \|A\|_2 \le C_M \Big(\sum_{p \subset Q(P)} \rho_G(U_p)^2 \Big)^{1/2}. \tag{7.7}$$

The local gauge can be extended to the torus, and by Proposition 6.2(6) its values outside the patch do not affect $(T_M U)_P$. In this gauge, we consider the functions

$$\Phi_P(A) = \operatorname{Log}\big((T_M e^A)_P\big), \qquad f_p(A) = \operatorname{Log}\big((e^A)_p\big),$$

and

$$G_P(A) = \Phi_P(A) - \sum_p \mathsf{L}_M(P,p) f_p(A).$$

Let $\delta_* \le \delta_M$ be so small that all link, path, and plaquette transports in the patch stay in a fixed ball strictly inside the domain of the principal logarithm whenever $\|A\|_\infty \le C_M \delta_*$. Since the distance of a product from I is at most its length times $\|A\|_\infty$, this choice is made on a fixed finite patch and does not depend on the side of the torus. On a slightly larger fixed ball, the finite-word bounds of Lemma 5.1 bound the Hessian of G_P in the Euclidean operator norm by a constant H_M. Indeed, each averaged link is a composition of finitely many word maps, logarithms, an arithmetic mean, and an exponential, whose first two derivatives are bounded on these balls, and the chain rule applies. The value and the first derivative of G_P vanish at zero, the latter by (7.5). By Taylor's formula along the segment tA, we have

$$|G_P(A)| \le \int_0^1 (1-t) H_M \|A\|_2^2 \, dt \le \tfrac{1}{2} H_M \sqrt{12M^3}\, \|A\|_\infty \|A\|_2,$$

where we used $\|A\|_2 \le \sqrt{12M^3}\|A\|_\infty$. Inserting (7.7), we obtain the estimate for $e_P = G_P(A)$ in (3). Here $\operatorname{Log}(U_p)^{(P)} = f_p(A)$ is the logarithm of the plaquette transport in the gauge of this patch, at the usual base point of p. Its norm is $\rho_G(U_p)$, although its direction in $\mathfrak{su}(2)$ may depend on P. By covariance of T_M, the coarse plaquette is conjugated by the axial gauge at its starting vertex, and we also have $|\Phi_P(A)| = \rho_G((T_M U)_P)$.

Overlap. A fine vertex belongs to exactly one block, and a block center is a corner of twelve positive coarse plaquettes: three orientations and four choices of the corner. If a fine plaquette lies in $Q(P)$, its vertices lie in the four corner blocks of P, so one of the at most four block centers of its vertices is a corner of P. Hence there are at most $4 \cdot 12 = 48$ such P; this count may be redundant, and it holds on every periodic lattice considered. Combining this count with the error estimate in (3), we find

$$\sum_{P \in \mathcal{A}} |e_P|^2 \le C_M \delta^2 \sum_{p \in \operatorname{Pa}(\mathcal{A})} \rho_G(U_p)^2, \tag{7.8}$$

where the sum on the right is over the union, without multiplicity.

Energy and curvature bounds. Let $F^2 = \sum_{p \in \operatorname{Pa}(\mathcal{A})} \rho_G(U_p)^2$. Although the gauges differ from one P to another, the Cauchy–Schwarz inequality in each row uses only the norms $|f_p| = \rho_G(U_p)$, so (7.6) bounds the squared norm of the linear term by MF^2. By (7.8), the error term has norm at most $C_M \delta F$. By the triangle inequality in the finite-dimensional Euclidean space of outputs, we have

$$\sum_{P \in \mathcal{A}} \rho_G\big((T_M U)_P\big)^2 \le \big(\sqrt{M} + C_M \delta\big)^2 F^2 \le M(1 + C_M \delta) F^2, \tag{7.9}$$

after enlarging C_M, for $0 \le \delta \le \delta_* \le 1$. On a single row, the error estimate and the row sum give

$$\rho_G\big((T_M U)_P\big) \le M^2\delta + C_M\delta\sqrt{12M^3}\,\delta \le M^2\delta + c_M\delta^2, \tag{7.10}$$

with $c_M \ge 1$. The linear coefficient M^2 is exact.

To pass to the Wilson energy, recall from Lemma 5.1 that, for a fine plaquette with $\rho_G(U_p) \le \delta$ and for every coarse plaquette,

$$\frac{\rho_G(U_p)^2}{8}\Big(1 - \frac{\delta^2}{48}\Big) \le q(U_p), \qquad q\big((T_M U)_P\big) \le \frac{\rho_G((T_M U)_P)^2}{8}.$$

The energy of the output plaquettes in $\mathcal{A}$ is therefore at most $M(1 + C_M\delta)(1 - \delta^2/48)^{-1}$ times the energy of $\mathrm{Pa}(\mathcal{A})$. Decreasing $\delta_* \le 1$ and enlarging C_M, we absorb the last factor into $1 + C_M\delta$. This proves the restricted inequality in (3); with all output plaquettes it proves the energy inequality in (1), and (7.10) proves the curvature inequality in (1). All estimates used only the plaquettes in the patches.

Iteration. Dividing the one-step energy inequality by $g_{j+1}^2 = Mg_j^2$, multiplying by 4, and iterating, we obtain the product in (4); since $1 + x \le e^x$ for $x \ge 0$, the exponential bound follows. For $d = 0$ the product is empty and (4) is an equality.

For (5), let $y_j = \delta(U^j)/\epsilon_j^2$. As long as the preceding inputs satisfy $\delta(U^i) \le \delta_*$, (7.10) and $\epsilon_{j+1} = M\epsilon_j$ imply

$$y_{j+1} \le y_j + \frac{c_M}{M^2}\epsilon_j^2 y_j^2, \qquad \sum_{j=0}^{d-1} \epsilon_j^2 = \frac{1 - M^{-2d}}{M^2 - 1} \le \frac{1}{M^2 - 1}. \tag{7.11}$$

The initial value is at most ε. Suppose that $y_i \le 2\varepsilon$ for all $i \le j$. Summing the recurrence up to j bounds y_{j+1} by

$$\varepsilon + \frac{4c_M\varepsilon^2}{M^2(M^2 - 1)} \le 2\varepsilon,$$

by the choice of ε_M. Each preceding curvature is then at most $2\varepsilon\epsilon_i^2 \le 2\varepsilon \le \delta_* \le \delta_M$, which verifies the hypothesis needed for the next application of the recurrence and of Lemma 7.2(3). This induction reaches $j = d$. Summing $\delta(U^j) \le 2\varepsilon\epsilon_j^2$ over $j < d$, we find the bound on the sum of the curvatures, and inserting it into (4) gives the last bound in (5).

For (6), note that $a_0 = a_* M^{-d} = a_*\epsilon_0$, so the hypothesis $\delta(U^0) \le C_A a_0^2$ is the hypothesis of (5) with $\varepsilon = C_A a_*^2$. Part (5) then implies $\delta(U^j) \le 2C_A a_j^2$. Applying Lemma 7.2(3) to each U^j, $j < d$, we find

$$\|z_j/g_j\|_\infty \le \frac{C_M\delta(U^j)}{g_j} \le \frac{2C_M C_A}{g_3}a_j^{3/2}, \qquad 0 \le j < d,$$

where $g_j = g_3\sqrt{a_j}$, in agreement with $g_n^2 = \gamma/n = g_3^2 a_n$ from Definition 4.1. If $C_A = 0$, the curvature recursion gives $\delta(U^j) = 0$ at every step and Lemma 7.2(3) gives $z_j = 0$, and the formulas hold directly. Every constant in the proof came from fixed patches of blocks, from the radii of the logarithm and the inverse coordinates, or from the constant C_A. □

7.3 Dependence sets and reflected cell partitions

To apply the chessboard estimates of Theorem 6.6 to plaquettes of the blocked configurations $V^j = T_M^j U$, we need to know on which fine links such a plaquette depends. We also need a partition of the lattice into cells, invariant under reflections, such that each cell contains these dependence sets. The relevant sets are shown in Figure 7.1. Because the blocks are centered and nested, the iterated dependence set of a coarse plaquette stays inside the four blocks at its corners, at every scale. Since a single tiling by cells of two coarse sites in each direction does not contain every plaquette in a cell, we use eight tilings, shifted by the parities of the starting vertex.

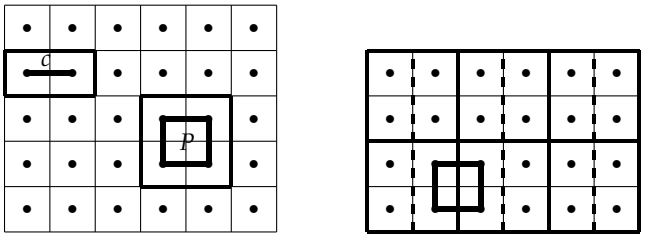

Figure 7.1. Left: the blocks of side m_j (thin squares) around the vertices of the level-j lattice, in a plane spanned by two coordinate directions. The patch of the coarse link c consists of its two blocks, and the patch of the coarse plaquette P consists of the four blocks at its corners (thick outlines). Right: cell boundaries of two of the eight shifted tilings, with shifts $(0,0)$ (solid) and $(1,0)$ (dashed) in the two directions shown; each cell is the union of the blocks of $2 \times 2 \times 2$ level-j vertices. The thick plaquette crosses a cell boundary of the first tiling, but lies in a cell of the second.

Lemma 7.4. *Fix an odd $M \geq 3$, integers $D \geq 0$ and $0 \leq j \leq D$, and the fine side $N = M^D n$ with $n \in 4\mathbb{N}$. Work in fine lattice units, put $m_j = M^j$ and $n_j = N/m_j$, and write $V^\ell = T_M^\ell U$.*

1. *For a plaquette P of the lattice at level j, define recursively $\mathcal{P}_j(P) = \{P\}$ and $\mathcal{P}_i(P) = \mathrm{Pa}(\mathcal{P}_{i+1}(P))$ for $i < j$, with* Pa *defined in Theorem 7.3(3); we call $\mathcal{P}_0(P)$ the energy-estimate predecessor set of P. Every fine plaquette in $\mathcal{P}_0(P)$ has its vertices in the union of the four blocks B_{m_j} at the corners of P. This union also contains all fine links on which V_P^j depends,*

including through the Borel extension of T_M, and all paths and plaquettes used in the patches of the intermediate steps. Further,

$$|\mathcal{P}_0(P)| \le C_M m_j^3, \qquad \operatorname{diam} \mathcal{P}_0(P) \le C_M m_j, \qquad \sup_p \#\{P : p \in \mathcal{P}_0(P)\} \le 48.$$

The same statements hold between any two intermediate levels, with the ratio of their meshes in place of m_j.

2. *For each shift $\eta \in \{0,1\}^3$, tile the vertices of the level-j lattice by the sets $\eta + 2t + \{0,1\}^3$, and define the cells of the fine lattice*

$$C_{j,t}^{\eta} = \bigcup_{\zeta \in \{0,1\}^3} \mathsf{B}_{m_j}\big(m_j(\eta + 2t + \zeta)\big).$$

These are disjoint cubes with $2m_j$ fine vertices in each direction, and there are $\mathfrak{m}_j = n_j^3/8$ of them in each tiling. If a level-j plaquette has all its vertices in the level-j vertices of a cell, then the plaquette and its energy-estimate predecessor set depend only on fine links with both endpoints in the cell. The reflections between adjacent cells are $x_i \mapsto (2\eta_i + 4t_i + 3)m_j - x_i$; their planes and the opposite planes bisect fine links, and these reflections map the blocks, the patches, and the sets $\mathcal{P}_\ell(P)$ at every level $\ell \le j$ onto the corresponding sets. Every level-j plaquette lies in a cell of at least one of the eight tilings.

3. *Let $j \ge 1$. For a cell C of one tiling $\mathcal{T}$, let $\mathcal{P}_{j-1}(C)$ be the union of the sets $\mathrm{Pa}(\{P\})$ of the six level-j plaquettes P in C. Then*

$$|\mathcal{P}_{j-1}(C)| \le 24M^3.$$

The sets obtained from $\mathcal{P}_{j-1}(C)$ by successive applications of Pa*, for distinct cells C of $\mathcal{T}$, are disjoint, and for individual level-j plaquettes the overlap bound 48 of (1) applies. For $0 \le \ell < j$ let*

$$\mathcal{F}_\ell(C) = \Big\{ p \in \mathcal{P}_{n_\ell} : \bigcup_{v \text{ a vertex of } p} \mathsf{B}_{m_\ell}(m_\ell v) \subset C \Big\},$$

where the vertices v are written in level-ℓ lattice units, and for $d_{\mathrm{cut}} > 0$ let

$$R_{<j}(C; d_{\mathrm{cut}}) = \bigcap_{\ell<j} \bigcap_{p \in \mathcal{F}_\ell(C)} \big\{ q(V_p^\ell) < d_{\mathrm{cut}} \big\}, \qquad R_{<j}^{\mathcal{T}}(d_{\mathrm{cut}}) = \bigcap_{C \in \mathcal{T}} R_{<j}(C; d_{\mathrm{cut}}).$$

These events impose the conditions on every $\mathcal{P}_\ell(P)$, $\ell < j$, for the six level-j plaquettes P in C. Further, put

$$\mathcal{P}_{j-1}^{\mathcal{T}} = \bigcup_{C \in \mathcal{T}} \mathcal{P}_{j-1}(C), \qquad Q_j^{\mathcal{T}} = \frac{4}{h_{n_{j-1}}} \sum_{p \in \mathcal{P}_{j-1}^{\mathcal{T}}} q(V_p^{j-1}),$$

where $h_n = g_n^2 = \gamma/n$.

4. *Put* $Q_{j,C} = (4/h_{n_{j-1}}) \sum_{p \in \mathcal{P}_{j-1}(C)} q(V_p^{j-1})$. *The following functions are nonnegative observables supported in the cell* C*, in the sense of Theorem 6.6(2), that is, bounded Borel functions of the fine links with both endpoints in* C *that are invariant under all periodic gauge transformations: the indicator of* $R_{<j}(C; d_{\mathrm{cut}})$*, the plaquette-energy sum* $Q_{j,C}$*, the functions* $\exp(\lambda Q_{j,C})$ *for* $\lambda \geq 0$*, and their products. Plaquettes crossing the boundaries of the cells of a tiling are not tested by the events of that tiling.*

All bounds are deterministic and do not depend on the coupling or on D*; the constant* C_M *depends only on* M*, not on any region of the lattice or on widths chosen later.*

Proof. Nesting. For odd $s \geq 1$ and $-R_M \leq \alpha \leq R_M$, the intervals of s consecutive integers centered at $v + s\alpha$ are disjoint and adjacent, with extreme endpoints $v - (Ms-1)/2$ and $v + (Ms-1)/2$. Taking products gives

$$\bigcup_{\alpha \in \{-R_M, \dots, R_M\}^3} \mathsf{B}_s(v + s\alpha) = \mathsf{B}_{Ms}(v). \tag{7.12}$$

This is the nesting identity of Proposition 6.2(6); it holds on the periodic lattice, since the blocks partition its vertices.

Containment. At a single step, a plaquette of $\mathrm{Pa}(\{P\})$ has its four vertices in the four corner blocks of P. Replacing each of these vertices by its own finer block keeps the union inside the same four larger blocks, by (7.12). By induction backwards from level j, we obtain the containment for $\mathcal{P}_0(P)$ and, in the same way, at every intermediate level. The same induction shows that the dependence sets are contained: at each step the dependence set of a link given by Proposition 6.2(6), its reference path, and the patch of four blocks used in Theorem 7.3 are included. The decision whether the Borel extension is used reads only the same based loop holonomies, and the value it assigns reads only the reference path. No continuity of T_M at such configurations is used.

Counting and overlap. The four corner blocks of side m_j contain $4m_j^3$ vertices and fit into a box with $2m_j$, $2m_j$, and m_j vertices in the three directions. Since at most three positive plaquettes start at each vertex, we have $|\mathcal{P}_0(P)| \leq 12m_j^3$, and the diameter in the lattice path metric is at most $5m_j$. Periodic identifications can only decrease these bounds. For the overlap, fix a fine plaquette p; each of its four vertices lies in one block of side m_j. If $p \in \mathcal{P}_0(P)$, all its vertices lie in corner blocks of P, so one of the at most four centers of these blocks is a corner of P. A center is a corner of twelve positive plaquettes, so there are at most $4 \cdot 12 = 48$ such P, also when some centers coincide. Starting the argument at an intermediate level replaces m_j by the ratio of the meshes and changes nothing else.

Cells and reflections. For the shift η, the coordinate interval of $C_{j,t}^{\eta}$ in direction i starts at $l_i = m_j(\eta_i + 2t_i) - (m_j - 1)/2$ and ends at $l_i + 2m_j - 1$; it contains $2m_j$ vertices, and the next interval starts at $l_i + 2m_j$. Since n_j is even, these intervals partition the coordinate circle, and their products give $(n_j/2)^3 = n_j^3/8$ disjoint cells. A level-j plaquette with all its vertices in a cell has its four corner blocks in the cell. By the containment just proved,

its energy-estimate predecessor set and all its dependencies are in the cell. Every link involved has both endpoints in the cell, including links in the boundary planes of the cell. The plane between the interval above and the next one is $x_i = l_i + 2m_j - 1/2$, and the reflection in it is $x_i \mapsto c_i - x_i$ with

$$c_i = 2l_i + 4m_j - 1 = (2\eta_i + 4t_i + 3)m_j.$$

Since m_j is odd, this number is odd, and the plane bisects fine links. The opposite plane has intercept larger by N, which is even, and it also bisects fine links. Since, for every level $\ell \le j$, the intercept divided by m_ℓ is still an odd integer, the reflection preserves the partition into blocks of side m_ℓ. By Proposition 6.2(4) it preserves the order of the coordinates in the root paths, and it maps a closed rectangular patch, with all its links and plaquettes, onto the reflected patch. Repeating this at every level proves the statement for all the sets $\mathcal{P}_\ell(P)$.

Coverage. Given a level-j *ik* plaquette with starting vertex v, we choose $\eta_i = v_i \bmod 2$ and $\eta_k = v_k \bmod 2$. Its two vertices in each of these directions then lie in one interval of the tiling. In the third direction either shift works, since the interval containing v contains the plaquette. Hence every plaquette lies in a cell of at least one of the eight tilings.

The sets of one cell. Let $j \ge 1$. Every plaquette of $\mathcal{P}_{j-1}(C)$ has its vertices among the $8M^3$ level-$(j-1)$ vertices whose blocks of side m_{j-1} form C, and there are at most $3 \cdot 8M^3 = 24M^3$ positive plaquettes with vertices there; the bound is for the union of the six patches, whose overlaps are not counted. Every backward expansion of this set stays in C, by (7.12). Since distinct cells have disjoint sets of vertices, the sets obtained from them by successive applications of Pa, and the links on which these depend, are disjoint. For individual target plaquettes the bound 48 of (1) still applies. When a plaquette occurs in one of the sets $\mathcal{P}_\ell(P)$, $\ell < j$, of a plaquette P in C, the union of the blocks of side m_ℓ of its four vertices lies in C, by the same nesting argument; this is the defining condition of $\mathcal{F}_\ell(C)$. The events $R_{<j}(C; d_{\mathrm{cut}})$ therefore impose the conditions on all these sets, and $Q_j^{\mathcal{T}}$ is the sum over the union of the sets $\mathcal{P}_{j-1}(C)$, each plaquette counted once, with the normalization $4/h_{n_{j-1}}$ of the Wilson action.

Observables. Each function $q(V_p^\ell)$ is Borel, since T_M is Borel (Proposition 6.2(2)), and gauge invariant, by gauge covariance of T_M and conjugation invariance of q. For $p \in \mathcal{F}_\ell(C)$ it depends only on links with both endpoints in C. The indicator of $R_{<j}(C; d_{\mathrm{cut}})$ is a finite product of Borel indicators of such events; it is Borel with values in $\{0, 1\}$. For $j \ge 1$, the sum $Q_{j,C}$ is a Borel gauge-invariant function of the links in C, and $0 \le q \le 2$ gives

$$0 \le Q_{j,C} \le \frac{8|\mathcal{P}_{j-1}(C)|}{h_{n_{j-1}}} \le \frac{8 \cdot 24M^3}{h_{n_{j-1}}}. \tag{7.13}$$

Hence, for every fixed $\lambda \ge 0$, $\exp(\lambda Q_{j,C})$ is bounded by the exponential of λ times this bound, and the indicator, the exponential, and their product are nonnegative bounded

Borel observables supported in C. The reflections between cells map each set of tested plaquettes onto the reflected set; they may reverse a plaquette or move its base point, and $q(HWH^{-1}) = q(W^{-1}) = q(W)$. Finally, the parity condition of Theorem 6.6 holds, since $n_j = M^{D-j}n \in 4\mathbb{N}$. The constants do not depend on the coupling, on D, or on any region or width. □

7.4 Lipschitz extensions and periodic gauge fixing

Regular lattice configurations and gauge fixing conditions are part of the renormalization group program of Bałaban for lattice gauge theories [14]. Here we need a particular quantitative statement: a configuration with small curvature on a periodic lattice has a periodic gauge transform with uniformly small links, with no restriction on its holonomies around the noncontractible cycles. The following example shows the form such a bound must take. Let $\theta \in \mathfrak{su}(2)$ with $0 < |\theta| < 2\pi$, and let U be the configuration on the lattice of side n with $U_e = e^{\theta/n}$ on the links in direction 1 and $U_e = I$ on all other links. Its curvature vanishes, and the transport around a cycle in direction 1 is e^{θ}. For every gauge transform U^k this transport is conjugate to e^{θ}. By the triangle inequality, some link satisfies $\rho_G(U_e^k) \geq |\theta|/n$. A bound of the form $C\sqrt{\delta}$ in terms of the maximal curvature δ alone is therefore impossible, and a term of order $1/n$ is needed. Spreading the holonomy evenly over the links of the cycle, as in the example, attains this order. At positive curvature δ the relevant length scale is $\delta^{-1/2}$. An axial gauge on a box of side R produces links of size about δR, while gluing such boxes requires gauge transformations varying by about $1/R$ per link; both are of order $\sqrt{\delta}$ when R is of order $\delta^{-1/2}$.

The construction glues local axial gauges on a partition of the torus into cells. In the gluing we extend group-valued maps successively over the edges, faces, and interiors of the cells. This is possible because $\mathrm{SU}(2) \simeq S^3$ has vanishing first and second homotopy groups, and Lemma 7.5 below gives Lipschitz bounds for the extensions. We prove the bounds on the extension, interpolation, and gluing directly, without an external extension theorem.

Lemma 7.5. *Use the bi-invariant metric of* $\mathrm{SU}(2) \simeq S^3$*, which is twice the round metric. There is an absolute constant C with the following properties.*

1. *Every map from the unit circle S^1 to* $\mathrm{SU}(2)$ *with Lipschitz constant B_0 extends to the unit disk with Lipschitz constant at most $C(1 + B_0)^2$, and every such map from the unit sphere S^2 extends to the unit ball of $\mathbb{R}^3$ with Lipschitz constant at most $C(1 + B_0)^5$; the extensions agree with the given maps on the boundary. For $A_0 \geq 1$ and a rectangle or a rectangular box with all side lengths between R/A_0 and A_0R, the corresponding boundary-preserving extensions of a map with Lipschitz constant B_0 on the boundary have Lipschitz constants at most*

$$C(A_0)R^{-1}(1 + B_0R)^2 \qquad \text{and} \qquad C(A_0)R^{-1}(1 + B_0R)^5.$$

2. *Fix the triangulation of every lattice cube into the six simplices determined by the orderings of the coordinates; it is consistent on common faces and invariant under translations, so it descends to periodic lattices, and it induces triangulations of the faces of lattice boxes. There is an absolute $c_0 > 0$ such that, if unit quaternions are prescribed at the vertices of a simplex with pairwise distances at most c_0, their normalized affine interpolation $\sum_i \lambda_i u_i / |\sum_i \lambda_i u_i|$ is defined, with denominator at least $1/2$. If vertex data on a lattice of mesh a satisfy $\operatorname{dist}(u_x, u_y) \le B_0 a$ for all nearest neighbors x, y, and $B_0 a \le c(A_0)$, then the interpolation has Lipschitz constant at most $C(A_0)B_0$, and the interpolations on two simplices agree on their common face.*
3. *For every $L > 0$, $\mathscr{K} \ge 0$, integer $n \ge 4$, and $a = L/n$, every periodic configuration on the lattice of side n and mesh a with $\max_p \rho_G(U_p) \le \mathscr{K} a^2$ admits a periodic gauge transformation k with*

$$\max_e \rho_G(U_e^k) \le \frac{Ca}{L}\bigl(1 + \mathscr{K} L^2\bigr)^{10}.$$

All holonomies around the cycles of the torus are allowed. If $a \le cL(1 + \mathscr{K} L^2)^{-2}$ for an absolute $c > 0$, the construction uses a partition of the torus into closed rectangular cells Q with side lengths between $L/8$ and $L/2$, each with a rooted axial gauge q_Q such that $\rho_G(U_e^{q_Q}) \le C\mathscr{K} La$ on every link of its closure, and the transition functions $t_{QR} = q_Q q_R^{-1}$ on common links (x, y) satisfy

$$t_{QR}(y) = \bigl(U_{xy}^{q_Q}\bigr)^{-1} t_{QR}(x)\, U_{xy}^{q_R}, \qquad \operatorname{dist}\bigl(t_{QR}(x), t_{QR}(y)\bigr) \le C\mathscr{K} La.$$

On coarser meshes the bound on $\max_e \rho_G(U_e^k)$ follows from the diameter of $\mathrm{SU}(2)$, after an absolute enlargement of C. When this bound is smaller than 2π, it bounds the principal logarithms of the links of U^k.

The constants in (1) and (2) depend only on A_0 and the triangulation, and the constant in (3) is absolute: it does not depend on n, L, $\mathscr{K}$, or the holonomies. No regularity of k as a function of U is claimed, and no estimate for differences of the link logarithms beyond the bound on each link is asserted.

We prove parts (1) and (2) first. Part (3) follows from the gluing estimate of Lemma 7.6 below.

Proof of Lemma 7.5(1) and (2). We identify $\mathrm{SU}(2)$ with the unit quaternions in $\mathbb{R}^4$. Its metric is twice the round metric of the unit sphere: the quaternion $\cos(t/2) + \omega \sin(t/2)$ is at distance $|t|$ from I for $0 \le |t| \le 2\pi$. Comparing arc and chord on a circle, we obtain, for $u, v \in S^3$,

$$2|u - v| \le \operatorname{dist}(u, v) \le \pi |u - v|. \tag{7.14}$$

All constants in the arguments on spheres below are absolute.

Covering. A unit sphere S^m, $m = 1, 2$, can be covered by at most $C_m r^{-m}$ balls of radius $r \le 1$. Indeed, consider a maximal set of points with mutual distances greater than r.

The balls of radius $r/2$ around them are disjoint, and each has volume at least $c_m r^m$, as one sees by integrating the polar density $(\sin t)^{m-1}$ and using $2t/\pi \le \sin t \le t$ for $0 \le t \le \pi/2$. A separated set is finite, since it has at most one point in each cube of a sufficiently fine subdivision of a cube containing the sphere, and maximality gives the cover. The same polar integration shows that a ball of radius 2ε in S^3 has volume at most $C\varepsilon^3$ for $\varepsilon \le c$.

Extension from a sphere. Let $f : S^m \to S^3$ have Lipschitz constant B_0. A cover of S^m by balls of radius $\varepsilon/(1+B_0)$ gives a cover of the image by at most $C((1+B_0)/\varepsilon)^m$ balls of radius ε, so the ε-neighborhood of the image has volume at most $C(1+B_0)^m \varepsilon^{3-m}$. Let

$$\varepsilon = c_m (1+B_0)^{-m/(3-m)}$$

with $c_m > 0$ so small that this volume is less than half the volume of S^3. Then some point p has distance at least ε from the image, and after a rotation we may take it to be the north pole. The stereographic projection from p is $\pi_p(u) = u_\perp/(1-u\cdot p)$, where $u_\perp$ is the component of u orthogonal to p. For points at round distance at least $\varepsilon/2$ from p it satisfies

$$|\pi_p(u)| \le C\varepsilon^{-1}, \qquad |\pi_p(u) - \pi_p(v)| = \frac{|u-v|}{\sqrt{(1-u\cdot p)(1-v\cdot p)}} \le C\varepsilon^{-2}|u-v|. \quad (7.15)$$

The equality follows by squaring both sides and using $|u| = |v| = 1$, and the inequalities follow from $1 - \cos t = 2\sin^2(t/2) \ge ct^2$ for $0 \le t \le \pi$; the factor two between the group metric and the round metric only changes constants. We conclude that $\psi = \pi_p \circ f$ has supremum at most $C\varepsilon^{-1}$ and Lipschitz constant at most $C\varepsilon^{-2}B_0$. On the source sphere the arc distance is at most $\pi/2$ times the chord distance, so this is also a Lipschitz bound with respect to the Euclidean metric, after an absolute change of the constant.

We extend ψ to the unit ball by $\Psi(r\omega) = r\psi(\omega)$, with $\Psi(0) = 0$. For $r \ge s$,

$$|r\psi(\omega) - s\psi(\eta)| \le (r-s)\|\psi\|_\infty + s\,\mathrm{Lip}(\psi)|\omega - \eta|,$$

and $r - s \le |r\omega - s\eta|$, $s|\omega - \eta| \le 2|r\omega - s\eta|$, so the Lipschitz constant of Ψ is at most $\|\psi\|_\infty + 2\,\mathrm{Lip}(\psi)$. The inverse stereographic projection is

$$\pi_p^{-1}(z) = \frac{(2z, |z|^2 - 1)}{1 + |z|^2}.$$

Its differential has Euclidean norm at most 2. Following the image of a line segment and using its round length, and doubling for the group metric, we find that π_p^{-1} has Lipschitz constant at most 4. Hence $\pi_p^{-1} \circ \Psi$ extends the given boundary map and has Lipschitz constant at most

$$C\big(\varepsilon^{-1} + B_0\varepsilon^{-2}\big) \le \begin{cases} C(1+B_0)^2, & m = 1, \\ C(1+B_0)^5, & m = 2. \end{cases}$$

This proves the extension bounds for spheres, including the case $B_0 = 0$.

Rectangles and boxes. In dimension $k = 2, 3$, the radial map $r\omega \mapsto r\omega/\|\omega\|_\infty$ takes the Euclidean unit ball onto $[-1,1]^k$ and the unit sphere onto its boundary. On the sphere, $1/\sqrt{k} \le \|\omega\|_\infty \le 1$ and $|\|\omega\|_\infty - \|\eta\|_\infty| \le |\omega - \eta|$, so the map is Lipschitz on the sphere, and so is its inverse, which has radial factor $\|\omega\|_\infty$ on each ray. The radial estimate used for Ψ shows that both maps are Lipschitz on the balls as well. A diagonal affine map onto a box with side lengths between R/A_0 and $A_0 R$ changes Lipschitz constants by factors at most $C(A_0)R$ and $C(A_0)/R$. Composing the extensions for spheres with these maps gives the bounds for rectangles and boxes. The same comparison bounds the intrinsic distance on the boundary of a box by $C(A_0)$ times the ambient distance: on a sphere, a shortest arc is at most $\pi/2$ times its chord, and the boundary maps just discussed transfer this inequality. This proves (1).

Interpolation. Let $c_0 > 0$ be so small that pairwise distances at most c_0 between the vertex values of a simplex imply $u_0 \cdot u_i \ge 3/4$; this follows from $u_0 \cdot u_i = 1 - |u_0 - u_i|^2/2$ and (7.14). For barycentric coordinates λ_i,

$$\Big|\sum_i \lambda_i u_i\Big| \ge u_0 \cdot \sum_i \lambda_i u_i \ge \frac{3}{4} \ge \frac{1}{2},$$

so the normalization is defined. The derivative of $z \mapsto z/|z|$ has operator norm at most 2 on $\{|z| \ge 1/2\}$. On a simplex of the triangulation, the affine interpolation has derivative at most $C(A_0)a^{-1}\max_{i,l}|u_i - u_l|$, as one sees by writing it in barycentric coordinates, whose gradients are bounded by $C(A_0)/a$ on the finitely many simplex shapes. Two vertices of a simplex are joined by at most three lattice links, so the maximum is at most CB_0a, and the derivative of the normalized interpolation, hence its Lipschitz constant for the group metric, is at most $C(A_0)B_0$. The condition $B_0 a \le c(A_0)$ ensures the smallness condition on the simplices. Since the restriction of the barycentric formula to a common face uses only the values at the common vertices, the interpolations agree there. This proves (2). □

Lemma 7.6. *Let $A_0 \ge 1$. There exist $c(A_0) > 0$ and $C(A_0) < \infty$ with the following property. Consider a periodic cubic lattice of mesh a and a face-to-face decomposition of the torus into closed coordinate boxes: each lifted cell has the form $\prod_{i=1}^3 [am_i, an_i]$, with integers $m_i < n_i$. Assume that every side length lies between R/A_0 and $A_0 R$ and that each cell lifts injectively to the covering lattice. Here face-to-face means that the intersection of two distinct cells is empty or a whole face, edge, or vertex of both cells. Suppose that each cell Q has a gauge transformation q_Q, defined on its vertices, such that*

$$\rho_G\big(U_{xy}^{q_Q}\big) \le B_0 a \qquad \text{for every link } (x,y) \text{ of the closure of } Q. \tag{7.16}$$

No bound on the gauge transformations q_Q themselves is assumed. Then there is a periodic gauge transformation k with

$$a \le c(A_0) R (1 + B_0 R)^{-2} \quad \Longrightarrow \quad \max_e \rho_G(U_e^k) \le \frac{C(A_0)\, a}{R} (1 + B_0 R)^{10}. \tag{7.17}$$

The constants do not depend on the number of cells.

Proof. On a link (x, y) common to two cells Q and R', let $t_{QR'} = q_Q q_{R'}^{-1}$. Direct multiplication gives

$$t_{QR'}(y) = \big(U_{xy}^{q_Q}\big)^{-1} t_{QR'}(x)\, U_{xy}^{q_{R'}}, \qquad \operatorname{dist}\big(t_{QR'}(x), t_{QR'}(y)\big) \le 2B_0 a. \tag{7.18}$$

This applies also to cells that meet only along an edge. We assign a single gauge transformation k at all vertices. Its coordinates in the frame of Q are $s_Q = k q_Q^{-1}$, so that $s_{R'} = s_Q t_{QR'}$. By bi-invariance, multiplying two group-valued maps adds their Lipschitz bounds, so passing from one incident frame to another increases the bound on neighbor distances by at most $2B_0 a$.

Vertices and edges of the cells. We set $k = I$ at every corner of a cell, once on the periodic lattice. For each edge of the cell partition, we choose one incident cell Q and join the two prescribed values of s_Q at its endpoints by a minimizing geodesic of $\mathrm{SU}(2)$, parametrized proportionally to arc length over the edge. Such a geodesic is an arc of a great circle in S^3; if its endpoints are antipodal, any great circle through them may be used. Since the diameter of $\mathrm{SU}(2)$ is 2π and the edge has length at least R/A_0, the speed is at most $C(A_0)/R$. At the lattice vertices of the edge, we set $k = s_Q q_Q$. These assignments reproduce the given values at the corners. In every incident frame the resulting vertex data satisfy $\operatorname{dist}(s(x), s(y)) \le B_1 a$ for neighbors on the edge, with

$$B_1 \le C(A_0)/R + 2B_0.$$

Faces of the cells. For each face of the cell partition, we choose one incident cell, express the values already assigned on the boundary of the face in its frame, and interpolate them along the lattice links of the boundary by Lemma 7.5(2). Provided $aB_1 \le c(A_0)$, this is a continuous loop with Lipschitz constant at most $C(A_0)B_1$. The comparison of intrinsic and ambient distances in the proof of Lemma 7.5(1) gives this bound also between points on different sides of the face. The extension over the disk, rescaled to the face, gives an extension with Lipschitz constant

$$B_2 \le \frac{C(A_0)}{R} (1 + B_1 R)^2.$$

We use it to assign $k = s_Q q_Q$ at the remaining lattice vertices of the face. Every vertex value assigned before is kept. Each face is treated once, including faces that meet the

periodic identifications. The vertices of an edge shared by several faces were assigned before and have a single value throughout.

Interiors of the cells. Consider a cell Q. On a face that was treated in the frame of a cell Q_F, the boundary values in the frame of Q are $s_Q = s_{Q_F} t_{Q_F Q}$, so by (7.18) neighboring values satisfy $\operatorname{dist}(s_Q(x), s_Q(y)) \le B_\partial a$ with

$$B_\partial \le B_2 + 2B_0 \le \frac{C(A_0)}{R}(1 + B_0 R)^2.$$

We interpolate the vertex values on the boundary of Q by the triangulation of Lemma 7.5(2). If $aB_\partial \le c(A_0)$, this is a continuous map on the boundary sphere with Lipschitz constant at most $C(A_0)B_\partial$. It is single valued at every edge and vertex, since the gauge transformation was assigned there only once. The extension over the ball gives an extension in the frame of Q with Lipschitz constant

$$B_3 \le \frac{C(A_0)}{R}(1 + B_\partial R)^5 \le \frac{C(A_0)}{R}(1 + B_0 R)^{10}.$$

At each interior vertex of Q, we assign $k = s_Q q_Q$ from this extension. Interior vertices belong to only one cell, and the boundary values are those assigned before. The result is a gauge transformation on the whole periodic lattice.

Links. Each lattice link lies in a closed cell, and the extension constructed for that cell represents both endpoint values, also when one or both endpoints lie on the boundary of the cell. Therefore

$$\rho_G\big(k_x U_{xy} k_y^{-1}\big) = \rho_G\big(s_Q(x) U_{xy}^{q_Q} s_Q(y)^{-1}\big) \le (B_0 + B_3)a.$$

Both smallness conditions $aB_1 \le c(A_0)$ and $aB_\partial \le c(A_0)$ follow from $a \le c(A_0)R(1 + B_0R)^{-2}$ after decreasing $c(A_0)$, and $(B_0 + B_3)a$ is at most the right side of (7.17). The constants do not depend on the number of cells: each change of frame compares two incident frames by a single transition (7.18), and no chain of comparisons through other cells is taken. Continuous extensions in different frames were required to agree only at the lattice vertices assigned earlier, and every later extension kept these values. This suffices for the bound on every link. □

Proof of Lemma 7.5(3). Suppose first that $n \ge 8$. We divide each coordinate circle at the vertices with indices 0, $\lfloor n/4 \rfloor$, $\lfloor n/2 \rfloor$, $\lfloor 3n/4 \rfloor$, and n; each interval has physical length between $L/8$ and $L/2$. The resulting 4^3 closed cells form a product, hence face-to-face, decomposition of the torus; they have bounded aspect ratios and lift injectively to the covering lattice, also when they meet the periodic identifications. On each cell, we use the rooted axial gauge of Lemma 7.1. Each link not in its axial tree is a product of at most CL/a conjugated plaquette variables along strips of width one, each at distance at most $\mathscr{K} a^2$ from I. Then (7.16) holds with $B_0 = C\mathscr{K} L$ and $R = L$. These gauges are rooted and

give the stated bound on every link of the closure of a cell; their transitions satisfy (7.18), which gives the stated transition bounds.

With the fixed aspect bound, the condition in (7.17) follows from $a \le cL(1+\mathscr{K}L^2)^{-2}$ after decreasing the absolute constant c; taking $c \le 1/8$ also guarantees $n \ge 8$. The conclusion of (7.17) is the asserted bound. If the condition on the mesh fails, we take $k = I$. Then $\rho_G(U_e) \le 2\pi$, while

$$\frac{a}{L}\big(1+\mathscr{K}L^2\big)^{10} > c\big(1+\mathscr{K}L^2\big)^{8} \ge c,$$

so an absolute enlargement $C \ge 2\pi/c$ gives the same bound on all such meshes, including $4 \le n < 8$. If the bound is smaller than 2π, the links of U^k differ from $-I$, and their principal logarithms have the same norms.

All assignments were made on the periodic lattice, not by identifying the values of independently chosen gauges afterwards, so arbitrary holonomies remain in the local gauges and in the assigned values throughout. □

7.5 Small-curvature gauge fixing and probability bounds

We apply the gluing lemma at cell size $R \approx \delta^{-1/2}$, and then estimate the probability of D_r^c using Theorem 6.6. Recall from Definition 4.4 the small-link domain and the gauge-invariant small-field domain; for $0 < r < 2\pi$ they are

$$B_r = \big\{V : \max_e \rho_G(V_e) < r\big\}, \qquad D_r = \big\{U : U^k \in B_r \text{ for some } k\big\},$$

where k runs over the periodic gauge transformations. The deterministic part of the following theorem, parts (1) and (2), is used at every scale in Sections 22 and 23; the probability bound in parts (3) and (4) concerns only the restriction of the Wilson measure on the finest lattice.

Theorem 7.7. *There exist absolute constants $C_{\mathrm{SG}} \ge 1$ and $\delta_{\mathrm{SG}} > 0$ with the following properties.*

1. *For every periodic cubic lattice of side $n \ge 4$, every $0 \le \delta \le \delta_{\mathrm{SG}}$, and every configuration U with $\max_p \rho_G(U_p) \le \delta$, there exists a periodic gauge transformation k with*

$$\max_e \rho_G(U_e^k) \le C_{\mathrm{SG}}\big(\sqrt{\delta} + n^{-1}\big).$$

   This includes $\delta = 0$ and arbitrary holonomies around the cycles of the torus.

2. *Fix $0 < r < 2\pi$ and set*

$$\delta_r = \min\big\{\delta_{\mathrm{SG}},\, (r/(4C_{\mathrm{SG}}))^2\big\}, \qquad d_r = \frac{\delta_r^2}{2\pi^2} = \min\Big\{\frac{\delta_{\mathrm{SG}}^2}{2\pi^2},\, \frac{r^4}{512\pi^2 C_{\mathrm{SG}}^4}\Big\}.$$

If $n \geq 4C_{SG}/r$, then

$$\{\max_p \rho_G(U_p) \leq \delta_r\} \subset D_r, \qquad \{\max_p q(U_p) \leq d_r\} \subset D_r.$$

Some lower bound on the side is necessary: for $n < 2\pi/r$, the flat configurations of the example at the beginning of Section 7.4 with $rn \leq |\theta| < 2\pi$ do not lie in D_r. The set D_r is open and gauge invariant, so these inclusions do not require a measurable choice of the gauge transformation.

3. *Let $n \in 4\mathbb{N}$ with $n \geq 4C_{SG}/r$, and let $\gamma > 0$ be such that $\beta_n = 4n/\gamma \geq 2$. Then the Wilson measure satisfies $\mu_{n,\gamma}(D_r^c) \leq \varepsilon_{n,r,\gamma}$, where*

$$\varepsilon_{n,r,\gamma} = \min\Big\{1,\ 3n^3 \exp\Big[\frac{1}{8}\Big(C_0 + 24\log 2 + \frac{36\log\beta_n}{n}\Big) - \frac{\beta_n \delta_r^2}{32\pi^2}\Big]\Big\}$$

and C_0 is the absolute constant of Theorem 6.6(3). The surface term $36\log\beta_n/n$ is kept for every (n,γ); no relation between n and γ is assumed.

4. *Under the assumptions of (3), $\mu_{n,\gamma}(D_r) > 0$, the conditioned measure $\mu_{n,\gamma}(\,\cdot \mid D_r)$ has total variation distance exactly $\mu_{n,\gamma}(D_r^c)$ from $\mu_{n,\gamma}$, and the partition function Z_{D_r} restricted to D_r satisfies*

$$\frac{Z_{D_r}}{Z} = \mu_{n,\gamma}(D_r), \qquad \Big|\log\frac{Z_{D_r}}{Z}\Big| \leq 2\varepsilon_{n,r,\gamma} \quad \text{if } \varepsilon_{n,r,\gamma} \leq 1/2.$$

The constants C_{SG} and δ_{SG} do not depend on L, γ, n, the number of averaging steps, or any widths of regions. The probability bound concerns the restriction to D_r of the Wilson measure on the full periodic lattice; it is not a conditional bound at a later scale.

Proof. Part (1). We use lattice spacing one. For $\delta = 0$, by Lemma 7.5(3) with $a = 1$, $L = n$, and $\mathscr{K} = 0$, we have $\max_e \rho_G(U_e^k) \leq C/n$ for every $n \geq 4$, including arbitrary flat holonomies. For $0 < \delta \leq 1$, let $R = \lceil \delta^{-1/2} \rceil$. Then

$$1 \leq \delta R^2 \leq 4. \tag{7.19}$$

If $n < 8R$, the same lemma with $\mathscr{K} = \delta$ gives

$$\max_e \rho_G(U_e^k) \leq \frac{C}{n}\big(1 + \delta n^2\big)^{10} \leq \frac{C'}{n},$$

with C' absolute, since $\delta n^2 < 64\delta R^2 \leq 256$.

Suppose now that $n \geq 8R$, and let $b = \lfloor n/R \rfloor \geq 8$. We divide each coordinate circle at the vertices $\lfloor in/b \rfloor$, $0 \leq i \leq b$. Since $R \leq n/b < R(1 + 1/b)$, the intervals have lengths between $R/2$ and $2R$ when $R \geq 2$. The closed cells form a product, hence face-to-face, decomposition; they have bounded aspect ratios, and they lift injectively since $2R \leq n/4$. By Lemma 7.1, the rooted axial gauges on these cells satisfy

$$\max_{e \subset Q} \rho_G\big(U_e^{q_Q}\big) \leq C\delta R.$$

Indeed, a link in direction 1 not in the axial tree is moved through one strip of width one in direction 3 and one in direction 2, of total length at most $4R$, and the counts for the other directions are smaller. Then Lemma 7.6 applies with mesh one, cell size R, and $B_0 = C\delta R$, and (7.19) implies $B_0 R \le 4C$. Fix an absolute $R_0 \ge 2$ so large that

$$1 \le c(A_0) R_0 (1 + 4C)^{-2}$$

for these fixed aspect bounds, and let $0 < \delta_{\mathrm{SG}} \le \min\{1, R_0^{-2}\}$. Then $R \ge R_0$, and the condition on the mesh in (7.17) holds. Its conclusion is

$$\max_e \rho_G(U_e^k) \le \frac{C}{R}(1 + B_0 R)^{10} \le \frac{C''}{R} \le C''\sqrt{\delta}.$$

As in the gluing lemma, these constants do not depend on the number b^3 of cells. Taking $C_{\mathrm{SG}} \ge \max\{1, C, C', C''\}$, we obtain (1) in all cases, with absolute constants and no condition on the holonomies.

Part (2). For δ_r and n as stated, the gauge transformation of part (1) satisfies

$$\max_e \rho_G(U_e^k) \le C_{\mathrm{SG}}\sqrt{\delta_r} + C_{\mathrm{SG}}/n \le r/4 + r/4 = r/2 < r < 2\pi.$$

These links have unique principal logarithms and lie in B_r, which proves the first inclusion, with a margin even at the closed threshold. By Lemma 5.1, $\rho_G(U_p)^2 \le 2\pi^2 q(U_p)$, so the event $\{\max_p q(U_p) \le d_r\}$ with $d_r = \delta_r^2/(2\pi^2)$ is contained in the first event. Squaring the two values in the minimum defining δ_r gives the formula for d_r. For fixed k the action of k is a homeomorphism of the configuration space, so D_r, a union of translates of the open set B_r, is open, and it is gauge invariant because gauge transformations compose. In particular, the existence of the constructed gauge transformation gives membership in a Borel set without a measurable choice. The example at the beginning of Section 7.4 shows that the term n^{-1} and the corresponding condition on the side are needed, also at zero curvature.

Part (3). Let $n \in 4\mathbb{N}$ and $\beta_n = 4n/\gamma \ge 2$, with $n \ge 4C_{\mathrm{SG}}/r$ as in part (2). In the notation of Definition 4.1 the exponent of the Wilson measure is $-\beta_n \sum_p q(U_p)$, so $\mu_{n,\gamma} = \mu_n^{\beta_n}$ in the notation of Theorem 6.6. We apply Theorem 6.6(3) with $\ell = 0$, the face set $S = \{p\}$, and $s = 1/2$; its hypotheses $n \in 4\mathbb{N}$ and $\beta_n \ge 2$ hold. The function $\exp(\beta_n q(U_p)/16)$ is gauge invariant, Borel, and between 1 and $e^{\beta_n/8}$, and p lies in a cell of one of the eight shifted tilings, by Lemma 7.4 with $j = 0$. We obtain

$$\mathbb{E}_{\mu_{n,\gamma}} \exp\big(\beta_n q(U_p)/16\big) \le \exp\Big[\frac{1}{8}\Big(C_0 + 24\log 2 + \frac{36\log\beta_n}{n}\Big)\Big].$$

Since $\{\rho_G(U_p) > \delta_r\} \subset \{q(U_p) > \delta_r^2/(2\pi^2)\}$, by Markov's inequality, we have

$$\mu_{n,\gamma}\{\rho_G(U_p) > \delta_r\} \le \exp\Big[\frac{1}{8}\Big(C_0 + 24\log 2 + \frac{36\log\beta_n}{n}\Big) - \frac{\beta_n \delta_r^2}{32\pi^2}\Big].$$

There are $3n^3$ positive plaquettes, and by part (2) the complement of D_r is contained in the union of these events. The union bound and the trivial bound by one give $\varepsilon_{n,r,\gamma}$. The calculation keeps the surface term for every n and γ and uses no bound on β_n/n.

Part (4). By Lemma 5.1, the open set B_r contains a product of balls of positive Haar measure. Since the density of the Wilson measure is strictly positive, we have $\mu_{n,\gamma}(D_r) > 0$. The identity for the total variation distance (in the convention $\|\mu - \nu\|_{\mathrm{TV}} = \sup_A |\mu(A) - \nu(A)|$), the identity $Z_{D_r}/Z = \mu_{n,\gamma}(D_r)$, and the bound $|\log(Z_{D_r}/Z)| \leq 2\mu_{n,\gamma}(D_r^c)$ when $\mu_{n,\gamma}(D_r^c) \leq 1/2$ are the conditioning identities of Lemma 5.5, applied with $S = D_r$. Since $\mu_{n,\gamma}(D_r^c) \leq \varepsilon_{n,r,\gamma}$, the last bound gives the stated one. The deterministic constants came only from the axial strips, the extension bounds, and the aspect bounds, and the probability constant is the absolute constant C_0. □

SECTION 8

Linearized averaging and effective quadratic forms

This section proves deterministic estimates for the block averaging map T_M of Definition 4.3. We compute the derivative of T_M^d at the identity, the transverse Gaussian covariance that it induces from an auxiliary Maxwell field, and the effective Maxwell quadratic form (Theorem 8.3). We also bound small translation-invariant kernels that annihilate gradients and commute with spatial inversion by the lattice Maxwell form (Lemma 8.6). We then construct the gauge-corrected iteration near a background with small curvature and prove locality and absolute derivative bounds at each fixed order, including volume-normalized column sums, uniformly in the number of averaging steps (Lemmas 8.10 and 8.11). The Gaussian fields in this section are auxiliary, and no statement concerns the Wilson measure. The estimates are used to construct the background fields in Part III.

We distinguish two statements with different proofs. The first is linear and exact: the derivative of T_M^d at the identity is the average K_{M^d} along straight segments of length M^d plus a lattice gradient,

$$D(T_M^d)(I) = K_{M^d} + \nabla \mathsf{R}_d$$

(Lemma 8.1). The second is nonlinear. Near a background configuration U_0 whose plaquettes are close to the identity, we multiply the output of each averaging step by gauge transformations at the two endpoints of each coarse link. In logarithmic coordinates divided by the lattice spacing, the resulting gauge-corrected step is a transported segment average plus errors that are summable over scales. The gauge-corrected iteration coincides with the iterated block averaging map after an explicit composed gauge transformation (Lemma 8.10). The gradient in the first statement and the gauge transformations in the second play analogous roles, but neither statement implies the other.

The inputs are the Hodge decomposition and Schur complement identities of Lemma 5.2, the weighted product and inverse estimates of Lemma 5.3, the coercivity of the curl on the constrained fluctuation space in Lemma 6.5, and the curvature iteration of Theorem 7.3. The lattice, the norms, and the conventions for constants are those of Definitions 4.1, 4.6, and 4.14. The results are used in Section 9 to construct coordinates on the constraint fibers (Theorems 9.3, 9.6, and 9.9), in Theorem 10.10 to identify the Hessian of the effective classical action, in Lemma 11.11 to factor perturbations of that Hessian, and in Section 31 for the normalization of the heat-smoothed circulations (Theorem 31.6).

The linear theory is part of Bałaban's analysis of Gaussian block integration for lattice gauge fields. The averages with and without endpoint paths, their action on gradients, their composition, and their Fourier representation appear in [10, (1.8)–(1.13), p. 19, Section B, and (1.29)–(1.32), p. 23]. We use centered blocks, a fixed order of coordinate paths, and a Borel extension at the singularity of the logarithm, and we prove the estimates below for these choices. Two points require care. First, the meromorphic formula for the inverse of the projected covariance has apparent singularities on the complex characteristic set $\Lambda_m(z) = 0$, which meets every neighborhood of the origin. We cancel these singularities before deducing exponential decay of the kernel. Second, the nonnegative scalar kernel of the transported segment average has row sums exactly one and counting column sums exactly M^{-3}. These masses must be kept exactly, since a fixed factor larger than one at each scale would destroy the uniformity in the number of averaging steps.

8.1 Linearized block averaging

Conventions. Unless physical units are displayed, a Fourier calculation in this section uses lattice coordinates with spacing one. For a finite matrix whose entries are color blocks, the row norm is the supremum over outputs of the sum over inputs of the operator norms of the blocks. The column norm is the supremum over inputs of the sum over outputs. Both use counting measure, and the subscript row + col denotes their sum, which is at least their maximum and at most twice it. A rate in the subscript, as in $\|\cdot\|_{a,\mathrm{row}+\mathrm{col}}$, means that the entry with indices x, y is multiplied by $e^{a\,\mathrm{dist}(x,y)}$ before summing. Distances between links are periodic ℓ^1 distances between their initial vertices. Moving the location of a link from its initial vertex to its midpoint changes these distances by at most one, and it changes any fixed exponentially weighted bound by at most a fixed factor. For the nonlinear maps in Sections 8.4 and 8.5, distances are measured in the physical units stated there.

Paths in the block averaging map. We recall the paths of Definition 4.3. We write $M = 2R_M + 1$. For a vertex $v \in M\mathbb{Z}^3$ of the coarse lattice, its block is $\mathsf{B}_M(v) = v + ([-R_M, R_M]^3 \cap \mathbb{Z}^3)$, and for $x \in \mathsf{B}_M(v)$ the coordinate path $\sigma_{v,x}$ from v to x changes the coordinates in the order $1, 2, 3$. For a coarse link $c = (v, v + Me_i)$, the reference path C_c is the straight path from v to $v + Me_i$, and for $x \in \mathsf{B}_M(v)$ the translated path with endpoint connectors is

$$F_{c,x} = \sigma_{v,x}\,[x, x + Me_i]\,\sigma^{-1}_{v+Me_i,x+Me_i};$$

see Figure 8.1. The block averaging map is

$$(T_M U)_c = \exp\Big\{M^{-3} \sum_{x \in \mathsf{B}_M(v)} \mathrm{Log}\big(U(F_{c,x})U(C_c)^{-1}\big)\Big\}U(C_c),$$

where $U(\eta)$ is the transport along a path η, and $(T_M U)_c = U(C_c)$ if one of the based loop holonomies $U(F_{c,x})U(C_c)^{-1}$ equals $-I$.

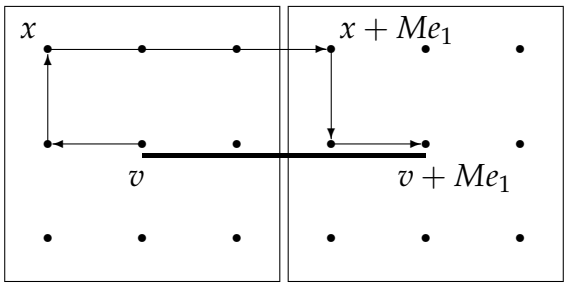

Figure 8.1. A two-dimensional slice of two neighboring blocks for $M = 3$. The thick line is the reference path C_c of the coarse link $c = (v, v + Me_1)$. The arrows show the translated path with endpoint connectors $F_{c,x}$: the coordinate path $\sigma_{v,x}$, the segment $[x, x + Me_1]$, and the reversed coordinate path $\sigma^{-1}_{v+Me_1,x+Me_1}$. At the identity the derivatives of the two connectors produce the gradient term in (8.1); in the gauge-corrected average of Section 8.4 they are canceled by gauge transformations at v and $v + Me_1$.

Lemma 8.1. *Fix an odd integer $M \geq 3$ and integers $d \geq 0$ and $n \geq 4$, and set $m = M^d$. On the fine torus of side mn, with coarse coordinates Y, let $\mathsf{I}_m = \{-(m-1)/2, \dots, (m-1)/2\}^3$ and define, for a one-cochain x and a scalar function f,*

$$(K_m x)_i(Y) = m^{-3} \sum_{r \in \mathsf{I}_m} \sum_{s=0}^{m-1} x_i(mY + r + se_i),$$
$$(\mathsf{A}_m f)(Y) = m^{-3} \sum_{r \in \mathsf{I}_m} f(mY + r).$$

For $d = 0$ both maps are the identity. Then the following statements hold.

1. *With the forward gradient $\nabla f(x, x + e_i) = f(x + e_i) - f(x)$,*

$$K_m \nabla_{\text{fine}} f = \nabla_{\text{coarse}} \mathsf{A}_m f, \qquad K_{m_2} K_{m_1} = K_{m_1 m_2}, \qquad \mathsf{A}_{m_2} \mathsf{A}_{m_1} = \mathsf{A}_{m_1 m_2},$$

   where in the last two identities m_1 and m_2 are odd, the first map averages by the factor m_1, and the second acts on the resulting lattice.

2. *There exists a linear map R_d from fine one-cochains to periodic scalar functions on the coarse torus such that*

$$D(T_M^d)(I)x = K_m x + \nabla_{\text{coarse}} \mathsf{R}_d x.$$

   In particular $\langle J, D(T_M^d)(I)x \rangle = \langle J, K_m x \rangle$ for every divergence-free coarse current J, that is, for every one-chain with zero signed incidence at each vertex.

3. *In units in which the coarse spacing is one, so that the fine spacing is $\epsilon = M^{-d}$, define the average of physical potentials by*
$$Q_d = \frac{1}{m} K_m.$$
Then Q_d maps every constant vector field to itself, $Q_d \nabla_{\text{phys,fine}} = \nabla_{\text{phys,coarse}} Q'_d$ with the scalar average $Q'_d = \mathsf{A}_m$, and if $d = d_1 + d_2$, then Q_d is the composition of the physical averages with factors M^{d_1} and M^{d_2} on the corresponding lattices.
4. *Translating the averaging box from $\{0, \dots, m-1\}^3$ to the centered box I_m multiplies the Fourier multiplier of K_m by the common phase $\exp[-i(m-1)\sum_j k_j/2]$, which is the same for all output directions and cancels in every product of the multiplier with its adjoint.*

These are identities for the derivative of T_M^d at the identity connection $U = I$; they do not identify a nonlinear average with factor m with T_M^d. They involve no coupling constant and no volume factor.

Proof. For a path σ, let $p_\sigma(x)$ be the signed sum of the one-cochain x along σ, so that a reversed link contributes the negative of the value on the positively oriented link. At the identity, the derivative of a path transport is the path sum. In the formula for T_M, the derivative of the final factor $U(C_c)$ cancels the reference-path sums inside the mean of the logarithms. The derivative on $c = (v, v + Me_i)$ is

$$M^{-3} \sum_{r \in \mathsf{I}_M} \Big\{ p_{\sigma_{v,v+r}}(x) + \sum_{s=0}^{M-1} x_i(v + r + se_i) - p_{\sigma_{v+Me_i, v+Me_i+r}}(x) \Big\}.$$

Let $p_v(x) = M^{-3} \sum_r p_{\sigma_{v,v+r}}(x)$. In the forward gradient convention of the statement we obtain

$$DT_M(I)x = K_M x - \nabla p(x). \tag{8.1}$$

The scalar p is periodic and linear in x. Its sign matters only for the definition of R_d and is fixed by (8.1).

For a scalar f, the inner sum over s in $K_m \nabla f$ telescopes to $f(mY + r + me_i) - f(mY + r)$, and averaging over r proves the gradient identity. For two successive odd factors, we expand both sums. The offsets in the box are $m_1 r_2 + r_1$, and the offsets along the segment are $m_1 s_2 + s_1$. The latter run once through $0, \dots, m_1 m_2 - 1$. In one coordinate, the former run once through the centered interval of length $m_1 m_2$: the intervals of length m_1 centered at the points $m_1 r_2$ are adjacent, and their extreme endpoints are $\pm(m_1 m_2 - 1)/2$. Taking products over the three coordinates and multiplying the weights gives both composition identities, including across the periodic seams.

Let $F_j = D(T_M^j)(I)$, and let $\mathsf{R}_0 = 0$. Suppose that $F_j = K_{M^j} + \nabla \mathsf{R}_j$. Since $T_M^j(I) = I$, using the chain rule, (8.1) at the next lattice, and the gradient identity, we obtain

$$F_{j+1} = K_{M^{j+1}} + \nabla\{\mathsf{A}_M \mathsf{R}_j - pF_j\}.$$

This defines the periodic linear map R_{j+1}. If J has zero signed incidence at every vertex, then $\nabla^{\mathsf{T}} J = 0$ and $\langle J, \nabla \mathsf{R}_d x \rangle = \langle \nabla^{\mathsf{T}} J, \mathsf{R}_d x \rangle = 0$.

A constant link-angle cochain is multiplied by m under K_m. If a physical potential on the fine lattice of spacing a/m is A, its link angles are $(a/m)A$, and dividing the coarse angles by a, we obtain $Q_d A = K_m A/m$. For a physical scalar gradient, the fine difference is multiplied by m/a and the coarse difference by $1/a$; the gradient identity becomes $Q_d \nabla_{\mathrm{phys,fine}} = \nabla_{\mathrm{phys,coarse}} \mathsf{A}_m$. The composition identity, with these divisions by the lattice spacings, gives the composition rule for Q_d.

Finally, moving the averaging box from the lower-corner position to the centered position translates each of its three coordinates by $-(m-1)/2$. Its Fourier multiplier is multiplied by $\exp[-i(m-1)\sum_j k_j/2]$, independently of the output direction, and multiplication by the adjoint cancels this phase at each frequency. All identities were obtained by differentiating at the identity or by finite sums, and no coupling or volume enters their coefficients. □

8.2 The effective Maxwell quadratic form

Fix $L > 0$, $\gamma > 0$, an odd integer $M \geq 3$, and integers $d \geq 0$ and $n \geq 4$. Set $m = M^d$, let $a = L/n$ be the coarse spacing, so that the fine spacing is a/m, and write $g_n^2 = g_3^2 a = \gamma/n$ and $g_{mn}^2 = \gamma/(mn) = g_n^2/m$ for the couplings at the coarse and fine lattices. For one color, let x be the centered Gaussian field of link angles on the fine torus of side mn with covariance $g_{mn}^2 (\mathrm{d}_{\mathrm{fine}}^{\mathsf{T}} \mathrm{d}_{\mathrm{fine}})^{\dagger}$, where $\mathrm{d}_{\mathrm{fine}}$ is the elementary curl from links to plaquettes and † denotes the Moore–Penrose inverse. By Lemma 5.2, the kernel of $\mathrm{d}_{\mathrm{fine}}$ consists of gradients and constant link fields, and this covariance vanishes on gradients and on constant fields. We push x forward by $D(T_M^d)(I)$ and project orthogonally onto the coarse transverse space, the orthogonal complement of the gradients and constant fields on the coarse torus. By Lemma 8.1, the projection removes the gradient term $\nabla \mathsf{R}_d x$, and the projected field is the projection of $K_m x$. By Lemma 5.2, the inverse covariance of a linear image of a Gaussian field is obtained by minimizing the quadratic form of the field under the corresponding linear constraint. This is why the inverse covariance computed below reappears as the Hessian at the identity of the effective classical action in Theorem 10.10.

Definition 8.2. Let $m = M^d$ with M and d as fixed above. For $z \in \mathbb{C}^3$ set

$$d_i(z) = 1 - e^{iz_i}, \qquad d_i^-(z) = 1 - e^{-iz_i}, \qquad \Lambda_m(z) = 4m^2 \sum_j \sin^2\big(z_j/(2m)\big),$$

and regard $d = (d_i)_i$ as a column vector and $d^- = (d_i^-)_i$ as a row vector; for real z we have $d^- = d^*$. For real $\theta \notin 2\pi\mathbb{Z}^3$ set

$$\lambda(\theta) = \sum_i |d_i(\theta)|^2, \qquad P(\theta) = I - \frac{d(\theta) d(\theta)^*}{\lambda(\theta)},$$

and for real k

$$b_{m,i}(k) = m^{-1} \sum_{s=0}^{m-1} e^{isk_i}, \qquad B_m(k) = \prod_j b_{m,j}(k).$$

For real $\theta \notin 2\pi\mathbb{Z}^3$ define

$$D_{m,i}(\theta) = \sum_r \frac{|B_m(k)|^2 |b_{m,i}(k)|^2}{\Lambda_m(\theta + 2\pi r)}, \qquad k = \frac{\theta + 2\pi r}{m},$$

where r runs over a complete set of representatives of $\mathbb{Z}^3/m\mathbb{Z}^3$; the points k are the m^3 fine frequencies with $mk \equiv \theta$ modulo 2π, called the aliases of θ, and each summand depends only on the class of r. Write $D = \operatorname{diag}(D_{m,i})$. Let

$$\beta_m(w) = \Big[\frac{\sin(w/2)}{m \sin(w/(2m))}\Big]^2,$$

extended by continuity at its removable singularities, let $\mathrm{I}_m^{(1)} = \{-(m-1)/2, \dots, (m-1)/2\}$, and define for $z \in \mathbb{C}^3$, wherever the denominators do not vanish,

$$D_{m,i}(z) = \sum_{r \in (\mathrm{I}_m^{(1)})^3} \frac{\prod_j \beta_m(z_j + 2\pi r_j)\, \beta_m(z_i + 2\pi r_i)}{\Lambda_m(z + 2\pi r)}, \tag{8.2}$$

and let $R_i(z)$ be the same sum restricted to $r \neq 0$. Finally set

$$\Lambda_0 = \Lambda_m(z), \qquad q_m(z) = \prod_j \beta_m(z_j), \qquad c_i(z) = q_m(z)\beta_m(z_i),$$

$$A_i(z) = c_i(z) + \Lambda_0 R_i(z), \qquad \omega_m(z) = q_m(z)^{-1} - \sum_i \frac{d_i^-(z) d_i(z) R_i(z)}{c_i(z) A_i(z)},$$

and $c_{\mathrm{av}} = (2/\pi)^{10}$, $C_{\mathrm{av}} = 1 + 3(1 + \pi^2/3)^3$.

For real $\theta \notin 2\pi\mathbb{Z}^3$ the two definitions of $D_{m,i}(\theta)$ agree; this is checked in Step 4 of the proof below. In the following theorem the coarse curl is denoted d, and $\mathrm{d}^{\mathsf{T}}\mathrm{d}$ is the lattice Maxwell form on the coarse torus.

Theorem 8.3. *Let $L > 0$, $\gamma > 0$, let $M \geq 3$ be odd, let $d \geq 0$ and $n \geq 4$ be integers, and let m, a, g_n, and the Gaussian field x be as above. Then the following statements hold.*

1. Covariance. *In unitary discrete Fourier coordinates on the coarse torus, at every nonzero frequency $\theta \in (2\pi/n)\mathbb{Z}^3/(2\pi\mathbb{Z})^3$, the covariance of the projected coarse field is*

   $$g_n^2 P(\theta) \operatorname{diag}_i\big(D_{m,i}(\theta)\big) P(\theta),$$

   and its zero-frequency component vanishes. For all values of the parameters, all i, and all $\theta \neq 0$,

   $$\frac{c_{\mathrm{av}}}{\lambda(\theta)} \leq D_{m,i}(\theta) \leq \frac{C_{\mathrm{av}}}{\lambda(\theta)}.$$

2. Inverse covariance. *Let $\mathsf{H}_m(\theta)$ be the inverse covariance of the projected coarse field after dividing the field by g_n, taken on the nonzero transverse space and extended by zero on gradients and constant fields. For $\theta \neq 0$,*

$$\mathsf{H}_m = D^{-1} - D^{-1} d \Big(\sum_i d_i^- d_i / D_{m,i} \Big)^{-1} d^- D^{-1}.$$

There exist absolute constants $\delta, a_0, C_0 > 0$ such that, for every m, this symbol has a 2π-periodic holomorphic continuation to the strip $\{z \in \mathbb{C}^3 : |\operatorname{Im} z_i| < \delta\}$, including a neighborhood of $z = 0$, bounded uniformly in m. On a neighborhood of the origin that does not depend on m, we have $A_i(z) = 1 + O(|z|^2)$ and $\omega_m(z) = 1 + O(|z|^2)$ uniformly in m, and

$$\mathsf{H}_m(z) = \Lambda_0 \operatorname{diag}(A_i^{-1}) - \frac{\operatorname{diag}(A_i^{-1})\, d\, d^- \operatorname{diag}(A_i^{-1})}{\omega_m(z)}.$$

The continuation satisfies $\mathsf{H}_m(z) d(z) = 0$ and $d^-(z) \mathsf{H}_m(z) = 0$, and $\mathsf{H}_m(0) = 0$. We call the corresponding periodic kernel $\mathsf{H}_{m,n}$ on the coarse torus the effective Maxwell quadratic form; it satisfies

$$\sup_x \sum_y e^{a_0 \operatorname{dist}_n(x,y)} \|\mathsf{H}_{m,n}(x,y)\| + \sup_y \sum_x e^{a_0 \operatorname{dist}_n(x,y)} \|\mathsf{H}_{m,n}(x,y)\| \le C_0.$$

As quadratic forms on coarse link fields,

$$C_{\mathrm{av}}^{-1} \mathrm{d}^{\mathsf{T}} \mathrm{d} \le \mathsf{H}_{m,n} \le c_{\mathrm{av}}^{-1} \mathrm{d}^{\mathsf{T}} \mathrm{d},$$

both sides vanishing on gradients and constant fields. With $\mathsf{H}_{\mathrm{Max}} = \lambda I - d d^-$ there exist absolute constants $\theta_0, C > 0$ such that $\|\mathsf{H}_m(\theta) - \mathsf{H}_{\mathrm{Max}}(\theta)\| \le C|\theta|^4$ for $|\theta| \le \theta_0$ and all m.

3. Next constrained fluctuation space. *Suppose that $n = M n_+$ with $n_+ \ge 4$, and let E_0 be the embedding of the next constrained fluctuation space of Lemma 6.5, on the torus of side n. Then*

$$\mathsf{K}_{m,n} = E_0^{\mathsf{T}} \mathsf{H}_{m,n} E_0$$

satisfies

$$c_M I \le \mathsf{K}_{m,n} \le C_M I, \qquad \|\mathsf{K}_{m,n}\|_{a_M,\mathrm{row+col}} + \|\mathsf{K}_{m,n}^{-1}\|_{a_M,\mathrm{row+col}} \le C_M$$

for constants $a_M, c_M, C_M > 0$ that depend only on M.

4. Normalization. *Let A be a smooth periodic connection on $\mathbb{T}_L^3$, and let $U^{(a)}$ be its link transports on the lattice of spacing a. Then*

$$\frac{S_W(U^{(a)})}{g_3^2 a} \longrightarrow \frac{1}{2g_3^2} \int_{\mathbb{T}_L^3} \sum_{i<j} |F_{ij}(A)|^2 \, dx \qquad (a \downarrow 0).$$

Let $A = g_3\mathcal{A}$ be the centered Gaussian transverse random distribution with zero constant mode, constructed by requiring that each finite symmetric Fourier truncation have density proportional to the exponential of minus the quadratic part of this action at $A = 0$, restricted to its real transverse coordinates. With the Fourier convention $\widehat{\mathcal{A}}(k) = \int_{\mathbb{T}^3_L} e^{-ik\cdot x}\mathcal{A}(x)\,dx$, the three colors of $\mathcal{A}$ are independent and

$$\mathbb{E}\widehat{\mathcal{A}}_i^{\alpha}(k)\widehat{\mathcal{A}}_j^{\beta}(k') = L^3\mathbf{1}_{\{k'=-k\}}\delta_{\alpha\beta}|k|^{-2}\Big(\delta_{ij} - \frac{k_ik_j}{|k|^2}\Big), \qquad k,k' \in (2\pi/L)\mathbb{Z}^3 \setminus \{0\}.$$

The constants $c_{\mathrm{av}}, C_{\mathrm{av}}, \delta, a_0, C_0, \theta_0$, and C are absolute, and a_M, c_M, C_M depend only on M; none of them depends on L, γ, n, or d.

Remark 8.4. The constant modes are set to zero only in the auxiliary Gaussian field. In the classical minimization of Section 10, coarse fields with nonzero constant modes are allowed, and the Schur complement identities of Lemma 5.2 apply to them. Accordingly, an inverse of $\mathsf{H}_{m,n}$ is asserted in part (3) only on the next constrained fluctuation space, where the averaging constraint removes the constant modes; no bound on an inverse of $\mathsf{H}_{m,n}$ on all transverse coarse fields, uniform in n, is asserted.

Remark 8.5. At each fixed nonzero θ, the alias sums have the limit

$$\lim_{d\to\infty} D_{M^d,i}(\theta) = D_{\infty,i}(\theta) = \sum_{r\in\mathbb{Z}^3} \frac{\prod_j \operatorname{sinc}^2\big((\theta_j + 2\pi r_j)/2\big)\ \operatorname{sinc}^2\big((\theta_i + 2\pi r_i)/2\big)}{|\theta + 2\pi r|^2}.$$

Indeed, choose $\theta_j \in [-\pi, \pi)$ and aliases with $\kappa_j = \theta_j + 2\pi r_j \in [-\pi m, \pi m)$. For a fixed integer vector r, as $m = M^d \to \infty$, the four squared averaging factors $|b_{m,j}(k)|^2 = \sin^2(\kappa_j/2)/(m^2\sin^2(\kappa_j/(2m)))$ converge to the four squared sinc factors, and $\Lambda_m(\kappa) \to |\kappa|^2$; each fixed alias is present for large m. By Step 2 of the proof below, after extension by zero outside the finite set of aliases, every nonzero-alias summand is bounded by $\prod_j w(r_j)/4$, where $w(0) = 1$ and $w(r) = r^{-2}$ for $r \neq 0$, and this bound is summable over $\mathbb{Z}^3$. Fix a finite cube of aliases outside which the sum of these bounds is less than a given $\eta > 0$, pass to the limit on that cube, and let $\eta \downarrow 0$. The zero alias is nonsingular at the fixed $\theta \neq 0$. This proves the limit.

Proof of Theorem 8.3. We begin with an outline. Part (1) is a Fourier computation followed by elementary bounds on the alias sums. For part (2), the formula for H_m is the inverse of the projected covariance on its range, and the comparison with the Maxwell form follows by inverting the bounds of part (1). The main point is the holomorphic continuation of H_m to a strip whose width does not depend on m; exponential decay of the kernel then follows by shifting contours. Near the origin, $D_{m,i} = A_i/\Lambda_0$, and the second term in the formula for H_m contains the inverse of $\sum_i d_i^- d_i/D_{m,i} = \Lambda_0 \sum_i d_i^- d_i/A_i$. The zero set of the holomorphic function $\Lambda_0 = \Lambda_m(z)$ near the origin is a complex hypersurface through 0,

and it contains nonreal points arbitrarily close to the origin. Although $\mathsf{H}_m(\theta) \to 0$ as real $\theta \to 0$, this does not show that H_m is holomorphic near 0. We rewrite H_m exactly so that its only denominators are A_i and ω_m, which equal $1 + O(|z|^2)$ uniformly in m. Part (3) combines the Maxwell comparison with Lemma 6.5 and the weighted inverse estimate of Lemma 5.3, and part (4) is a direct calculation.

Step 1: Fourier conventions and the covariance. On a torus of side N we use the unitary transform

$$\widehat{x}_i(k) = N^{-3/2} \sum_{z \in \mathbb{Z}^3_N} e^{-ik\cdot z} x_i(z), \qquad x_i(z) = N^{-3/2} \sum_k e^{ik\cdot z} \widehat{x}_i(k).$$

The gradient has symbol $-d(k)$, and the elementary curl has symbol

$$(\mathrm{d}x)^{\wedge}_{ij}(k) = -d_i(k)\widehat{x}_j(k) + d_j(k)\widehat{x}_i(k), \qquad i < j.$$

Expanding the three squares, we find for $k \neq 0$ that

$$\mathrm{d}(k)^*\mathrm{d}(k) = \lambda(k) I - d(k)d(k)^* = \lambda(k) P(k). \tag{8.3}$$

This identifies the null modes used in the Gaussian convention: the multiples of $d(k)$ at $k \neq 0$, which are the gradients, and all of $k = 0$, which are the constant fields, in agreement with Lemma 5.2.

For the lower-corner box, before restriction to the coarse lattice, the operator K_m is diagonal in Fourier space with multiplier $T_i(k) = mB_m(k)b_{m,i}(k)$. The centered box adds the common phase computed in Lemma 8.1. We substitute the inverse fine transform into $K_m x(Y)$ and take the coarse transform. Only the frequencies with $mk \equiv \theta$ modulo 2π survive the sum over coarse vertices, and the restriction to the coarse lattice contributes a factor $m^{-3/2}$ for each of these m^3 aliases. Summing the finite geometric series, we obtain

$$m b_{m,i}(k) d_i(k) = d_i(\theta).$$

Then $T(k)d(k) = B_m(k)d(\theta)$, with the same common phase in the centered convention, and $P(\theta)T(k)d(k) = 0$. The longitudinal part of the fine covariance vanishes after the projections on both sides, alias by alias.

The fine coupling is $g^2_{mn} = g^2_n/m$. The fine frequency $k = (\theta + 2\pi r)/m$ has $\lambda(k) = \Lambda_m(\theta + 2\pi r)/m^2$, and the inverse of the fine Laplacian at k is $m^2/\Lambda_m(\theta + 2\pi r)$. Combining the coupling, the factor from the restriction to the coarse lattice, the square of the segment multiplier m, and the inverse Laplacian, we obtain

$$\frac{g^2_n}{m} \cdot m^{-3} \cdot m^2 \cdot m^2 = g^2_n.$$

Since $P(\theta)$ removes the gradient term $\nabla \mathsf{R}_d x$ of Lemma 8.1, this is the covariance of the projection of $D(T^d_M)(I)x$, which proves the covariance formula. At $\theta = 0$, every alias

with $r \not\equiv 0$ modulo m has a vanishing factor in B_m, since $\sum_{s=0}^{m-1} e^{2\pi i r_j s/m} = 0$ when $r_j \not\equiv 0$ modulo m. The remaining alias is the fine constant mode, which has zero covariance. This shows that the zero-frequency component vanishes.

Step 2: Real bounds for the alias sums. We take $\theta_j \in [-\pi, \pi)$ and aliases with $\kappa_j = \theta_j + 2\pi r_j \in [-\pi m, \pi m)$. For the alias $r = 0$ we have

$$|b_{m,j}(\theta/m)| = \frac{|\sin(\theta_j/2)|}{m|\sin(\theta_j/(2m))|} \geq \frac{2}{\pi}, \qquad \lambda(\theta) \leq \Lambda_m(\theta) \leq |\theta|^2 \leq \frac{\pi^2}{4}\lambda(\theta),$$

where the value at a zero coordinate is understood by continuity. The first inequality for Λ_m follows from the concavity of the sine, $\sin(t/m) \geq \sin(t)/m$ for $0 \leq t \leq \pi/2$, and the last from $|\sin t| \geq 2|t|/\pi$ for $|t| \leq \pi/2$. These inequalities, together with the factor $(2/\pi)^8$ from the four squared averaging factors, prove the lower bound. The contribution of $r = 0$ to the upper bound is at most $1/\lambda(\theta)$.

For every other alias, the same chord inequality implies that

$$|b_{m,j}(k)| \leq \min\{1, \pi/|\kappa_j|\}, \qquad \Lambda_m(\kappa) \geq (4/\pi^2)|\kappa|^2.$$

If $r_j \neq 0$, then $|\kappa_j| \geq \pi|r_j|$. With $w(0) = 1$ and $w(r) = r^{-2}$ for $r \neq 0$, the numerator without its extra factor $|b_{m,i}(k)|^2$ is at most $\prod_j w(r_j)$, the extra factor is at most one, and the denominator is at least four. Since $\sum_{r \geq 1} r^{-2} = \pi^2/6$, we have $\sum_{r \in \mathbb{Z}} w(r) = 1 + \pi^2/3$, and the nonzero aliases contribute at most $(1 + \pi^2/3)^3/4$. Since $\lambda \leq 12$, this is at most $3(1 + \pi^2/3)^3/\lambda$, and the upper bound with the constant C_{av} follows.

Step 3: The transverse inverse and the Maxwell comparison. Fix real $\theta \neq 0$, write $D^{-1} = \mathrm{diag}(D_{m,i}^{-1})$, and set $s = d^- D^{-1} d = \sum_i d_i^- d_i / D_{m,i}$, which is positive. The matrix

$$H = D^{-1} - D^{-1} d\, s^{-1} d^- D^{-1}$$

is Hermitian, satisfies $Hd = 0$ and $d^- H = 0$, and $HD = I - D^{-1} d s^{-1} d^*$, so that $HDP = P$ since $d^* P = 0$. Since $HP = PH = H$, the matrix H is the inverse of PDP on $\operatorname{ran} P$. This proves the inverse formula. Note that we invert the projected covariance PDP, not the diagonal matrix D. Inverting the inequalities

$$\frac{c_{\mathrm{av}}}{\lambda} I_{\operatorname{ran} P} \leq (PDP)|_{\operatorname{ran} P} \leq \frac{C_{\mathrm{av}}}{\lambda} I_{\operatorname{ran} P}$$

from part (1) and using (8.3), we obtain the comparison with the Maxwell form at each nonzero frequency. Both sides vanish on gradients and at zero frequency, which proves the comparison of quadratic forms.

Step 4: Uniform bounds for the continued alias sums. The identity

$$\beta_m(w) = \Big(m^{-1}\sum_{s=0}^{m-1} e^{isw/m}\Big)\Big(m^{-1}\sum_{t=0}^{m-1} e^{-itw/m}\Big)$$

shows that the singularities of β_m are removable and that β_m is entire and even; no complex conjugation enters. For real θ each squared modulus in the real alias sum is the product of the multipliers at opposite frequencies, $|b_{m,j}(k)|^2 = \beta_m(\theta_j + 2\pi r_j)$, and (8.2), with the residue set $(\mathrm{I}_m^{(1)})^3$, agrees with the real formula. Increasing a coordinate of z by 2π permutes the aliases; the alias that leaves the residue set changes its coordinate by $2\pi m$, and both β_m and Λ_m are invariant under this change. This shows that (8.2) is 2π-periodic in each coordinate.

Let $z = x + iy$ with $|x_j| \le \pi$ and $|y_j| \le \delta_0$, for a sufficiently small absolute $\delta_0 > 0$. For our residue set, $|x_j + 2\pi r_j|/(2m) \le \pi/2$. Using $|\sin(u+iv)|^2 = \sin^2 u + \sinh^2 v$, we find for $r_j \neq 0$ that

$$|m\sin\big((z_j + 2\pi r_j)/(2m)\big)| \ge m|\sin\big((x_j + 2\pi r_j)/(2m)\big)| \ge |x_j + 2\pi r_j|/\pi \ge |r_j|.$$

The numerator $\sin((z_j + 2\pi r_j)/2)$ is bounded on this tube, and for $r_j = 0$ the finite-sum representation shows that β_m is uniformly bounded there. We obtain

$$|\beta_m(z_j + 2\pi r_j)| \le C w(r_j). \tag{8.4}$$

The extra factor $\beta_m(z_i + 2\pi r_i)$ is bounded by the same finite-sum formula. Since $\operatorname{Re}\sin^2(u+iv) = \sin^2 u - \cos(2u)\sinh^2 v$ and $\sinh|v| \le 2|v|$ for $|v| \le 1$, we have

$$\operatorname{Re}\Lambda_m(z + 2\pi r) \ge (4/\pi^2)|x + 2\pi r|^2 - 4|y|^2.$$

For $r \neq 0$ this is at least $2|r|^2$ after choosing δ_0 small. In particular no denominator of a nonzero alias vanishes on the tube, and its summand is bounded by $C\prod_j w(r_j)/|r|^2$. Summing and using (8.4), we obtain a uniform bound for every R_i on the whole tube over the real cube, with holomorphy in its interior. Bounds for derivatives on smaller neighborhoods follow from Cauchy's formula on fixed circles in each coordinate. For $m = 1$ these remainders vanish. For the zero alias the lower bound reads

$$\operatorname{Re}\Lambda_m(z) \ge (4/\pi^2)|x|^2 - 4|y|^2.$$

On any real region $|x| \ge \rho > 0$, the functions $D_{m,i}$ and their first derivatives are bounded and holomorphic, uniformly in m, in a tube whose width depends only on ρ.

Step 5: Cancellation on the complex characteristic set. On a small polydisc about zero that does not depend on m, the finite-sum formula and evenness imply that $\beta_m(z_j) = 1 + O(|z_j|^2)$ uniformly in m. We obtain

$$q_m = 1 + O(|z|^2), \qquad c_i = 1 + O(|z|^2), \qquad \Lambda_0 = O(|z|^2), \qquad A_i = 1 + O(|z|^2);$$

for the last assertion we used the bounds for R_i from Step 4. Since $d_i^-(z)d_i(z) = 4\sin^2(z_i/2)$ and $\beta_m(z_i) = \sin^2(z_i/2)/(m^2\sin^2(z_i/(2m)))$, we have the exact identity

$$\sum_i \frac{d_i^- d_i}{c_i} = q_m^{-1} \sum_i \frac{4\sin^2(z_i/2)}{\beta_m(z_i)} = \frac{\Lambda_0}{q_m},$$

valid also at the removable values. Using $A_i^{-1} = c_i^{-1} - \Lambda_0 R_i/(c_i A_i)$, we obtain

$$\sum_i \frac{d_i^- d_i}{A_i} = \Lambda_0 \omega_m, \qquad \omega_m = q_m^{-1} - \sum_i \frac{d_i^- d_i R_i}{c_i A_i} = 1 + O(|z|^2). \tag{8.5}$$

We fix an absolute radius $\rho > 0$ such that q_m, c_i, A_i, and ω_m have modulus at least $1/2$ on the polydisc $|z_j| < 2\rho$; this is possible uniformly in m by the preceding quadratic estimates. The zero alias of (8.2) is c_i/Λ_0. Where the alias sum is regular, we have

$$D_{m,i} = \frac{A_i}{\Lambda_0}, \qquad \sum_i \frac{d_i^- d_i}{D_{m,i}} = \Lambda_0^2 \omega_m.$$

Substituting these identities into the inverse formula, we obtain exactly the expression for $\mathsf{H}_m(z)$ in part (2). Its denominators A_i and ω_m do not vanish on the polydisc, including the points where $\Lambda_0 = 0$. This proves holomorphy there and the bound $\|\mathsf{H}_m(z)\| \le C|z|^2$, since Λ_0 and dd^- are $O(|z|^2)$. Multiplying by d on the right and by d^- on the left and using (8.5), we obtain $\mathsf{H}_m d = 0$ and $d^- \mathsf{H}_m = 0$; the value at zero is zero.

Step 6: The strip, the periodic kernel, and the comparison at low frequency. On the real complement of the smaller neighborhood $|z_j| < \rho$, part (1) implies that $D_{m,i} \ge c_{\mathrm{av}}/12$ and

$$\sum_i d_i^- d_i / D_{m,i} \ge \lambda^2 / C_{\mathrm{av}} \ge c_\rho > 0.$$

By the bounds of Step 4, the first derivatives there have a common bound C_ρ. We shrink the tube so that $D_{m,i}$ changes by less than $c_{\mathrm{av}}/24$ from its real value; its reciprocal then has bounded value and bounded first derivatives. After one more shrinking, we may assume that $\sum_i d_i^- d_i / D_{m,i}$ changes by less than $c_\rho/2$. The inverse formula of part (2) is then holomorphic and uniformly bounded on this tube. Across the faces of the real cube we use the periodicity of (8.2); the same real lower bounds hold there.

We fix an absolute width $\delta > 0$ below these widths and so small that points whose real parts lie in $|x_j| < \rho$ remain in the polydisc $|z_j| < 2\rho$. The two expressions for H_m agree on their common regular set; multiplying by their nonvanishing denominators shows that they agree throughout each overlap, including removable points. They define one bounded periodic holomorphic function on the strip of width δ.

Let its Fourier coefficients be

$$h_m(\zeta) = (2\pi)^{-3} \int_{[-\pi,\pi]^3} e^{i\theta\cdot\zeta} \mathsf{H}_m(\theta)\, d\theta, \qquad \zeta \in \mathbb{Z}^3.$$

For $0 < \delta_1 < \delta$, shift the three integration contours by $\pm i\delta_1$, with the signs chosen according to the signs of the components of ζ so as to decrease the exponential factor. The vertical sides cancel by periodicity, and from the uniform bound on the strip we obtain

$$\|h_m(\zeta)\| \le C e^{-\delta_1 |\zeta|_1}.$$

The Fourier series of H_m converges absolutely. Sampling it at the frequencies of the torus of side n and using the orthogonality of the finite characters, we obtain

$$\mathsf{H}_{m,n}(x,y) = \sum_{\zeta \equiv x-y \pmod{n}} h_m(\zeta).$$

For each representative, $\mathrm{dist}_n(x,y) \le |\zeta|_1$. For any $0 < a_0 < \delta_1$, each of the two weighted sums in part (2) is at most

$$C \sum_{\zeta \in \mathbb{Z}^3} e^{-(\delta_1 - a_0)|\zeta|_1} = C\Big(\frac{1 + e^{-(\delta_1 - a_0)}}{1 - e^{-(\delta_1 - a_0)}}\Big)^3,$$

which gives the kernel bound with a constant C_0 independent of n and d.

The comparison at low frequency follows from the same identities. On the real axis near zero, $\mathrm{diag}(A_i^{-1}) = I + O(|\theta|^2)$ and $\omega_m^{-1} = 1 + O(|\theta|^2)$. Since the Taylor remainder of the sine is uniform in $m \ge 1$, we have $\Lambda_m(\theta) - \lambda(\theta) = O(|\theta|^4)$. Since $dd^- = O(|\theta|^2)$, the two terms in the formula of part (2) differ from λI and dd^-, respectively, by $O(|\theta|^4)$. This proves $\|\mathsf{H}_m(\theta) - \mathsf{H}_{\mathrm{Max}}(\theta)\| \le C|\theta|^4$.

Step 7: Restriction to the next constrained fluctuation space. Let $a = E_0 z$. The embedding of Lemma 6.5 vanishes on the links of the centered block trees, which are the links of the coordinate paths $\sigma_{v,x}$, and every path sum $p_{\sigma_{v,x}}(a)$ in (8.1) vanishes. The linearized constraint $DT_M(I)a = 0$ says $K_M a = 0$. A fixed input link occurs exactly M times in the straight segments of the coarse sum, each time with weight M^{-3}. Summing over the coarse links, we find

$$\sum_Y (K_M a)_i(Y) = M^{-2} \sum_x a_i(x).$$

This shows that a has zero spatial mean in each component and has no constant mode. By the comparison with the Maxwell form in part (2) and the lower bound of Lemma 6.5, we have

$$\langle z, E_0^{\mathsf{T}} \mathsf{H}_{m,n} E_0 z \rangle \ge C_{\mathrm{av}}^{-1} \|\mathrm{d} E_0 z\|_2^2 \ge c_M \|z\|_2^2,$$

after renaming the constant. The upper comparison and the upper bound of the same lemma imply that $\mathsf{K}_{m,n} \le C_M I$. The rows and columns of E_0 have finite range and bounded sums depending only on M, by the same lemma. They transfer the weighted bounds for $\mathsf{H}_{m,n}$ to $\mathsf{K}_{m,n}$: each endpoint of a contributing stencil moves by at most a distance depending on M. The index set of the free coordinates has counting growth

$\#\{z : \operatorname{dist}(z, z_0) \le R\} \le D_M(1+R)^3$. We now apply the inverse estimate of Lemma 5.3. Its hypotheses are a self-adjoint matrix with a positive lower bound, bounded off-diagonal row and column sums with an exponential weight, and polynomial counting growth of the index set. We have verified them with lower bound c_M, rate a_0, a bound on the weighted sums depending only on M, and growth exponent three. The lemma gives exponentially weighted bounds for $\mathsf{K}_{m,n}^{-1}$ at a smaller rate. Taking a_M to be the smaller of the two rates and enlarging C_M proves part (3).

Step 8: Normalization. Let $U_i^{(a)}(x)$ be the transport of the smooth connection A along the link $(x, x + ae_i)$. Iterating the integral equation of the transport twice, we find uniformly in x that

$$U_i^{(a)}(x) = I + aA_i(x) + \tfrac{1}{2}a^2\{\partial_i A_i(x) + A_i(x)^2\} + O_A(a^3).$$

The remaining ordered integrals are bounded by $C_A a^3$, uniformly in x. We insert the four expansions, with the shifted arguments on the two shifted sides, into the plaquette product. The terms of degree one cancel, and the terms of degree two are $\partial_i A_j - \partial_j A_i + [A_i, A_j]$; hence $\operatorname{Log} U_{p_{ij}(x)} = a^2 F_{ij}(x) + O_A(a^3)$. For real $X = x^a \tau_a$, the Pauli identity implies that $X^2 = -|x|^2 I/4$. Then $\operatorname{tr}(e^X)/2 = \cos(|x|/2)$ and $4q(e^X) = |X|^2/2 + O(|X|^4)$. We obtain

$$\frac{S_W(U^{(a)})}{g_3^2 a} = \frac{1}{2g_3^2} a^3 \sum_x \sum_{i<j} |F_{ij}(x)|^2 + O_{A,L,g_3}(a),$$

and the Riemann sum converges because the integrand is smooth on the fixed torus. This proves the first assertion of part (4).

The quadratic part of the continuum action at $A = 0$ is $(2g_3^2)^{-1} \int \sum_{i<j} |\partial_i A_j - \partial_j A_i|^2 \, dx$. With the Fourier convention of the statement, we have $A(x) = L^{-3} \sum_k e^{ik\cdot x} \widehat{A}(k)$. Integrating the products of exponentials, we find that on any finite symmetric set of nonzero frequencies the quadratic part is

$$\frac{1}{2g_3^2 L^3} \sum_{k \neq 0} \widehat{A}(k)^* \big(|k|^2 I - kk^{\mathsf{T}}\big) \widehat{A}(k).$$

We restrict to $\widehat{A}(k) \perp k$ and impose the reality condition $\widehat{A}(-k) = \overline{\widehat{A}(k)}$. For one representative of each pair $\{k, -k\}$, the corresponding term is $|k|^2 |\widehat{A}(k)|^2 / (g_3^2 L^3)$. For a transverse real or imaginary coordinate u, the one-variable density is therefore proportional to $\exp[-|k|^2 u^2 / (g_3^2 L^3)]$, and differentiating the Gaussian integral gives the variance $g_3^2 L^3 / (2|k|^2)$; different coordinates, pairs, and colors are independent. We realize the field by independent centered real Gaussian variables with these variances, one for each transverse real and imaginary coordinate of one representative of each pair and each color. The remaining coordinates are defined by the reality condition. Then $A = g_3 \mathcal{A}$ has exactly the covariance displayed in part (4); in particular $\mathbb{E}\widehat{\mathcal{A}}(k)\widehat{\mathcal{A}}(k)^{\mathsf{T}} = 0$ for $k' = k \neq -k$, since the real and imaginary parts have equal variances.

These coordinates define a random distribution almost surely. Indeed,

$$\mathbb{E} \sum_{k \neq 0} (1 + |k|^2)^{-2} |\widehat{\mathcal{A}}(k)|^2 < \infty :$$

the summands are nonnegative with expectations at most $C_L(1 + |k|)^{-6}$, and the number of frequencies in the shell $R \leq |k| < R + 1$ is at most $C_L(1 + R)^2$, as one sees by covering their disjoint cubes of fixed volume by a shell of fixed extra thickness. Markov's inequality applied to the increasing partial sums shows that their supremum is finite almost surely, and on that event the Cauchy–Schwarz inequality pairs the Fourier sequence continuously with every smooth test function. Alternatively, each such pairing converges in mean square, since repeated integration by parts bounds the Fourier coefficients of a smooth test function f by $C_{f,s}(1 + |k|)^{-s}$ for every s. Limits of the characteristic functions of the finite truncations show that these pairings are jointly Gaussian with the stated covariance, and the covariance identity for arbitrary pairs of frequencies already holds at every finite truncation. The three colors are independent because their quadratic forms add.

The constants in Steps 1–6 are absolute; only the stencils, the lower bound, and the counting growth in Step 7 introduce dependence on M. No step used L, γ, n, or d in a constant. This completes the proof. □

8.3 Gradient annihilation and spatial inversion

The effective Maxwell quadratic form of Theorem 8.3 vanishes identically on the constant modes because of the convention for the auxiliary Gaussian field. The Hessians that occur later are perturbations of such forms by small translation-invariant kernels that annihilate gradients (by gauge invariance) and commute with spatial inversion, but need not vanish on the constant modes. The following lemma shows that such a kernel is bounded by the lattice Maxwell form, with an exponentially small error from its zero-frequency block. It is used in Lemma 11.11.

Spatial inversion and midpoint coordinates. Spatial inversion maps the vertex x of the periodic lattice of side n to $-x$. It maps the positive link $(x, x + e_i)$ to the reversed link of $(-x - e_i, -x)$, so it acts on link fields by

$$(\mathsf{I}v)_i(x) = -v_i(-x - e_i).$$

Let H be a translation-invariant kernel on link fields, written $H_{ij}(x, y) = h_{ij}(y - x)$, where $h_{ij}(t)$ is the block from a j-link with initial vertex y to an i-link with initial vertex x. The midpoint displacement of this entry is

$$t = y - x + (e_j - e_i)/2 \mod n\mathbb{Z}^3.$$

We lift it to $\mathbb{R}^3$ by choosing in each coordinate a representative of smallest absolute value. If a coordinate has two such representatives, which happens when it equals $n/2$ modulo n, we divide the coefficient equally between them. With several such coordinates, we take the product of these equal divisions. For example, in one dimension with $n = 4$ a coefficient at displacement 2 is split into two halves placed at 2 and -2. Denote the lifted coefficients by $\widetilde{h}_{ij}(t)$, $t \in \mathbb{R}^3$, and define the midpoint interpolation

$$\widetilde{H}_{ij}(k) = \sum_t \widetilde{h}_{ij}(t) e^{ik\cdot t}, \qquad k \in \mathbb{R}^3.$$

At a frequency $k \in (2\pi/n)\mathbb{Z}^3$ of the torus, lifts differing by elements of $n\mathbb{Z}^3$ have the same phase. Then $\widetilde{H}(k)$ is the Fourier block of H in midpoint coordinates, which differs from the Fourier block in initial-vertex coordinates by diagonal unitary phases on the links.

Lemma 8.6. *Fix a rate $a > 0$ and a finite color dimension. For every periodic side $n \geq 4$, let H be a real, self-adjoint, translation-invariant kernel on link fields of the torus of side n such that*

$$H\nabla = 0 = \nabla^{\mathsf{T}} H, \qquad H\mathsf{I} = \mathsf{I}H, \qquad \|H\|_{a,\mathrm{row+col}} \leq \varepsilon.$$

Then there exist $C(a), c(a) > 0$, depending only on a and the color dimension, such that with $w_n = (1+n)^3 e^{-c(a)n}$ the following hold.

1. *The zero-frequency block satisfies $\|\widehat{H}(0)\| \leq C(a)\varepsilon w_n$.*
2. *For every real or complex link field v, with the Hermitian pairing for complex v,*

$$|\langle v, Hv\rangle| \leq C(a)\varepsilon \|\mathrm{d}v\|_2^2 + C(a)\varepsilon w_n \|v\|_2^2.$$

3. *The midpoint interpolation is even, $\widetilde{H}(-k) = \widetilde{H}(k)$ for $k \in \mathbb{R}^3$, and at every frequency k of the torus, represented with $k_j \in [-\pi, \pi]$,*

$$\|\widetilde{H}(k)\| \leq C(a)\varepsilon\Big(\sum_i 4\sin^2(k_i/2) + w_n\Big).$$

The proof uses inversion in all three coordinates; a reflection in a single coordinate would not make the first derivative of $\widetilde{H}$ vanish at zero. The zero-frequency block is estimated, not assumed to vanish.

Proof. Let r be the color dimension; constants below may depend on r. The weighted hypothesis bounds each row sum and each column sum of H by ε.

We first estimate the zero-frequency block, without using inversion. Let $n \geq 32$, represent vertex coordinates in $[-n/2, n/2)^3$, and fix a Lipschitz function χ on $\mathbb{R}$ with $0 \leq \chi \leq 1$, equal to one on $[-1/8, 1/8]$, and vanishing outside $(-1/4, 1/4)$. The periodic function

$$f_j(x) = x_j \prod_{\ell=1}^{3} \chi(x_\ell/n)$$

has discrete first differences bounded by a fixed constant. The difference of x_j contributes at most one, and a difference of a cutoff contributes at most $\mathrm{Lip}(\chi)/n$ times a coordinate of size at most $n/2$. Its gradient coincides with the constant j-directed link field $\mathbf{1}_j$ on links whose initial vertices have ℓ^∞ norm at most $n/8-1$. For a color vector b with $|b|=1$, applying the identity $H\nabla=0$ to f_jb in the row of an i-link with initial vertex zero, we obtain

$$(H(\mathbf{1}_jb))_i(0)=\big(H(\mathbf{1}_jb-\nabla(f_jb))\big)_i(0).$$

Every nonzero input on the right is at periodic distance at least $n/16$ from this row and is bounded by a fixed constant. By the weighted row bound, the right side is at most $C\varepsilon e^{-an/16}$. The left side is the ij block of $\widehat{H}(0)b$. Summing over the finitely many blocks, we obtain $\|\widehat{H}(0)\|\le C\varepsilon e^{-an/16}$. For $4\le n<32$, the unweighted row bound implies that $\|\widehat{H}(0)\|\le\varepsilon$, and enlarging the constant covers these finitely many sides. With $c(a)=a/32$ both ranges give part (1).

We next use inversion. Both oriented links of an entry acquire a minus sign, and their initial vertices become $-x-e_i$ and $-y-e_j$. In terms of the entries, $H\mathsf{I}=\mathsf{I}H$ reads

$$h_{ij}(y-x)=h_{ij}(-y+x+e_i-e_j),$$

and the midpoint displacement of the right side is $-t$. Since ties were split symmetrically, we have $\widetilde{h}_{ij}(t)=\widetilde{h}_{ij}(-t)$. Then $\widetilde{H}$ is even and $D\widetilde{H}(0)=0$. The lifts of each coefficient sum to that coefficient, and the weighted absolute sums of the lifted coefficients are at most $C_a\varepsilon$, since the shortest midpoint distance exceeds the vertex distance by at most one. All representatives have $|t_\ell|\le n/2$. Since $\sup_{u\ge0}u^2e^{-au}<\infty$, the second derivatives satisfy

$$\sup_{k\in\mathbb{R}^3}\|D^2\widetilde{H}(k)\|\le C\sum_{i,j,t}|t|_1^2\|\widetilde{h}_{ij}(t)\|\le C(a)\varepsilon.$$

At $k=0$ all phases are one, and $\widetilde{H}(0)=\widehat{H}(0)$. By Taylor's formula along the segment from 0 to k and part (1), we have $\|\widetilde{H}(k)\|\le C(a)\varepsilon(w_n+|k|^2)$. For $k_j\in[-\pi,\pi]$ we have $|k|^2\le(\pi^2/4)\sum_j 4\sin^2(k_j/2)$, which proves part (3).

To pass to quadratic forms, set $q_i(k)=2\sin(k_i/2)$ and $\lambda_q=\sum_i q_i^2$. After we move the phases from the initial vertices to the midpoints of the links and plaquettes, the gradient becomes multiplication by iq, and the curl from links to plaquettes becomes

$$(D(k)u)_{ij}=i(q_iu_j-q_ju_i),\qquad D(k)^*D(k)=\lambda_qI-qq^{\mathsf{T}}.$$

At a frequency $k\neq0$, the identities $H\nabla=0=\nabla^{\mathsf{T}}H$ say that $\widetilde{H}(k)$ vanishes on q and maps into $q^\perp$. If u_T is the component of u orthogonal to q, then Hermitian symmetry and part (3) imply that

$$|\langle u,\widetilde{H}(k)u\rangle|\le C(a)\varepsilon\lambda_q|u_T|^2+C(a)\varepsilon w_n|u|^2=C(a)\varepsilon|D(k)u|^2+C(a)\varepsilon w_n|u|^2.$$

At $k=0$ we use part (1). The unitarity of the finite Fourier transform and the triangle inequality over the frequencies imply part (2) for real and complex link fields. □

Remark 8.7. On the transverse fields with nonzero frequency, the quadratic form of H factors through the curl with a bounded factor: there is an operator T on plaquette fields, diagonal in Fourier space, with $\|T\|_{\mathrm{op}} \le C(a)\varepsilon$ uniformly in n, such that $\langle v, Hv\rangle = \langle \mathrm{d}v, T\mathrm{d}v\rangle$ for every v orthogonal to the gradients and the constant fields. Indeed, at each frequency $k \neq 0$ set

$$T(k) = \lambda_q^{-2} D(k)\widetilde{H}(k)D(k)^*,$$

and set $T(0) = 0$. Since $D^*D = \lambda_q P_q$, where P_q is the orthogonal projection onto $q^\perp$, and $\widetilde{H}(k) = P_q \widetilde{H}(k) P_q$, we have $D(k)^* T(k) D(k) = \widetilde{H}(k)$, and $T(k)$ vanishes on the plaquette directions orthogonal to the range of $D(k)$. Since $\|D(k)\| = \lambda_q^{1/2}$, part (3) implies that $\|T(k)\| \le C(a)\varepsilon(1 + w_n/\lambda_q)$. Every nonzero frequency has $\lambda_q \ge 4\sin^2(\pi/n) \ge 16/n^2$ by the chord inequality, and $\sup_{n\ge 4} n^2(1+n)^3 e^{-c(a)n} < \infty$, so $\|T\|_{\mathrm{op}} \le C(a)\varepsilon$ uniformly in n. The zero-frequency block of H is not part of this factorization; it is estimated separately in part (1). This construction controls only the operator norm of T, and no exponential decay of the kernel of T follows from it. A factorization with exponentially local factors and an exponentially small remainder is proved separately in Lemma 11.11.

8.4 The gauge-corrected block average

In this section and the next we study the iterated block averaging map near a background configuration with small curvature. The background is fixed, and all derivatives are taken with respect to a fluctuation. Gauge-corrected averages, in which the output of each averaging step is multiplied by gauge transformations at the endpoints of the coarse links, occur in Bałaban's averaging construction [12, (61)–(63), p. 28], and their composition is treated in [12, (78)–(92), pp. 30–31; (97)–(100), p. 32]. We use the centered blocks of Definition 4.3, and we derive below the derivative of the corrected step, its endpoint terms, and the order of the composed gauge transformations.

We explain why the estimates are uniform in the number d of averaging steps. We use units in which the coarse spacing after d steps is one, so that the spacing at level j is $\epsilon_j = M^{j-d}$. If $\delta(U_0) \le \varepsilon\epsilon_0^2$, then by Theorem 7.3 the plaquette angles δ_j of $T_M^j U_0$ satisfy $\delta_j \le 2\varepsilon\epsilon_j^2$; they scale like the square of the spacing, as for a smooth field. One gauge-corrected step, written for the potential $A_j = \epsilon_j^{-1} \operatorname{Log} V_j$, has the form

$$A_{j+1} = Q_{U_j} A_j + O_M\big(\epsilon_{j+1}|A_j|^2\big),$$

where the row sums of Q_{U_j} are at most $1 + C_M\delta_j$. The relative errors at level j are of order $\delta_j + \epsilon_{j+1}|A_j|$, and

$$\sum_{j<d} \delta_j \le \frac{2\varepsilon}{M^2-1}, \qquad \sum_{j<d} \epsilon_{j+1} \le \frac{M}{M-1}$$

are bounded independently of d. This is why the constants below do not depend on d, and why the scalar weights of the transported segment average must sum to exactly one in each row, rather than to $1 + c$ for a fixed $c > 0$. All smallness assumptions concern plaquettes and holonomies of contractible closed paths; the background may have arbitrary holonomies around the cycles of the torus.

Definition 8.8. Let U be an $\mathrm{SU}(2)$-valued configuration on a periodic lattice of side Mn' with $n' \geq 4$, and let $V = (V_e)_e$ be a link field with values in $\mathrm{SL}(2,\mathbb{C})$. For a coarse vertex v set

$$\mathsf{h}_{v;U}(V) = \exp\Big[-M^{-3} \sum_{x \in \mathsf{B}_M(v)} \mathrm{Log}\big((VU)(\sigma_{v,x})U(\sigma_{v,x})^{-1}\big)\Big],$$

where $VU = (V_e U_e)_e$, and write $\mathsf{h}_U(V)$ for the gauge transformation $(\mathsf{h}_{v;U}(V))_v$ on the coarse vertices. For a coarse link $c = (v, s)$, $s = v + Me_i$, define the gauge-corrected block average

$$(\mathscr{M}_U(V))_c = \mathsf{h}_{v;U}(V)\,(T_M(VU))_c\,\mathsf{h}_{s;U}(V)^{-1}\,(T_M U)_c^{-1}.$$

For a fine spacing $\epsilon > 0$ and a link field A of potentials, set

$$\Psi_{U,\epsilon}(A) = (M\epsilon)^{-1}\,\mathrm{Log}\,\mathscr{M}_U(e^{\epsilon A}).$$

All logarithms are identity-chart logarithms; Lemma 8.9 shows that they are defined in the domains used below.

In other words, $\mathscr{M}_U(V)\,T_M U$ is the gauge transform of $T_M(VU)$ by $\mathsf{h}_U(V)$, and $\mathscr{M}_U(V)$ is its transport relative to the background output $T_M U$. The endpoint gauge transformation at v is chosen so that its derivative cancels the contribution of the connectors $\sigma_{v,x}$ in Figure 8.1. For a gauge transformation k on the vertices of a lattice, we write $k|_{\mathrm{roots}}$ for its restriction to the vertices of the next coarser lattice, which are the centers of the blocks.

Lemma 8.9. *Fix an odd $M \geq 3$, a radius $0 < \rho_{\log} < 2\pi$ inside the real identity chart of $\mathrm{SU}(2)$, and a radius $0 < r_{\log} < 1$ for the matrix logarithm series. There exist $b_M, \delta_M > 0$ and $q_M, C_M < \infty$, depending only on these data, such that the following holds for every application of T_M from a periodic lattice of side Mn' to the lattice of side n', $n' \geq 4$.*

1. *For each coarse link $c = (v, v + Me_i)$, the paths C_c, $F_{c,x}$, $\sigma_{v,x}$, and $\sigma_{v+Me_i,x+Me_i}$, $x \in \mathsf{B}_M(v)$, have at most q_M links and lie in a neighborhood of c of radius depending only on M, and each fine link belongs to at most a number depending only on M of these neighborhoods.*
2. *If U is $\mathrm{SU}(2)$-valued and $\delta(U) = \max_p \rho_G(U_p) \leq \delta$ with $0 \leq \delta < \delta_M$, then every based loop holonomy $U(F_{c,x})U(C_c)^{-1}$ has an identity-chart logarithm of norm at most $C_M\delta$.*
3. *For such U and complex link variables with $\max_e |X_e| < b_M$, the path products with links $e^{X_e}U_e$, their relative logarithms, and the logarithm $\mathrm{Log}\,\mathscr{M}_U(e^X)$ of the gauge-corrected average are holomorphic in X. On a fixed smaller ball, each partial derivative of fixed order*

in the finitely many relevant X_e is bounded by a constant depending only on M, the order, and the radii $\rho_{\log}$, $r_{\log}$. The logarithm $\operatorname{Log} \mathscr{M}_U(e^X)$ vanishes at $X = 0$.

These bounds are independent of the holonomies of U around the cycles of the torus and of n', and they include reversed links.

Proof. Each coordinate path has length at most $3(M-1)/2$, and the middle segment has length M. The union of the two adjacent centered blocks has extent $2M-1$ in the direction of the link and $M-1$ in the other two. Since the fine side is $Mn' \geq 4M$, this union lifts to a box in $\mathbb{Z}^3$ without winding. All occurrences of a fixed fine link lie in a bounded number of such neighborhoods: their coarse vertices are within a distance depending on M, and there are three orientations and boundedly many paths.

We next prove a filling estimate. In a lifted box of maximal extent D, we choose its lower corner and the coordinate paths, ordered $1, 2, 3$, from it to every vertex. For a positive link in direction i, we append the link to the ordered path of its initial vertex and move it to the left past the portions of the path in directions greater than i. Each interchange replaces two adjacent perpendicular links by the other two links of their elementary square. There are at most $3D$ interchanges, all within the box. Inserting a square changes the transport by a conjugate of the plaquette transport or its inverse. Hence, in the frame given by the ordered paths, the transport of this link is a product of at most $3D$ conjugated plaquette transports. For a reversed link we take the inverse. Along a closed path of length q the frames cancel at successive vertices, and the transport around the path is, up to one conjugation, a product of at most $3Dq$ conjugated plaquette transports. We apply this to $F_{c,x}C_c^{-1}$ in the box above, with $D \leq 2M-1$ and $q \leq q_M$, which gives at most $s_M = 3(2M-1)q_M$ plaquette factors. A product of s elements of $\mathrm{SU}(2)$, each within group distance δ of the identity, is within group distance $s\delta$ of the identity, as one sees by concatenating the shortest one-parameter subgroups and using the bi-invariance of the metric. Let $0 < \delta_M \leq \rho_{\log}/(2s_M)$. For $0 \leq \delta < \delta_M$, every based loop holonomy is within group distance $s_M\delta < \rho_{\log}$ of the identity, so its identity-chart logarithm exists and has norm at most $s_M\delta$. This proves part (2), and further decreases of δ_M below preserve it.

For the complex bounds, write a positive link as $e^{X_e}U_e$ and a reversed link as $U_e^{-1}e^{-X_e}$. For a path product W, moving the fixed $\mathrm{SU}(2)$-valued factors to the right writes $W(X)W(0)^{-1}$ as a product of at most q_M exponentials of $\pm X_e$, each conjugated by an $\mathrm{SU}(2)$-valued partial transport. On the complexified color space these conjugations are unitary, so in a fixed matrix norm

$$\|W(X)W(0)^{-1} - I\| \leq \exp\bigl(Cq_M \max_e |X_e|\bigr) - 1,$$

as one sees by expanding each exponential absolutely and multiplying the bounds. For a based loop holonomy, the value at $X = 0$ is within $C_M\delta$ of the identity by part (2).

Choosing b_M and δ_M small puts all these matrices in the ball $\|Z - I\| < r_{\log}$, on which $\operatorname{Log} Z = \sum_{\ell \geq 1} (-1)^{\ell+1} (Z-I)^{\ell}/\ell$ converges absolutely. Its derivatives on smaller balls are bounded by the differentiated series, and the exponential series has the same property everywhere. The endpoint gauge transformations equal the identity at $X = 0$, and there the output of T_M equals the background output, so $\mathscr{M}_U(e^0) = I$. After decreasing b_M, its logarithm lies in the same chart. At most q_M distinct link variables enter, even when a link occurs repeatedly. Bounds for every partial derivative of fixed order follow by differentiating these finite products and series, or by Cauchy's formula on fixed circles in these finitely many complex variables. Neither method introduces a dependence on the side or the depth. □

Lemma 8.10. *Fix an odd $M \geq 3$ and the radii $\rho_{\log}, r_{\log}$ of Lemma 8.9. There exist $\varepsilon_*, a_*, \delta_{\mathrm{av}}, C_M > 0$, depending only on these data, with $2\varepsilon_* \leq \delta_{\mathrm{av}} < \delta_M$, such that the following holds for all integers $d \geq 0$ and $n \geq 4$. Use units in which the spacing of the coarse lattice of side n is one, so that the lattice at level j has side $M^{d-j}n$ and spacing $\epsilon_j = M^{j-d}$, $0 \leq j \leq d$.*

1. One step. *Let U be an $\mathrm{SU}(2)$-valued configuration on a periodic lattice of side Mn', $n' \geq 4$, with $\delta(U) = \delta \leq \delta_{\mathrm{av}}$, and let $0 < \epsilon \leq 1/M$. On the complex ball $\|A\|_\infty < 2a_*$,*

$$\Psi_{U,\epsilon}(A) = Q_U A + \mathscr{E}_{U,\epsilon}(A), \qquad \|Q_U\|_{\mathrm{row}} \leq 1 + C_M\delta,$$
$$\|\mathscr{E}_{U,\epsilon}(A)\|_\infty \leq C_M M\epsilon \|A\|_\infty^2, \qquad \|D\mathscr{E}_{U,\epsilon}(A)\|_{\mathrm{row}} \leq C_M M\epsilon \|A\|_\infty,$$

   where $Q_U = D\Psi_{U,\epsilon}(0)$ does not depend on ϵ. Its principal part is the transported segment average

$$(Q_U^{\mathrm{main}} A)_c = M^{-4} \sum_{x \in \mathsf{B}_M(v)} \sum_{e \in [x, x+Me_i]} \operatorname{Ad}\big(U(\sigma_{v,x}[x, e^-])\big) A_e, \qquad c = (v, v + Me_i),$$

   where e^- is the initial vertex of e and $\sigma_{v,x}[x, e^-]$ is the path $\sigma_{v,x}$ followed by the segment from x to e^-. The scalar averaging weights in each row of Q_U^{main} sum to exactly one, the norms of its color blocks in each row sum to at most one, and $Q_U - Q_U^{\mathrm{main}}$ has row norm at most $C_M\delta$.

2. Iteration. *Let U_0 be an $\mathrm{SU}(2)$-valued configuration on the lattice of side $M^d n$ with $\delta(U_0) \leq \varepsilon\epsilon_0^2$ for some $0 \leq \varepsilon \leq \varepsilon_*$, and set $U_j = T_M^j U_0$. Then $\delta_j = \delta(U_j) \leq 2\varepsilon\epsilon_j^2$ for $0 \leq j \leq d$. For $\|A\|_\infty < a_*$ define*

$$V_0 = e^{\epsilon_0 A}, \qquad V_{j+1} = \mathscr{M}_{U_j}(V_j), \qquad A_j = \epsilon_j^{-1} \operatorname{Log} V_j.$$

   The recursion is defined and holomorphic on this ball, and for $0 \leq j \leq d$

$$\|A_j\|_\infty \leq 2\|A\|_\infty, \qquad \|D_A A_j\|_{\mathrm{row}} \leq \exp\Big[C_M \sum_{\ell < j} (\delta_\ell + \epsilon_{\ell+1}\|A_\ell\|_\infty)\Big] \leq C_M.$$

The coordinate $(A_j)_c$ depends only on the variables A_e with $\operatorname{dist}(c,e) \le C_M\epsilon_j$, where distances are measured in the units above, in which the coarse spacing is one. For every fixed $a_{\mathrm{sp}} \ge 0$ we have $\|D_A A_j\|_{a_{\mathrm{sp}},\mathrm{row}} \le C_{M,a_{\mathrm{sp}}}$ on the same ball. For every fixed $s \ge 1$, on the ball $\|A\|_\infty < a_*/2$, every coarse link c and all link fields $B_1,\dots,B_s$,

$$\left|\left(D_A^s A_j(A)[B_1,\dots,B_s]\right)_c\right| \le C_{M,s,a_{\mathrm{sp}}} \prod_{\ell=1}^{s} \sup_e e^{-a_{\mathrm{sp}}\operatorname{dist}(c,e)} |(B_\ell)_e|.$$

3. Composed gauge transformation. *Define gauge transformations on the vertices of the lattice at level j by*

$$\mathsf{G}_0 = I, \qquad \mathsf{G}_{j+1} = \mathsf{h}_{U_j}(V_j)\,(\mathsf{G}_j|_{\mathrm{roots}}).$$

Then

$$V_j U_j = \left(T_M^j(e^{\epsilon_0 A}U_0)\right)^{\mathsf{G}_j}, \qquad 0 \le j \le d.$$

For real A the gauge transformations G_j are $\mathrm{SU}(2)$-valued. On a fixed smaller complex ball they and their inverses have uniformly bounded holomorphic logarithms; the factors satisfy $\|\operatorname{Log}\mathsf{h}_{U_j}(V_j)\| \le C_M\epsilon_j\|A_j\|_\infty$, whose sum over j is bounded.

The constants in parts (1)–(3) do not depend on n, n', d, j, the holonomies of the background around the cycles of the torus, L, or γ; the constants $C_{M,a_{\mathrm{sp}}}$ and $C_{M,s,a_{\mathrm{sp}}}$ depend in addition only on a_{sp} and s.

Proof. We begin with the curvature along the background trajectory. Let $0 < \varepsilon_* \le \varepsilon_M$, with ε_M as in Theorem 7.3. At level j the background has side $M^{d-j}n$, and every step $j < d$ goes from side $M \cdot M^{d-j-1}n$ to side $M^{d-j-1}n \ge n \ge 4$, with the factor M and spacings $\epsilon_j = M^{j-d}$. For $0 < \varepsilon \le \varepsilon_*$, the hypothesis $\delta(U_0) \le \varepsilon\epsilon_0^2$ is the hypothesis of the curvature iteration in Theorem 7.3, which shows that T_M is given by its logarithmic formula at every step and yields the curvature bounds below. If $\varepsilon = 0$, then $\delta(U_0) = 0$, and for every $\eta \in (0,\varepsilon_M]$ the same background satisfies $\delta(U_0) \le \eta\epsilon_0^2$. We apply the same theorem with η in place of ε. The iterates $U_j = T_M^j U_0$ do not depend on η, and each application bounds the same fields by $\delta_j \le 2\eta\epsilon_j^2$; letting $\eta \downarrow 0$, we obtain $\delta_j = 0$ for every j, and any one application with positive η shows that the logarithmic formula applies. When $d = 0$ the bound is the hypothesis and the sums below are empty. In all cases, for $0 \le \varepsilon \le \varepsilon_*$,

$$\delta_j \le 2\varepsilon\epsilon_j^2, \qquad \sum_{j<d} \delta_j \le \frac{2\varepsilon}{M^2-1}. \tag{8.6}$$

We fix $0 < \delta_{\mathrm{av}} < \delta_M$, with δ_M from Lemma 8.9, and impose $2\varepsilon_* \le \delta_{\mathrm{av}}$. Every application below with $0 \le \delta \le \delta_{\mathrm{av}}$ then satisfies the curvature hypothesis $\delta < \delta_M$ of that lemma. We decrease ε_*, δ_{av}, and the fluctuation radius finitely many times below.

Step 1: The one-step differential and its endpoint terms. Fix an $\mathrm{SU}(2)$-valued U with $\delta(U) = \delta \le \delta_{\mathrm{av}}$, and write X for a link field of infinitesimal fluctuations. For a path η, the product rule and $(e^{tX_e}U_e)^{-1} = U_e^{-1}e^{-tX_e}$ give the left-trivialized derivative of the transport,

$$p_\eta(X) = \sum_{\substack{\text{positive}\\ \text{occurrences } e}} \mathrm{Ad}\big(U(\eta_{\text{before } e})\big)X_e - \sum_{\substack{\text{negative}\\ \text{occurrences } \bar e}} \mathrm{Ad}\big(U(\eta_{\text{before } \bar e})U_e^{-1}\big)X_e,$$

where $\eta_{\text{before } e}$ is the part of η preceding the occurrence. All transports in this formula are $\mathrm{SU}(2)$-valued, hence orthogonal on colors.

To differentiate T_M without discarding a term, let $F_x = U(F_{c,x})$, $C = U(C_c)$, $L_x = F_xC^{-1}$, $Z = M^{-3}\sum_x \operatorname{Log} L_x$, and $O = e^ZC = (T_MU)_c$. Let $f_x = \dot F_x F_x^{-1}$ and $c_0 = \dot C C^{-1}$, where the dot denotes the derivative in the direction X, and introduce the left-trivialized differentials

$$\mathcal{E}_Z(Y) = (D\exp_Z Y)e^{-Z}, \qquad \mathcal{L}_{L_x}(Y) = D\operatorname{Log}_{L_x}(YL_x).$$

By the product rule, we have

$$\dot O O^{-1} = \mathcal{E}_Z\Big[M^{-3}\sum_x \mathcal{L}_{L_x}\big(f_x - \mathrm{Ad}(L_x)c_0\big)\Big] + \mathrm{Ad}(e^Z)c_0. \tag{8.7}$$

By Lemma 8.9, $|\operatorname{Log} L_x| \le C_M\delta$ and $|Z| \le C_M\delta$. Using the convergent exponential and logarithm series, we obtain $\mathcal{E}_Z = I + O_M(\delta)$, $\mathcal{L}_{L_x} = I + O_M(\delta)$, $\mathrm{Ad}(L_x) = I + O_M(\delta)$, and $\mathrm{Ad}(e^Z) = I + O_M(\delta)$ as operators. Their absolute local coefficient sums have the same bounds, because at most q_M local labels occur. Replacing these four operators by I in (8.7) cancels the two terms containing c_0 and leaves $M^{-3}\sum_x f_x$. The replacement error, as a linear map of X, has absolute row norm at most $C_M\delta$.

We split the derivative along the path at its two endpoint connectors:

$$f_x = p_{\sigma_{v,x}}(X) + p^{\mathrm{seg}}_{v,x}(X) - \mathrm{Ad}(F_x)p_{\sigma_{s,x+Me_i}}(X), \qquad s = v + Me_i.$$

The middle term is the sum of the variations of the M links of the segment $[x, x+Me_i]$, transported first along $\sigma_{v,x}$ and then along the segment up to the link. Differentiating the endpoint gauge transformation, we find

$$\dot{\mathsf{h}}_{v;U}(I) = -M^{-3}\sum_x p_{\sigma_{v,x}}(X).$$

The left-trivialized derivative of the gauge-corrected output is the derivative of T_M minus this mean over the initial connectors, plus $\mathrm{Ad}(O)$ times the corresponding mean over the terminal connectors. The terms of the initial connectors cancel exactly. The remaining terminal terms are

$$M^{-3}\sum_x \{\mathrm{Ad}(O) - \mathrm{Ad}(F_x)\}p_{\sigma_{s,x+Me_i}}(X);$$

here the average over $x + Me_i$ is exactly the average over $\mathsf{B}_M(s)$ in the definition of $\mathsf{h}_{s;U}$, with the same paths. These terms have absolute row norm at most $C_M\delta$, since $OF_x^{-1} = e^Z L_x^{-1}$ is within $C_M\delta$ of the identity and $\mathrm{SU}(2)$-valued transports have norm one.

The remaining segment derivative is

$$M^{-3} \sum_{x \in \mathsf{B}_M(v)} \sum_{e \in [x, x+Me_i]} \mathrm{Ad}\big(U(\sigma_{v,x}[x, e^-])\big) X_e.$$

For $X = \epsilon A$, division by the coarse length $M\epsilon$ gives Q_U^{main}. There are M^4 occurrences of weight M^{-4}, each an orthogonal map on colors. The scalar weights in each row therefore sum to one, and the norms of the color blocks in each row sum to at most one. The endpoint and coefficient errors above, divided by M, are still bounded by $C_M\delta$. We conclude that $Q_U = D\Psi_{U,\epsilon}(0)$ does not depend on ϵ and satisfies the row estimates of part (1).

Step 2: The one-step remainder. Let $F_U(X) = \mathrm{Log}\, \mathscr{M}_U(e^X)$, which vanishes at $X = 0$. By Lemma 8.9, its second derivative has absolute row norm at most C_M on a fixed complex ball of X, uniformly in U. Here the row sums over both inputs, and the bounded size of the stencils justifies this absolute bound. Since $\Psi_{U,\epsilon}(A) = (M\epsilon)^{-1} F_U(\epsilon A)$, on a fixed complex ball of A with $\epsilon \le 1/M$,

$$\|D_A^2 \Psi_{U,\epsilon}\|_{\mathrm{row}} \le C_M \frac{\epsilon^2}{M\epsilon} = C_M \epsilon / M \le C_M M\epsilon.$$

The quadratic bound for $\mathscr{E}_{U,\epsilon}$ follows from Taylor's formula along the segment tA, $0 \le t \le 1$. Integrating the second derivative along the same segment gives the bound for its first derivative. This proves part (1) on $\|A\|_\infty < 2a_*$, after choosing $2a_*$ inside that ball.

Step 3: Uniform iteration. Let C dominate the constants of part (1). Since $A_{j+1} = \Psi_{U_j,\epsilon_j}(A_j)$, $M\epsilon_j = \epsilon_{j+1}$, and $\epsilon_j \le 1/M$ for $j < d$, the norms $b_j = \|A_j\|_\infty$ satisfy, whenever the iteration is defined,

$$b_{j+1} \le b_j\big(1 + C\delta_j + C\epsilon_{j+1} b_j\big), \qquad \sum_{j<d} \epsilon_{j+1} \le \frac{M}{M-1}.$$

We choose the radii so small that

$$C\Big(\frac{2\varepsilon_*}{M^2 - 1} + \frac{2a_* M}{M-1}\Big) < \log(3/2). \tag{8.8}$$

For an input with $\|A\|_\infty = t < a_*$, as long as $b_\ell \le 2t$ for $\ell < j$, multiplying the inequalities and using $\log(1+u) \le u$, we obtain

$$b_j \le t \exp\Big[C \sum_{\ell<j} \delta_\ell + 2Ct \sum_{\ell<j} \epsilon_{\ell+1}\Big] < \tfrac{3}{2} t.$$

In particular b_j never reaches $2t$, so the bound holds for all $j \le d$, and each step stays in the domain $b_j < 2a_*$ of part (1). Since a finite composition of holomorphic maps is holomorphic, the recursion is holomorphic on the input ball at every finite depth. For $t = 0$ it vanishes identically, and for $d = 0$ it is the identity.

The derivative of one step at A_j, including the nonlinear remainder, has row norm at most $1 + C_M(\delta_j + \epsilon_{j+1} b_j)$. By the submultiplicativity of absolute row sums, we obtain the bound for $D_A A_j$ in part (2). By (8.6) and the bootstrap, its exponent is at most

$$C_M\Big(\frac{2\varepsilon_*}{M^2-1} + \frac{2a_*M}{M-1}\Big),$$

which does not depend on d, n, or j.

Step 4: Locality and directional derivatives. An output of one step depends only on inputs within a neighborhood of radius $r_M^{\mathrm{loc}}\epsilon_j$, where $r_M^{\mathrm{loc}} < \infty$ is a fixed stencil radius. If r_j is the dependence radius at level j, measured in the units in which the coarse spacing is one, then $r_{j+1} \le r_j + r_M^{\mathrm{loc}}\epsilon_j$ and $r_0 = 0$. Summing the geometric series, we find $r_j \le C_M\epsilon_j$. The same recursion bounds the background links on which the coefficients depend, since each preceding application of T_M has a neighborhood of the same scale. The assertion holds on the torus, since each neighborhood can be lifted to a box before returning to the torus. Inserting the weight $e^{a_{\mathrm{sp}}\,\mathrm{dist}(c,e)}$ multiplies the bound for the first derivative by at most $e^{a_{\mathrm{sp}}C_M\epsilon_j} \le e^{a_{\mathrm{sp}}C_M}$.

For the higher derivatives, take the smaller ball $\|A\|_\infty < a_*/2$. For link fields $B_1, \dots, B_s$ with $\|B_\ell\|_\infty \le 1$, the map $(t_1, \dots, t_s) \mapsto A_j(A + \sum_\ell t_\ell B_\ell)$ is bounded by $2a_*$ for $|t_\ell| < a_*/(4s)$. Cauchy's formula on these circles bounds its mixed coefficient, and hence $\|D_A^s A_j(A)[B_1, \dots, B_s]\|_\infty$, by $2a_*(4s/a_*)^s$. This bounds a multilinear operator norm; absolute sums of coefficients over the inputs are treated in Lemma 8.11. For the weighted bound, restrict each B_ℓ to the dependence neighborhood of the fixed output c, which does not change the derivative by locality. On that neighborhood $|(B_\ell)_e| \le e^{a_{\mathrm{sp}}C_M} \sup_{e'} e^{-a_{\mathrm{sp}}\,\mathrm{dist}(c,e')}|(B_\ell)_{e'}|$, so the multilinear bound acquires at most the factor $e^{sa_{\mathrm{sp}}C_M}$.

Step 5: The composed gauge transformation. For a gauge transformation k, a transport along a path from v to s transforms as $k_v U(\eta) k_s^{-1}$. The based loop holonomies $U(F_{c,x})U(C_c)^{-1}$ are conjugated by k_v. Within the identity chart the logarithm series and the exponential are equivariant under conjugation, and substituting into the formula for T_M, we obtain

$$T_M(W^k) = (T_M W)^{k|_{\mathrm{roots}}}.$$

For SU(2)-valued gauge transformations this also holds at the configurations where the Borel extension is used, since the exceptional matrix $-I$ is central. For complex gauge transformations we use only the domain where all logarithms are given by their series.

Let $Z_j = T_M^j(e^{\epsilon_0 A}U_0)$. If $V_jU_j = Z_j^{\mathsf{G}_j}$, then by the definition of $\mathscr{M}$ and the gauge identity we have

$$V_{j+1}U_{j+1} = \big(T_M(V_jU_j)\big)^{\mathsf{h}_{U_j}(V_j)} = (T_MZ_j)^{\mathsf{h}_{U_j}(V_j)(\mathsf{G}_j|_{\mathrm{roots}})},$$

where we used $(W^k)^l = W^{lk}$. Starting at $j = 0$, induction proves the identity of part (3) with the stated order of the factors. For real A, every relative transport in an endpoint gauge transformation is $\mathrm{SU}(2)$-valued with small logarithm in $\mathfrak{su}(2)$. Then every factor and every G_j is $\mathrm{SU}(2)$-valued.

For complex A, Lemma 8.9 and the definition of h imply that

$$\|\mathrm{Log}\,\mathsf{h}_{U_j}(V_j)\| \le C_M\epsilon_j b_j, \qquad \sum_{j<d}\epsilon_j b_j \le \frac{2\|A\|_\infty}{M-1}.$$

It follows that all partial products and their inverses have norm at most $\exp(C_M\|A\|_\infty)$ and differ from the identity by at most $\exp(C_M\|A\|_\infty) - 1$. We decrease a_* once so that the last quantity is less than $1/2$. The logarithms then exist by the same convergent series and are holomorphic and uniformly bounded.

It remains to check that the gauge identities do not leave the logarithm chart. At level j, every based loop holonomy of V_jU_j differs from the identity by at most $C_M(\delta_j + \epsilon_j b_j)$, by Lemma 8.9. The corresponding based loop holonomy of Z_j is its conjugate by G_j^{-1}, and its distance to the identity in matrix norm is larger by at most the factor $\exp(C_M\|A\|_\infty)$. The bounds $\delta_j \le 2\varepsilon_*\epsilon_j^2$ and $b_j \le 2a_*$ allow one further decrease of ε_* and a_* after which both based loop holonomies lie strictly inside the chart. The conjugation identity for the logarithm series then holds term by term, and the induction above applies at every level on this ball. This shows that the complex gauge relation is an identity of holomorphic maps, not only of Taylor coefficients. All choices involved only M and the radii $\rho_{\log}$, $r_{\log}$. □

8.5 Volume-normalized column sums and derivative bounds

We now prove bounds on absolute sums of derivative coefficients of the iterates $A_j = \Phi_j(A)$ of Lemma 8.10, with either the output or any one input held fixed. Two normalizations of column sums occur. For a matrix P from link fields at spacing ϵ_0 to link fields at spacing ϵ_j, the counting column norm is $\sup_e \sum_c \|P(c,e)\|$. The volume-normalized column norm of Definition 4.6, with $a_{\mathrm{out}} = \epsilon_j$ and $a_{\mathrm{in}} = \epsilon_0$, is $(\epsilon_j/\epsilon_0)^3$ times the counting column norm. A fine link contributes to few coarse links, each time with a small weight. The counting column sums of $D\Phi_j$ are therefore of order $(\epsilon_0/\epsilon_j)^3 = M^{-3j}$, and the volume-normalized column sums are bounded. For derivatives of higher order with one input fixed, exactly one such volume factor appears. For example, with one fixed input e_1,

$$D^2(\Psi\circ\Phi)[e_1,e_2] = D^2\Psi\big[D\Phi\,e_1, D\Phi\,e_2\big] + D\Psi\,D^2\Phi[e_1,e_2];$$

in the first term, the branch that contains e_1 is summed with a column sum of $D\Phi$ and the other branch with a row sum, and only one factor $(\epsilon_0/\epsilon_j)^3$ is produced. The proof below organizes this observation by an induction over the order, using the set-partition form of the chain rule.

Lemma 8.11. *Assume the hypotheses of part (2) of Lemma 8.10, and let A range over a fixed smaller complex ball on which the bounds of Lemmas 8.9 and 8.10 hold with a fixed margin. Write $\Phi_j(A) = A_j$ and, for $j < d$, $e_j = \delta_j + \epsilon_{j+1}\|A_j\|_\infty$. The derivative of one step decomposes as*

$$L_j = D\Psi_{U_j,\epsilon_j}(A_j) = K_j + E_j, \qquad K_j = Q_{U_j}^{\mathrm{main}},$$

and the nonnegative scalar kernel of occurrences

$$k_M(c,e) = M^{-4}\#\big\{(x,s) : x \in \mathsf{B}_M(v),\ 0 \le s < M,\ e = (x + se_i, x + (s+1)e_i)\big\}$$

for $c = (v, v + Me_i)$, has row sums exactly 1 and column sums exactly M^{-3}; the sums of the norms of the color blocks of K_j are no larger. With counting column norms,

$$\begin{aligned} \|L_j\|_{\mathrm{row}} &\le 1 + C_M e_j, & \|L_j\|_{\mathrm{col}} &\le M^{-3}(1 + C_M e_j),\\ \|E_j\|_{\mathrm{row}} &\le C_M e_j, & \|E_j\|_{\mathrm{col}} &\le M^{-3} C_M e_j. \end{aligned}$$

Set $S_j = \sum_{\ell<j} e_\ell$, $P_j = L_{j-1}\cdots L_0 = D\Phi_j$, and $P_j^0 = K_{j-1}\cdots K_0$, empty products being the identity. Then

$$\begin{aligned} \|P_j\|_{\mathrm{row}} &\le e^{C_M S_j}, & \|P_j\|_{\mathrm{col}} &\le (\epsilon_0/\epsilon_j)^3 e^{C_M S_j},\\ \|P_j - P_j^0\|_{\mathrm{row}} &\le C_M S_j e^{C_M S_j}, & \|P_j - P_j^0\|_{\mathrm{col}} &\le C_M (\epsilon_0/\epsilon_j)^3 S_j e^{C_M S_j}, \end{aligned}$$

and these bounds follow from the identity

$$P_j - P_j^0 = \sum_{\ell<j} K_{j-1}\cdots K_{\ell+1} E_\ell L_{\ell-1}\cdots L_0.$$

For every fixed $a_{\mathrm{sp}} \ge 0$, the coefficients of the last iterate satisfy

$$\|D_{A_e}\Phi_d(c)\| \le C_{M,a_{\mathrm{sp}}} \epsilon_0^3 e^{-a_{\mathrm{sp}}\,\mathrm{dist}(c,e)},$$

and $D\Phi_j$ is bounded from ℓ^2 with weight ϵ_0^3 to ℓ^2 with weight ϵ_j^3, uniformly. For every fixed $s \ge 1$ and $0 \le j \le d$, with $\mathtt{t}(c, e_1, \dots, e_s)$ the length of a shortest connecting network of the locations of $c, e_1, \dots, e_s$, measured in the units in which the coarse spacing is one,

$$\begin{aligned} \sup_c \sum_{e_1,\dots,e_s} e^{a_{\mathrm{sp}}\mathtt{t}(c,e_1,\dots,e_s)} \|D_{A_{e_1}}\cdots D_{A_{e_s}}\Phi_j(c)\| &\le C_{M,s,a_{\mathrm{sp}}},\\ \sup_{e_1} \sum_{c,e_2,\dots,e_s} e^{a_{\mathrm{sp}}\mathtt{t}(c,e_1,\dots,e_s)} \|D_{A_{e_1}}\cdots D_{A_{e_s}}\Phi_j(c)\| &\le C_{M,s,a_{\mathrm{sp}}} (\epsilon_0/\epsilon_j)^3. \end{aligned}$$

In the second bound any one input may be fixed, and multiplying by $(\epsilon_j/\epsilon_0)^3$ gives a bounded volume-normalized column sum in the sense of Definition 4.6. All orientations, repeated inputs, and periodic identifications are included. The constants may depend on M, s, a_{sp}, the radii of Lemma 8.9, and the ratio of the nested balls, but not on j, d, n, L, γ, or the holonomies of the background. The bounds hold for each fixed order s; no bound uniform in s, such as a factorial bound, and no factor ϵ_0^{3s} for individual coefficients of order s, is asserted.

Proof. The background configurations $U_0, \dots, U_d$ are fixed and are not differentiated. We shrink the ball of fluctuations inside the ball of Lemma 8.10, so that the derivative bounds of Lemma 8.9 hold with a fixed margin.

Step 1: Exact incidence and the first derivative of one step. A coarse i-link has M^3 segment starts and M positively oriented links in each segment, and its scalar row sum is $M^4M^{-4} = 1$. For a fixed fine link $e = (z, z + e_i)$, the segment starts whose segments contain e are exactly $x = z - se_i$, $0 \le s < M$. Each start lies in exactly one centered block, and the vertex of that block determines exactly one coarse link in direction i. There are exactly M occurrences, and the scalar column sum is $MM^{-4} = M^{-3}$. If several occurrences share a coefficient block, combining their orthogonal transports cannot increase the sum of the norms, so the color-block sums of K_j obey the same upper bounds. The count also holds across the periodic seams: the fine side of a single averaging step is at least $4M$; the M starts are distinct, and the centered blocks partition the vertices. No reversed link occurs in K_j; reversed links and mixed orientations in the other paths are covered by the bound on overlaps in Lemma 8.9.

By the proof of Lemma 8.10, we have $\|E_j\|_{\mathrm{row}} \le C_M(\delta_j + \epsilon_{j+1}\|A_j\|_\infty) = C_M e_j$. Let J_M be the largest number of coarse output stencils that contain a given fine input link, counting all orientations and repetitions. Each coefficient norm is bounded by the row sum of its output, so $\|E_j\|_{\mathrm{col}} \le J_M C_M e_j$. Since M is fixed, we replace the constant by $M^3 J_M C_M$ and write this as $\|E_j\|_{\mathrm{col}} \le M^{-3} C_M e_j$, which keeps the factor M^{-3} of the column sum of K_j. Adding the bounds for K_j proves the four one-step estimates. This also applies for complex A_j, since orthogonality was used only for K_j, whose transports are those of the background.

Step 2: Products and the ordered telescope. For counting norms, $\|(AB)_{xz}\| \le \sum_y \|A_{xy}\|\|B_{yz}\|$ gives submultiplicativity of row sums and of column sums. As in Step 3 of the proof of Lemma 8.10, we obtain

$$\|P_j\|_{\mathrm{row}} \le \prod_{\ell<j}(1 + C_M e_\ell) \le e^{C_M S_j}, \qquad \|P_j\|_{\mathrm{col}} \le M^{-3j} e^{C_M S_j},$$

and $M^{-3j} = (\epsilon_0/\epsilon_j)^3$. For the telescope, we replace the leftmost factor L_{j-1} by $K_{j-1} + E_{j-1}$ and keep the term with E_{j-1}; then we make the same replacement in the next factor of the remaining product of factors K, and so on. After the last replacement the remaining

product is P_j^0, which gives the identity in the statement. Its summand with index ℓ has row norm at most $C_M e_\ell e^{C_M S_j}$. Its column norm contains exactly j factors M^{-3}, including the one in E_ℓ, and is at most $M^{-3j} C_M e_\ell e^{C_M S_j}$. Summing over ℓ proves the bounds for $P_j - P_j^0$; the error is proportional to S_j rather than to the number of levels. We also recall from the proof of Lemma 8.10 the uniform bound

$$S_j \le \frac{2\varepsilon_*}{M^2-1} + \frac{2a_* M}{M-1}. \tag{8.9}$$

Step 3: Pointwise and ℓ^2 bounds. Each coefficient $D_{A_e}\Phi_d(c)$ is bounded by the counting column sum containing it, hence by $C_M\epsilon_0^3$, since $\epsilon_d = 1$. It vanishes unless e is within distance C_M of c, by the locality in Lemma 8.10. Multiplying by $e^{a_{\mathrm{sp}} C_M}$ proves the pointwise exponential bound for every fixed $a_{\mathrm{sp}} \ge 0$. For a block matrix P with row bound R and column bound C, the weighted Cauchy–Schwarz inequality at each output implies that

$$\sum_c \Big| \sum_e P_{ce} u_e \Big|^2 \le R \sum_{c,e} \|P_{ce}\| |u_e|^2 \le RC \sum_e |u_e|^2.$$

For $P = P_j$ we have $RC \le C_M(\epsilon_0/\epsilon_j)^3$. Multiplying the left side by ϵ_j^3, we find that it is at most $C_M\epsilon_0^3 \sum_e |u_e|^2$, as required.

Step 4: Absolute bounds for higher derivatives of one step. For $r \ge 2$, we apply the derivative bounds of Lemma 8.9 to $\Psi_{U_j,\epsilon_j}(A) = \epsilon_{j+1}^{-1} F_{U_j}(\epsilon_j A)$. Every partial derivative of order r carries the factor $\epsilon_j^r/\epsilon_{j+1} = \epsilon_j^{r-1}/M$, which is at most ϵ_{j+1} since $\epsilon_j \le 1/M$. Summing over the at most q_M^r tuples of local inputs, we obtain, with $\Psi_j = \Psi_{U_j,\epsilon_j}$ evaluated at A_j,

$$\begin{aligned} \sup_c \sum_{b_1,\dots,b_r} \|D_{b_1}\cdots D_{b_r}\Psi_j(c)\| &\le C_{M,r}\epsilon_{j+1}, \\ \sup_{b_1} \sum_{c,b_2,\dots,b_r} \|D_{b_1}\cdots D_{b_r}\Psi_j(c)\| &\le M^{-3} C_{M,r}\epsilon_{j+1}. \end{aligned} \tag{8.10}$$

The second estimate uses the bound J_M on output stencils and absorbs $M^3 J_M$ into the constant, as in Step 1. These absolute sums use only that finitely many local variables enter, not directional Cauchy estimates. By symmetry of derivatives, any input may be the fixed one in the second line.

Step 5: Induction over the order. We first omit the spatial weights and set

$$R_s(j) = \sup_c \sum_{e_1,\dots,e_s} \|D_{e_1}\cdots D_{e_s}\Phi_j(c)\|, \qquad C_s(j) = \sup_{e_1} \sum_{c,e_2,\dots,e_s} \|D_{e_1}\cdots D_{e_s}\Phi_j(c)\|,$$

and $\widehat{C}_s(j) = (\epsilon_j/\epsilon_0)^3 C_s(j)$. Step 2 bounds R_1 and $\widehat{C}_1$. For $s \geq 2$ both vanish at $j = 0$, since $\Phi_0(A) = A$. By the set-partition form of the chain rule (Faà di Bruno's formula), the derivatives of $\Phi_{j+1} = \Psi_j \circ \Phi_j$ are

$$D^s\Phi_{j+1}[u_1, \dots, u_s] = \sum_{\pi} D^{|\pi|}\Psi_j(A_j)\Big[D^{|B|}\Phi_j(A)[u_\ell : \ell \in B] : B \in \pi\Big], \tag{8.11}$$

where π runs over the set partitions of $\{1, \dots, s\}$. The formula follows by induction on s: a further derivative either differentiates the outer tensor, creating a new block, or differentiates exactly one inner tensor, enlarging its block, and these alternatives produce each partition once.

For the sums with the output fixed, the partition with one block contributes at most $(1 + C_M e_j)R_s(j)$. Every other partition has at least two blocks, and all inner orders are smaller than s. Summing the inner coefficients at each fixed intermediate label uses $R_{|B|}(j)$, and summing the outer coefficients then uses the first line of (8.10). By induction on s we obtain, with a constant $B_{M,s}$ determined by the lower orders,

$$R_s(j+1) \leq (1 + C_M e_j)R_s(j) + B_{M,s}\epsilon_{j+1}.$$

For the sums with one input fixed, fix e_1 and, in each partition, let B_* be the block containing it. We sum the inner tensor of B_* using $C_{|B_*|}(j)$ and every other inner tensor using $R_{|B|}(j)$. With the intermediate input of B_* fixed, the remaining outer sum uses the second line of (8.10). This is the rule for contractions with a fixed input in Lemma 5.3, applied with counting volumes. The partition with one block contributes at most $M^{-3}(1 + C_M e_j)C_s(j)$, and, by the induction bounds for the lower orders, the other partitions contribute at most

$$M^{-3}B_{M,s}\epsilon_{j+1}(\epsilon_0/\epsilon_j)^3.$$

Multiplying the recurrence by $(\epsilon_{j+1}/\epsilon_0)^3 = M^3(\epsilon_j/\epsilon_0)^3$ cancels the factor M^{-3} exactly, and we find

$$\widehat{C}_s(j+1) \leq (1 + C_M e_j)\widehat{C}_s(j) + B_{M,s}\epsilon_{j+1}.$$

This is why exactly one volume factor appears.

Both recurrences start at zero. Expanding the products of their first-order factors and using (8.9), we find that their solutions are bounded by

$$B_{M,s}\sum_{\ell<j}\epsilon_{\ell+1}\exp\Big(C_M\sum_{\ell<j}e_\ell\Big) \leq B_{M,s}\frac{M}{M-1}\exp\Big[C_M\Big(\frac{2\varepsilon_*}{M^2-1} + \frac{2a_*M}{M-1}\Big)\Big].$$

There are finitely many partitions for each fixed s, so the induction closes at every fixed order and gives bounds for $R_s(j)$ and $\widehat{C}_s(j)$ that are uniform in j, d, and n. The same argument applies with any fixed input, either by selecting its block or by the symmetry of derivatives.

Step 6: Spatial weights. A nonzero derivative coefficient of $\Phi_j(c)$ has all its inputs within distance $C_M\epsilon_j$ of c, by the locality in Lemma 8.10. Joining each input to c by a shortest periodic path gives a connected network of length at most $sC_M\epsilon_j \le sC_M$, and the length of a shortest connecting network is no larger. Inserting the weight $e^{a_{\mathrm{sp}}\mathrm{t}}$ multiplies each of the sums above by at most $e^{a_{\mathrm{sp}}sC_M}$, which proves the two weighted bounds. Repeated inputs are ordinary terms of these ordered sums, and all orientations and periodic identifications were included in the one-step bounds. Multiplying the column bound by $\epsilon_j^3/\epsilon_0^3$ gives the volume-normalized column sum of Definition 4.6. This completes the proof. □

PART III

Classical background fields

SECTION 9

Constraint coordinates and local gauge fixing

Fix an odd integer $M \geq 3$, integers $n \geq 4$ and $d \geq 0$, and set $\epsilon = M^{-d}$. Let b be a configuration close to the identity on the coarse lattice of side n. In this section we describe the configurations near the identity on the fine lattice of side $M^d n$ whose image under d steps of the gauge-corrected averaging of Lemma 8.10 is b, choose a gauge compatible with this constraint, and prove that the Wilson action is uniformly strictly convex in the remaining coordinates. The statements are deterministic and finite-dimensional, and all constants are independent of d and n. The existence of the constrained minimizer (the classical background field) is proved in Section 10 (Theorem 10.6); here we show only that a critical point in the chart is unique and is a strict minimum there.

We explain the construction of the coordinates. With background connection $U_0 = I$, write $\mathsf{F}_d(A)$ for the logarithm of the output of d gauge-corrected averaging steps applied to the fine field $e^{\epsilon A}$. By Lemmas 8.1 and 8.10, $\mathsf{F}_d(A) = Q_d A + \mathscr{E}_d^{\mathrm{av}}(A)$, where Q_d is the linear average of physical potentials and $\mathscr{E}_d^{\mathrm{av}}$ is quadratically small. If H_d is a linear right inverse of Q_d, then for a fine field w and a coarse field η,

$$\mathsf{F}_d(w - H_d\eta) = Q_d w - \eta + \mathscr{E}_d^{\mathrm{av}}(w - H_d\eta).$$

The constraint $\mathsf{F}_d(w - H_d\eta) = Q_d w$ reduces to the coarse fixed-point equation $\eta = \mathscr{E}_d^{\mathrm{av}}(w - H_d\eta)$, which we solve by a contraction; the fine parameter $(I - H_d Q_d)w$ is unchanged. For the contraction to be uniform in d, the right inverse must have exponentially decaying kernels, with bounds on the potential and its first differences. Further, the counting column sums of the derivatives of $\mathscr{E}_d^{\mathrm{av}}$, which are of size ϵ^3, must cancel the counting column sums of H_d, which are of size ϵ^{-3}. We take for H_d the minimizing linear extension of Bałaban [10, 11], translated to our centered averages.

The gauge condition is $\mathsf{P}_d \operatorname{div}_\epsilon A = 0$, where P_d is the orthogonal projection onto $\mathscr{L}_\epsilon \ker Q'_d$, $\mathscr{L}_\epsilon$ is the positive scalar Laplacian, and Q'_d is the scalar block average. At $(A, \lambda) = (0, 0)$, the derivatives with respect to the gauge parameter λ of the divergence map and of the logarithmic coarse gauge map are $-\mathscr{L}_\epsilon \lambda$ and $Q'_d \lambda$, respectively. Thus $\ker Q'_d$ consists of the infinitesimal parameters preserving the coarse gauge at the identity, and their divergence variations span $\mathscr{L}_\epsilon \ker Q'_d$. The corresponding nonlinear equations, with prescribed coarse gauge, are solved in Theorem 9.9. This projected condition is the one used by Bałaban [10, (1.39)–(1.44), pp. 24–25]; it is not the ordinary condition $\operatorname{div}_\epsilon A = 0$.

After fixing the lattices and norms in Section 9.1, we transfer Bałaban's linear estimates through finite covers (Section 9.2) and construct H_d (Theorem 9.3). We then construct the constraint coordinates (Theorem 9.6), prove the constrained Hessian bound (Theorem 9.7), solve the scalar and nonlinear gauge equations (Lemma 9.8 and Theorem 9.9), and give the trial configuration (Corollary 9.10); the plaquette estimates used throughout are collected in Lemma 9.4.

The inputs are the weighted product and inverse estimates of Lemma 5.3, the inverse branch of the averaging constraint and its domain in Lemma 6.3, the identification of the coordinates of a configuration with small curvature with that branch in Lemma 7.2, the linear identities and nonlinear estimates of Lemmas 8.1, 8.10, and 8.11, and Bałaban's estimates for the linear theory [10, 11, 13]. The results are used in Section 10 to construct the background field and prove its symmetries and the nested minimization identity for the effective classical action (Theorems 10.6 and 10.10 and Lemma 10.8), in Section 11, and in the quartic expansion of Theorem 36.2.

Our choice of gauge representatives and our nonlinear solution of the averaging constraint follow the background-field program of Bałaban [14, 16], in particular his strategy of fixing the gauge and linearizing the constraint [14, Theorem 2, p. 83], [16, Theorem 1, p. 279]. The linear estimates are taken from [10, 11, 13] after the identifications checked below. The nonlinear right inverse, the coordinates on the fibers, and the gauge fixing with prescribed coarse gauge are constructed here for the centered averaging map. For comparison, the axial gauge of Dimock [70] concerns an Abelian theory and does not supply these non-Abelian statements.

9.1 Lattices, scalar products, and norms

Fix an odd integer $M \geq 3$, a depth $d \geq 0$, and a coarse side $n \geq 4$. We set $m = M^d$ and $\epsilon = M^{-d}$, and we use the fine torus $\epsilon\mathbb{Z}^3/(n\mathbb{Z})^3$ and the coarse torus $\mathbb{Z}^3/(n\mathbb{Z})^3$; lengths are measured in units in which the coarse spacing is one. The vector average $Q_d = K_m/m$ and the scalar average $Q'_d = \mathsf{A}_m$ are those of Lemma 8.1. These definitions are used for every torus side that occurs, including the covers of Section 9.2.

The coefficient of a positive fine link $e = (x, x + \epsilon e_i)$ is located at x, and that of a fine plaquette at its lower vertex. Changing these locations within their cells changes each spatial estimate by a constant independent of d and n. Scalar, link, and plaquette scalar products on the fine torus are ϵ^3 times the counting sums, each positive orientation counted once, and on the coarse torus they are counting sums. We write

$$(\nabla_{\epsilon,i} f)(x) = \frac{f(x + \epsilon e_i) - f(x)}{\epsilon}, \qquad \operatorname{div}_\epsilon A(x) = \sum_i \frac{A_i(x - \epsilon e_i) - A_i(x)}{\epsilon},$$

$$(\mathrm{d}_\epsilon A)_{ij}(x) = \nabla_{\epsilon,i} A_j(x) - \nabla_{\epsilon,j} A_i(x), \qquad i < j,$$

and $\mathscr{L}_\epsilon = \operatorname{div}_\epsilon \nabla_\epsilon = -\Delta_\epsilon \geq 0$. Then $\operatorname{div}_\epsilon = \nabla_\epsilon^\sharp$, where $^\sharp$ always denotes the adjoint with respect to the scalar products just described; adjoints between the fine and the coarse torus contain the ratio of the cell volumes. These formulas fix the sign of the scalar Laplacian and of the linearized gauge action. We use the color norm of Definition 4.1, and set

$$\|v\|_\epsilon^2 = \epsilon^3 \sum_e |v_e|^2, \qquad \|v\|_{H^1_\epsilon}^2 = \|v\|_\epsilon^2 + \sum_\mu \|\nabla_{\epsilon,\mu} v\|_\epsilon^2.$$

Let P_d be the orthogonal projection onto $\mathscr{L}_\epsilon \ker Q'_d$, and let

$$\mathcal{V}_d = \{v : Q_d v = 0,\ \mathsf{P}_d \operatorname{div}_\epsilon v = 0\}.$$

Unless stated otherwise, constants in this section depend only on M and on the following fixed choices. In an estimate on a ball of radius r inside a larger analytic ball of radius $R > r$, constants may depend on the chosen radii and on $R - r$. In a weighted composition estimate they may also depend on the input and output exponential decay rates and on their positive difference. This is the dependence described in item (2) of Definition 4.14. They do not depend on d, n, L, γ, or on the integer J that fixes the length of a renormalization group step. Additional parameters are listed where they occur.

Lemma 9.1. *Let K be a matrix from a field space on a lattice of spacing b_{in} to a field space on a lattice of spacing b_{out}, written in counting coordinates. If*

$$R = \sup_x \sum_y \|K(x,y)\|, \qquad C = \sup_y \frac{b_{\mathrm{out}}^3}{b_{\mathrm{in}}^3} \sum_x \|K(x,y)\|,$$

then the operator norm of K from ℓ^2 with weight b_{in}^3 to ℓ^2 with weight b_{out}^3 is at most $\sqrt{RC}$. The same holds for each component of a left gradient of K.

Proof. For each output, by the triangle inequality and the Cauchy–Schwarz inequality, we have

$$|(Ku)(x)|^2 \leq \Big(\sum_y \|K(x,y)\|\Big) \sum_y \|K(x,y)\| |u(y)|^2.$$

Multiplying by b_{out}^3, summing over x, and exchanging the finite sums, we find that the coefficient of $b_{\mathrm{in}}^3 |u(y)|^2$ is at most RC. The argument applies to color blocks, and a finite collection of gradient components changes only a dimensional constant. □

9.2 Transfer of periodic kernels through finite covers

Bałaban's linear estimates are proved for periodic lattices whose periods are compatible with an auxiliary system of blocks used in the proofs. A general side $n \geq 4$ need not have this property. We apply the estimates on a finite periodic cover whose side is a

suitable multiple of n, and transfer them to the torus of side n by the following lemma. The transfer uses uniqueness of the solutions and deck invariance, and it does not use any estimate for an inverse.

Lemma 9.2. *Fix an odd $M \geq 3$. Fix, as functions of M, integers R_0 and M_0, which are powers of M, and an integer K_{loc} such that $M_{\mathrm{loc}} = K_{\mathrm{loc}} R_0 M_0 \geq M_1(3, M)$, where the subdivisions and the lower bound $M_1(3, M)$ for the size of the localization cubes are those of [13, Section 3C, pp. 408–409]. Let $k = 6M_{\mathrm{loc}}$. Then the following statements hold for all integers $n \geq 4$ and $d \geq 0$.*

1. Geometry. *The periodic lattice of side kn at mesh $\epsilon = M^{-d}$, called the cover, satisfies $M_{\mathrm{loc}} \mid kn$ and $kn \geq 24M_{\mathrm{loc}}$. At every mesh $\epsilon_j = M^{j-d}$, $0 \leq j \leq d$, the whole cover is tiled by the auxiliary localization blocks of [13, Section 3C], and its localization cubes, of side at most $12M_{\mathrm{loc}}$, have injective lifts to coordinate cubes. With the domain at every scale equal to the whole torus, the separation conditions of [11, (2.1)–(2.4), p. 224] are vacuous.*
2. Projection and constrained space. *Let π^* map fields on the torus of side n to fields on the cover by periodic repetition, and let the deck group $\mathcal{D} = (\mathbb{Z}/k\mathbb{Z})^3$ act on the cover by translations by multiples of n. The averages Q_d and Q'_d, the physical differences, and their adjoints commute with π^*, and*

$$\mathsf{P}_d^{(kn)} \pi^* = \pi^* \mathsf{P}_d^{(n)}, \qquad \mathcal{V}_d^{(kn)} \cap \operatorname{Fix} \mathcal{D} = \pi^* \mathcal{V}_d^{(n)}.$$

3. Kernels. *Let T be the solution operator of one of the following linear problems at the identity connection, on the torus of side $r \in \{n, kn\}$: the scalar problem $(\mathscr{L}_\epsilon + \alpha (Q'_d)^\sharp Q'_d)\lambda = f$ with $\alpha > 0$; the scalar system with projected Laplacian and prescribed scalar average; the minimization of $\|\mathrm{d}_\epsilon A\|_\epsilon^2$ under the constraints $Q_d A = u$ and $\mathsf{P}_d \operatorname{div}_\epsilon A = 0$; or a problem $A \in \mathcal{V}_d$, $\langle \mathrm{d}_\epsilon A, \mathrm{d}_\epsilon v \rangle_\epsilon = \langle f, v \rangle_\epsilon$ for $v \in \mathcal{V}_d$, under the assumption that the curl form is positive definite on $\mathcal{V}_d$. Suppose that the problem has a unique solution on both tori. Then $T^{(kn)} \pi^* = \pi^* T^{(n)}$, and their matrices in the coordinate bases satisfy*

$$T^{(n)}(e, f) = \sum_{h \in \mathcal{D}} T^{(kn)}(\widetilde{e}, \widetilde{f} + nh),$$

where $\widetilde{e}, \widetilde{f}$ are fixed lifts; any physical source volume is already contained in these matrices. The same formula holds for the first physical differences of the output. In particular, for every $b > 0$,

$$\sum_f e^{b \operatorname{dist}_n(e,f)} \|T^{(n)}(e, f)\| \leq \sum_{f'} e^{b \operatorname{dist}_{kn}(\widetilde{e}, f')} \|T^{(kn)}(\widetilde{e}, f')\|,$$

and a bound $Ce^{-b \operatorname{dist}_{kn}}$ for the response to a source supported in one coarse block descends to the torus of side n with C replaced by $k^3 C$.

In the applications, estimates proved on the cover are transferred to the torus of side n by part (3), uniformly in d; each application checks the constraints and the uniqueness required there.

Proof. The auxiliary data are fixed before n and d. The integers R_0 and M_0 are powers of M chosen large enough for the auxiliary construction, and $M_{\mathrm{loc}} = K_{\mathrm{loc}} R_0 M_0$ is an integer multiple with $M_{\mathrm{loc}} \geq M_1(3, M)$. This is the subdivision of [13, Section 3C, pp. 408–409]: an auxiliary localization block is a union of $R_0 M_0$-blocks, and a localization cube is a union of auxiliary localization blocks. The required lower bounds depend only on M and the dimension three, and these choices can be made as functions of M; none uses n, d, a coupling, or J.

Let $n_{\mathrm{cov}} = kn = 6M_{\mathrm{loc}} n$. It is a multiple of M_{loc} and $n_{\mathrm{cov}} \geq 24 M_{\mathrm{loc}}$. At the mesh $\epsilon_j = M^{j-d}$ the number of sites in each coordinate direction is $n_{\mathrm{cov}}/\epsilon_j = knM^{d-j}$, which is divisible by M_{loc} for $0 \leq j \leq d$. The whole torus at every scale has a periodic partition into auxiliary localization blocks, and the subdivision into $R_0 M_0$-blocks is periodic as well. We take the domain sequence $\Omega_0 = \Omega_1 = \cdots = \Omega_d$ equal to the whole fine torus, with $A_j = \varnothing$ for $j < d$ and A_d the whole coarse torus. This whole-torus specialization is allowed in [11, (2.1)–(2.4), p. 224], and each complement in the separation condition (2.2) there is empty. The enlarged localization cubes of the background-field construction have side $(2 + 2r) M_{\mathrm{loc}} \epsilon_j$ with $r \leq 5$ [13, Section 3C, pp. 408–409]. This side is at most $12 M_{\mathrm{loc}} < n_{\mathrm{cov}}$, and each cube has an injective lift to a coordinate cube of the cover. The tori of [10, pp. 17–18] have general rectangular periods $2L_\mu$, and we take $L_\mu = n_{\mathrm{cov}}/2 = 3M_{\mathrm{loc}} n$; that definition does not require the period to be a power of M. The auxiliary localization blocks are used only in the proofs of the cited estimates and do not enter the definitions of the averages, the projection, or the solution operators. A deck translation need not preserve the auxiliary partition; the invariance of the operators is proved next from the averaging partitions and their equations.

For each scalar, link, or plaquette space, $\pi^* u$ is the field u repeated in the k^3 translates of a fundamental cell of side n, and the image of π^* is $\operatorname{Fix} \mathcal{D}$. Since the fine meshes agree on both tori, we have

$$\langle \pi^* u, \pi^* v \rangle_{\epsilon, kn} = k^3 \langle u, v \rangle_{\epsilon, n}, \tag{9.1}$$

and the coarse counting products satisfy the same identity. Forward differences, their adjoints, and the curl are given by the same periodic finite stencils on both tori, and they commute with π^*. The formulas for Q_d and Q'_d in Lemma 8.1 use the same centered block and segment at each coarse vertex. A deck translation moves the fine lattice by nm sites and preserves the averaging partitions at every scale. Repeating an input repeats the outputs. The adjoints for the scalar products of Section 9.1 also commute with π^*: if $Q_d(c, e)$ denotes the matrix of Q_d in the coordinate bases, then

$$(Q_d^\sharp b)(e) = \epsilon^{-3} \sum_c Q_d(c, e)^* b(c), \qquad ((Q'_d)^\sharp b)(x) = b(Y) \quad \text{for } x \text{ in the block of } Y,$$

and the occurrences and volume factors are the same on the cover. The translation between the centered and the lower-corner averages commutes with deck translations and with π^* for the same reason.

For the projection, define $S^{(r)} = \mathscr{L}_\epsilon^{(r)} \ker Q_d'^{(r)}$ for $r = n, kn$, and $\mathcal{A}_\mathcal{D} = k^{-3} \sum_{h \in \mathcal{D}} \tau_{nh}$, where τ_{nh} is the translation by nh. The deck translations are unitary, preserve $S^{(kn)}$, and commute with $\mathscr{L}_\epsilon$ and Q_d'. First, $\pi^* S^{(n)} \subset S^{(kn)} \cap \operatorname{Fix} \mathcal{D}$. Conversely, let $f = \mathscr{L}_\epsilon^{(kn)} \lambda$ with $Q_d'^{(kn)} \lambda = 0$ and $\tau_{nh} f = f$ for all h. Then

$$Q_d'^{(kn)} \mathcal{A}_\mathcal{D} \lambda = 0, \qquad \mathscr{L}_\epsilon^{(kn)} \mathcal{A}_\mathcal{D} \lambda = f.$$

The averaged preimage is invariant, hence equal to $\pi^* \lambda_0$ for some λ_0, and since π^* is injective, we have $Q_d'^{(n)} \lambda_0 = 0$. We conclude that

$$S^{(kn)} \cap \operatorname{Fix} \mathcal{D} = \pi^* S^{(n)}. \tag{9.2}$$

Since $S^{(kn)}$ and its orthogonal complement are invariant under the deck group, the projection $\mathsf{P}_d^{(kn)}$ commutes with every deck translation. For a fine scalar u, $\mathsf{P}_d^{(kn)} \pi^* u$ lies in the left side of (9.2), and $\pi^* u - \mathsf{P}_d^{(kn)} \pi^* u$ is orthogonal to $\pi^* S^{(n)}$. By (9.1), the unique vector with these two properties is $\pi^* \mathsf{P}_d^{(n)} u$. This proves

$$\mathsf{P}_d^{(kn)} \pi^* = \pi^* \mathsf{P}_d^{(n)}. \tag{9.3}$$

Applying it to the divergence and using the commutation for Q_d, we obtain the identity for the invariant part of $\mathcal{V}_d$.

We next consider one of the problems in part (3). For the scalar problem with penalty $\alpha > 0$, the weak equation is

$$\langle \nabla_\epsilon \lambda, \nabla_\epsilon \phi \rangle_\epsilon + \alpha \langle Q_d' \lambda, Q_d' \phi \rangle = \langle f, \phi \rangle_\epsilon \quad \text{for every fine scalar } \phi,$$

and all its operators commute with the deck group. For the scalar system with prescribed scalar average and projected Laplacian, the same commutation follows from (9.3). For the minimizing extension, the affine constraints are $Q_d A = u$ and $\mathsf{P}_d \operatorname{div}_\epsilon A = 0$, and the stationarity equation is $\langle \mathrm{d}_\epsilon A, \mathrm{d}_\epsilon v \rangle_\epsilon = 0$ for every $v \in \mathcal{V}_d$. For the constrained curl problem, if the curl form is positive definite on the finite-dimensional space $\mathcal{V}_d$, its Gram matrix in an orthonormal basis of $\mathcal{V}_d$ is invertible, and the problem is uniquely solvable.

On the cover with repeated data, a deck translate of a solution solves the same equation with the same data. By uniqueness, the solution is invariant and equals $\pi^* A_0$ (or $\pi^* \lambda_0$). The identities above show that the descended field satisfies the constraints and the coarse data on the torus of side n. For every test field on the torus of side n, its repetition is a test field on the cover, and by (9.1) every quadratic and source pairing is multiplied by the same factor k^3. Canceling this factor, we obtain the variational equation on the torus of side n, and uniqueness identifies the solution operator applied to the data. This proves $T^{(kn)} \pi^* = \pi^* T^{(n)}$; for the scalar system the same argument uses the

commutation in its two equations directly. An invertible coarse Schur matrix formed from commuting factors also commutes with π^*, and applying it to both sides gives the corresponding identity for its inverse. When a scalar source is naturally restricted to $\operatorname{Ran} \mathsf{P}_d$, we use the source $\mathsf{P}_d f$ for an arbitrary fine field f. This fixes its matrix in the coordinate basis on the whole coordinate space, and (9.3) preserves this convention.

Finally we write the operators in the coordinate bases. For an input u on the torus of side n, expanding $(T^{(kn)}\pi^* u)(\widetilde{e})$ first over a fundamental set of lifts of the sources and then over their k^3 deck images, we obtain

$$\sum_f \Big(\sum_{h \in \mathcal{D}} T^{(kn)}(\widetilde{e}, \widetilde{f} + nh) \Big) u(f).$$

Comparing coefficients proves the formula for $T^{(n)}$. A physical source volume is part of the matrix coefficient and is the same on both tori. Physical first differences of the output commute with repetition and with finite sums, which gives their formula. For every rate $b > 0$,

$$\begin{aligned} \sum_f e^{b \operatorname{dist}_n(e,f)} \| T^{(n)}(e,f) \| &\le \sum_{f,h} e^{b \operatorname{dist}_{kn}(\widetilde{e}, \widetilde{f}+nh)} \| T^{(kn)}(\widetilde{e}, \widetilde{f} + nh) \| \\ &= \sum_{f'} e^{b \operatorname{dist}_{kn}(\widetilde{e}, f')} \| T^{(kn)}(\widetilde{e}, f') \|, \end{aligned} \tag{9.4}$$

since the lifts of the sources partition the cover and periodic distances can only decrease on passing to the smaller torus. A weighted row bound on the cover descends with the same constant. A source in one coarse block has k^3 images on the cover, and by the triangle inequality for their responses, we obtain the bound $Ck^3 e^{-b \operatorname{dist}_n(e, \text{source block})}$. These arguments apply also to the first output differences. All these factors depend only on the auxiliary data, hence only on M. Neither uniqueness nor this transfer produces an estimate for first differences; such an estimate must be proved for the operator on the cover. □

The specialization of Bałaban's linear estimates. We use the estimates for the Gaussian theory at the identity connection collected in Table 9.1. They are applied on the cover of Lemma 9.2 in the following specialization, which we check once here and use in the proofs of Theorem 9.3 and Lemma 9.8. The geometry is periodic, with one region, equal to the whole torus at every scale, so that the separation conditions are vacuous by part (1) of Lemma 9.2. The coarse spacing is one, the fine scalar products carry the volume ϵ^3, and the coarse ones are counting sums. The background is the identity connection. The gradient of the Wilson action at the background vanishes, the regularity conditions [13, (3.35)–(3.36), p. 396] hold with zero left sides, and the smallness requirement of [13, Theorem 3.1] holds for every sufficiently small positive regularity parameter. The

averages in these papers are the lower-corner averages, which are related to ours by the translation T_d of Theorem 9.3. The auxiliary localization size M_{loc} is fixed as a function of M; it is distinct from the blocking factor M. In [11, p. 249], the bound following Corollary 2.8 is printed with the number (1.151); in the sequential numbering of that paper it is (2.151), and we cite it as "the bound printed as (1.151)".

Table 9.1. Linear estimates of Bałaban used in this section, at the identity connection, and their relation to the operators defined here.

9.3 The constrained linear extension

Theorem 9.3. *Use the lattices, scalar products, and operators of Section 9.1. Let* $\mathsf{T}_d A(x) = A(x - \epsilon t_m)$, *where* $t_m = ((m-1)/2, (m-1)/2, (m-1)/2)$ *in fine lattice units, and let* Q_d^{pub} *and* $(Q'_d)^{\mathrm{pub}}$ *be the lower-corner physical averages of [10, (1.11), p. 19; (1.18), p. 20] at the identity connection. Then the following statements hold.*

1. $Q_d = Q_d^{\mathrm{pub}}\mathsf{T}_d$ *and* $Q'_d = (Q'_d)^{\mathrm{pub}}\mathsf{T}_d$.
2. *Set*

$$\mathscr{D}_d^0 = \mathrm{d}_\epsilon^\sharp \mathrm{d}_\epsilon + \nabla_\epsilon \mathsf{P}_d \,\mathrm{div}_\epsilon + Q_d^\sharp Q_d.$$

There exist $c_0, C, a_0 > 0$, *depending only on* M, *such that*

$$\mathscr{D}_d^0 \geq c_0(I + \nabla_\epsilon^\sharp \nabla_\epsilon), \qquad \|\mathrm{d}_\epsilon v\|_\epsilon^2 \geq c_0 \|v\|_{H_\epsilon^1}^2 \quad (v \in \mathcal{V}_d),$$

where $\nabla_\epsilon^\sharp \nabla_\epsilon$ *acts componentwise.*

3. *The map Q_d is onto, and the operator*

$$H_d = (\mathscr{D}_d^0)^{-1} Q_d^\sharp \big[Q_d (\mathscr{D}_d^0)^{-1} Q_d^\sharp \big]^{-1}$$

satisfies

$$H_d = \mathsf{T}_d^{-1} H_d^{\mathrm{pub}}, \qquad Q_d H_d = I, \qquad \mathsf{P}_d \operatorname{div}_\epsilon H_d = 0,$$

where H_d^{pub} is the extension of [10, (1.60)–(1.64), pp. 28–29; (1.103), p. 34]. For each coarse field u, $H_d u$ is the unique minimizer of $\|\mathrm{d}_\epsilon A\|_\epsilon^2$ among the fields A with $Q_d A = u$ and $\mathsf{P}_d \operatorname{div}_\epsilon A = 0$; in particular $\langle \mathrm{d}_\epsilon H_d u, \mathrm{d}_\epsilon v \rangle_\epsilon = 0$ for $v \in \mathcal{V}_d$. Constant fields are preserved: $H_d u = u$ for every constant coarse field u.

4. *The kernel of H_d satisfies*

$$|H_d(e,c)| + |\nabla_\epsilon H_d(e,c)| \le C e^{-a_0 \operatorname{dist}(e,c)},$$

and for every $0 < a < a_0$

$$\sup_e \sum_c e^{a \operatorname{dist}(e,c)} \big(|H_d(e,c)| + |\nabla_\epsilon H_d(e,c)| \big) \le C_a,$$
$$\sup_c \epsilon^3 \sum_e e^{a \operatorname{dist}(e,c)} \big(|H_d(e,c)| + |\nabla_\epsilon H_d(e,c)| \big) \le C_a.$$

It follows that $\|H_d u\|_\infty + \|\nabla_\epsilon H_d u\|_\infty \le C \|u\|_\infty$ and $\|H_d u\|_{H^1_\epsilon} \le C \|u\|_2$.

The constant C_a depends only on M and a. The translation T_d relates the linear averages at the identity; it does not relate nonlinear block averages.

The positivity in part (2) is a form estimate. The kernel bounds in part (4) are a separate regularity estimate, which we take from [11]; they do not follow from the form estimate.

Proof. We treat $d \ge 1$ first and verify the case $d = 0$ at the end without the cited kernel estimate.

Step 1: The averages. We write a fine point as $x = \epsilon r'$, and let $\mathsf{I}_m = \{-(m-1)/2, \dots, (m-1)/2\}^3$. By Lemma 8.1,

$$(Q_d A)_i(Y) = m^{-4} \sum_{r \in \mathsf{I}_m} \sum_{s=0}^{m-1} A_i\big(Y + \epsilon(r + s e_i)\big), \qquad (Q_d' f)(Y) = m^{-3} \sum_{r \in \mathsf{I}_m} f(Y + \epsilon r). \tag{9.5}$$

There are m^4 vector occurrences, and a constant physical potential is mapped to itself. The lower-corner formula in [10, (1.11), p. 19; (1.18), p. 20] has coefficient $m^{-4} = \epsilon^4$ and $r \in \{0, \dots, m-1\}^3$. Subtracting the integer vector t_m maps this box bijectively onto I_m, which proves part (1), including at the periodic seams.

Since fine translations are unitary for the physical scalar products and commute with the physical differences, we have

$$\mathsf{P}_d = \mathsf{T}_d^{-1}\mathsf{P}_d^{\mathrm{pub}}\mathsf{T}_d, \qquad \mathscr{D}_d^0 = \mathsf{T}_d^{-1}(\mathscr{D}_d^0)^{\mathrm{pub}}\mathsf{T}_d. \tag{9.6}$$

Indeed, the translation maps the Laplacian image of the kernel of the lower-corner scalar average onto $\mathscr{L}_\epsilon \ker Q_d'$, and orthogonality gives the first identity. Taking adjoints, we obtain $Q_d^\sharp = \mathsf{T}_d^{-1}(Q_d^{\mathrm{pub}})^\sharp$, and the second identity follows term by term.

Step 2: The cited estimates on the cover. We apply the estimates of Table 9.1 first on the cover of side kn of Lemma 9.2, in the specialization described after that lemma; the penalty in the vector operator is one. The projected gauge of [10, (1.39)–(1.44), pp. 24–25] projects onto the Laplacian image of the kernel of the scalar average. By [10, Proposition 1.1, (1.89)–(1.90), p. 33], the vector operator with penalty one is bounded below by $c_0(I + \nabla_\epsilon^\sharp \nabla_\epsilon)$. The extension of [10, (1.60)–(1.64), pp. 28–29; (1.103), p. 34] is a right inverse of the vector average, has zero projected divergence, minimizes the curl form under these two constraints, and equals

$$\big((\mathscr{D}_d^0)^{\mathrm{pub}}\big)^{-1}(Q_d^{\mathrm{pub}})^\sharp\big[Q_d^{\mathrm{pub}}\big((\mathscr{D}_d^0)^{\mathrm{pub}}\big)^{-1}(Q_d^{\mathrm{pub}})^\sharp\big]^{-1}.$$

These statements concern one real color, and we apply them to each of our three colors. No restriction to mean zero is made on coarse data; the constant fields are kept. Conjugation by T_d gives the same statements for the centered operators on the cover.

Step 3: Coercivity on the torus of side n. Before transferring any regularity estimate, we prove the finite-dimensional statements on the torus of side n. The commutation of P_d, of the differences, and of the averages and their adjoints with π^* (Lemma 9.2) implies that $\mathscr{D}_d^{0,(kn)}\pi^* = \pi^*\mathscr{D}_d^{0,(n)}$. For every fine vector field v on the torus of side n, we then have

$$\langle v, \mathscr{D}_d^{0,(n)} v\rangle_{\epsilon,n} = k^{-3}\langle \pi^* v, \mathscr{D}_d^{0,(kn)}\pi^* v\rangle_{\epsilon,kn} \geq c_0 \|v\|^2_{H^1_{\epsilon,n}}, \tag{9.7}$$

where we used (9.1) also for each first difference. This shows that $\mathscr{D}_d^{0,(n)}$ is positive definite. For $v \in \mathcal{V}_d^{(n)}$, the averaging and projected divergence terms vanish, which leaves the curl coercivity in part (2).

Step 4: Construction and identification of the extension. For a coarse field u on the torus of side n, let $A_{\mathrm{cov}} = H_d^{(kn)}\pi^* u$ be the centered cover extension. The cover minimizer is unique: the difference of two minimizers lies in $\mathcal{V}_d^{(kn)}$; subtracting their stationarity identities tested on this difference shows that its curl vanishes, and by the coercivity on the cover the difference vanishes. Deck translations preserve both constraints and the curl energy, and they fix the data. By uniqueness, A_{cov} is invariant and equals $\pi^* A_0$. By

the commutation relations, we have $Q_d^{(n)} A_0 = u$ and $\mathsf{P}_d^{(n)} \operatorname{div}_\epsilon A_0 = 0$. For every $v \in \mathcal{V}_d^{(n)}$, the repetition $\pi^* v$ lies in the constrained space on the cover, and by stationarity there we have

$$0 = \langle \mathrm{d}_\epsilon A_{\mathrm{cov}}, \mathrm{d}_\epsilon \pi^* v \rangle_{\epsilon,kn} = k^3 \langle \mathrm{d}_\epsilon A_0, \mathrm{d}_\epsilon v \rangle_{\epsilon,n}.$$

The energy at $A_0 + v$ exceeds the energy at A_0 by $\|\mathrm{d}_\epsilon v\|^2_{\epsilon,n}$, and the coercivity of Step 3 shows that A_0 is the unique constrained minimizer on the torus of side n. We set $H_d^{(n)} u = A_0$; this also shows that $Q_d^{(n)}$ is onto.

The formula for H_d also descends. For $r = n, kn$, let $G_0^{(r)} = (\mathscr{D}_d^{0,(r)})^{-1}$ and $C_0^{(r)} = Q_d^{(r)} G_0^{(r)} (Q_d^{(r)})^\sharp$. Both are positive definite, the latter because the average is onto. The commutation relations and uniqueness of these finite-dimensional inverses imply that

$$G_0^{(kn)} \pi^* = \pi^* G_0^{(n)}, \qquad (C_0^{(kn)})^{-1} \pi^* = \pi^* (C_0^{(n)})^{-1};$$

for example, the first identity follows by applying $\mathscr{D}_d^{0,(kn)}$ to both sides, and the second uses in addition the commutation of Q_d and $Q_d^\sharp$ with π^* and the positivity of C_0. The formula on the cover identifies the descended operator with $G_0^{(n)} Q_d^\sharp (C_0^{(n)})^{-1}$, and translation identifies it with $\mathsf{T}_d^{-1} H_d^{\mathrm{pub}}$ on the torus of side n. This proves all identities of part (3) without using any regularity estimate. If u is constant, the constant fine field equal to u satisfies both constraints and has zero curl, and by uniqueness $H_d u = u$.

Step 5: Kernel bounds. We apply [11, Proposition 2.7, (2.149), and Corollary 2.8, (2.150) and the bound printed as (1.151), p. 249] on the cover. In this whole-torus specialization the receiving and source regions both have coarse spacing one. The source integration factor in (2.150) and the scale factors for the potential and its first gradient in the bound printed as (1.151) are equal to one. We obtain

$$|H_d^{\mathrm{pub},(kn)}(e,c)| + |\nabla_\epsilon H_d^{\mathrm{pub},(kn)}(e,c)| \le C e^{-a_0 \operatorname{dist}_{kn}(e,c)},$$

including the constant fields. If the auxiliary penalty at the coarse scale is written as a_d in the multiscale convention of [10], it adds only the term $a_d \|u\|_2^2$ on the set of fields with fixed average u. The minimizing extension and the projected gauge subspace are therefore unchanged. Since $|\epsilon t_m| \le \sqrt{3}/2$, the centered cover kernel and its first gradient satisfy the same bound after multiplying C by at most $e^{a_0\sqrt{3}/2}$.

The minimization property, the uniqueness, and both constraints were verified in Step 4, and part (3) of Lemma 9.2 applies to the extension. For its matrix in the coordinate bases and the first physical differences of its output,

$$\begin{aligned} H_d^{(n)}(e,c) &= \sum_{h \in \mathcal{D}} H_d^{(kn)}(\widetilde{e}, \widetilde{c} + nh), \\ \nabla_\epsilon H_d^{(n)}(e,c) &= \sum_{h \in \mathcal{D}} \nabla_\epsilon H_d^{(kn)}(\widetilde{e}, \widetilde{c} + nh). \end{aligned} \tag{9.8}$$

Since every distance on the cover is at least the corresponding distance on the torus of side n, the pointwise estimate of part (4) follows with at most an additional factor k^3, which depends only on M. Weighted rows also descend without this factor, by (9.4).

To control the fine column sums, note that for a periodic mesh $b \le 1$ with period at least four and every $\eta > 0$,

$$\sup_x b^3 \sum_y e^{-\eta \operatorname{dist}(x,y)} \le C_\eta. \tag{9.9}$$

Indeed, choose representatives of the mesh points in a fundamental cube centered at x and assign to them disjoint mesh cubes. Distances vary by at most $\sqrt{3}b$ on such a cube, so the sum is bounded by $e^{\eta\sqrt{3}}$ times the integral of $e^{-\eta|z|}$ over $\mathbb{R}^3$. The same argument with $b = 1$ bounds the coarse counting sums, and the fixed number of orientations changes only a dimensional constant. Applying (9.9) with $\eta = a_0 - a$ to the pointwise estimate, we obtain the weighted rows and the weighted columns with the factor ϵ^3. The rows imply the supremum estimate, and Lemma 9.1, applied also to the gradient, gives the H^1_ϵ estimate.

Step 6: Depth zero. At $d = 0$ we have $Q_0 = H_0 = I$ and $\mathsf{P}_0 = 0$ directly. Also $\sum_\mu \|\nabla_{1,\mu} v\|_2^2 \le 12\|v\|_2^2$, so after reducing c_0 to at most $1/13$ the inequality of part (2) holds at unit mesh. □

9.4 Plaquette expansions

The following elementary estimates for the logarithm of a plaquette transport are used for the curvature and action bounds in Sections 9.6, 9.8, and 9.9. They involve only the four link variables of the plaquette and no differences of the field.

Lemma 9.4. *There exist $\rho_0, C > 0$ such that the following holds for every $\epsilon \in (0,1]$ and every fine plaquette p. For a complex link field A with $\|A\|_\infty \le \rho_0$, let $X_p(A) = \operatorname{Log}((e^{\epsilon A})_p)$ be the logarithm of the transport of the configuration $e^{\epsilon A}$ around p. For a complex link field z, write $Z_p = \sum_{e\in\partial p} |z_e|$. Then*

$$|X_p(A) - \epsilon^2 (\mathrm{d}_\epsilon A)_p| \le C\epsilon^2 \sum_{e\in\partial p} |A_e|^2, \tag{9.10}$$

$$|DX_p(A)[z] - \epsilon^2 (\mathrm{d}_\epsilon z)_p| \le C\epsilon^2 \|A\|_\infty Z_p, \tag{9.11}$$

$$|D^2 X_p(A)[z,z]| \le C\epsilon^2 Z_p^2. \tag{9.12}$$

Moreover, in the color normalization of Definition 4.1, the function $\varphi(X) = q(e^X)$ satisfies

$$D\varphi(X) = \tfrac{1}{4}X + O(|X|^3), \qquad D^2\varphi(X) = \tfrac{1}{4}I + O(|X|^2)$$

for small X, where $D\varphi$ is the gradient with respect to the color inner product, and $q(e^X) \le C|X|^2$ for real X in the identity chart.

Proof. Regard the four link variables of p as independent, with signs fixed by the orientation of the boundary, and write

$$X_p = \operatorname{Log}\bigl(e^{\epsilon A_1} e^{\epsilon A_2} e^{-\epsilon A_3} e^{-\epsilon A_4}\bigr).$$

This is a holomorphic function of four variables on a fixed product ball that does not depend on ϵ. Its Taylor term of degree one is $\epsilon(A_1 + A_2 - A_3 - A_4) = \epsilon^2 (\mathrm{d}_\epsilon A)_p$, and every monomial of degree at least two contains at least two factors ϵ. Since the series in these four variables converges absolutely on a larger ball, its tail is bounded by $C\epsilon^2 (\sum_e |A_e|)^2$, the first derivative of the tail by $C\epsilon^2 (\sum_e |A_e|) Z_p$, and the second derivative of X_p by $C\epsilon^2 Z_p^2$. There are four links, which gives (9.10), (9.11), and (9.12). The formulas for φ follow by differentiating the convergent series of $1 - \cos(|X|/2)$, which is an analytic function of $|X|^2$; at $X = 0$ they refer to its analytic quadratic extension. The last bound holds since $1 - \cos t \le t^2/2$. □

9.5 Local coordinates on constraint fibers

We use the following form of the contraction principle several times.

Lemma 9.5. *Let* B *be a closed ball in a finite-dimensional complex normed space, let* $\mathcal{O}$ *be an open subset of a finite-dimensional complex space, and let* $\Phi(t, x)$ *be holomorphic on* $\mathcal{O} \times \mathcal{U}$ *for an open set* $\mathcal{U} \supset \mathsf{B}$*. Suppose that* $\Phi(t, \cdot)$ *maps* B *into itself and is Lipschitz on* B *with constant* $\kappa < 1$*, uniformly in* $t \in \mathcal{O}$*. Then for every* $t \in \mathcal{O}$ *there is a unique fixed point* $x(t) \in \mathsf{B}$*, and* $t \mapsto x(t)$ *is holomorphic. If, in addition,* B *is invariant under complex conjugation and* $\Phi(\bar t, \bar x) = \overline{\Phi(t, x)}$ *in the real coordinates, then* $x(t)$ *is real for real* t*.*

Proof. We start the iteration $x_{k+1}(t) = \Phi(t, x_k(t))$ at a point $x_0 \in \mathsf{B}$ that does not depend on t. Then $\|x_{k+1} - x_k\| \le \kappa^k \|x_1 - x_0\|$, and the geometric sum shows that the iterates converge uniformly on $\mathcal{O}$ to a fixed point, which is unique in B since $\kappa < 1$. Since the iterates are holomorphic and Cauchy's formula on coordinate polydiscs passes to their uniform limit, the fixed point is holomorphic. At a real parameter, the complex conjugate of the fixed point is another fixed point in B when B is invariant under conjugation and $\Phi(\bar t, \bar x) = \overline{\Phi(t, x)}$. By uniqueness, the fixed point is real. No constant in this argument depends on the dimension of the space. □

In the following theorem, w denotes a fine link field; it is unrelated to the normalized fluctuation variables of Section 12. For the sums of absolute derivative coefficients we use the conventions of Definition 4.6. For each fixed order, the row is the sum over all inputs with the output fixed, and the column is the sum over the output and the other inputs with one input fixed. Both are weighted by $e^{a\mathsf{t}}$, where t is the length of a shortest connecting network of the locations, measured in units in which the coarse spacing is

one. A counting column sums with counting measure over fine outputs; a column with fine outputs summed with the weight ϵ^3 is volume-normalized.

Theorem 9.6. *Use the geometry and operators of Theorem 9.3, and let $V_d(A)$ be the gauge-corrected iteration of Lemma 8.10 with background connection $U_0 = I$, applied to the fine field $e^{\epsilon A}$. Write*

$$\mathsf{F}_d(A) = \operatorname{Log} V_d(A) = Q_d A + \mathscr{E}_d^{\mathrm{av}}(A), \qquad \mathscr{E}_d^{\mathrm{av}}(0) = D\mathscr{E}_d^{\mathrm{av}}(0) = 0.$$

There exist $r_*, \theta_*, C > 0$, independent of d and n, such that the following statements hold.

1. The remainder. *F_d is holomorphic on $\|A\|_\infty < r_*$, and*

$$\|\mathscr{E}_d^{\mathrm{av}}(A)\|_\infty \le C\|A\|_\infty^2, \qquad \|D\mathscr{E}_d^{\mathrm{av}}(A)\|_{\mathrm{row}} \le C\|A\|_\infty,$$
$$\|D\mathscr{E}_d^{\mathrm{av}}(A)\|_{\text{counting col}} \le C\epsilon^3\|A\|_\infty.$$

   These bounds, and the first-order bounds below, also hold with one fixed positive exponential weight in the distance, on fixed smaller domains.

2. An analytic right inverse. *The radii can be chosen so that $2\|H_d\|_{\infty\to\infty}\theta_* < r_*$ and so that, for every complex coarse field θ with $\|\theta\|_\infty < \theta_*$, the equation*

$$q_d(\theta) = \theta - \mathscr{E}_d^{\mathrm{av}}\big(H_d q_d(\theta)\big)$$

   has a unique solution in the coarse ball of radius $2\theta_*$, and $\|q_d(\theta)\|_\infty \le 2\|\theta\|_\infty$. The map $A_{\mathrm{sec},d}(\theta) = H_d q_d(\theta)$ is holomorphic, real for real θ, and satisfies

$$\mathsf{F}_d(A_{\mathrm{sec},d}) = \theta, \qquad \|A_{\mathrm{sec},d}\|_\infty + \|\nabla_\epsilon A_{\mathrm{sec},d}\|_\infty \le C\|\theta\|_\infty, \qquad \|q_d(\theta)\|_2 \le C\|\theta\|_2.$$

   For every fixed $s \ge 1$, the sums of the absolute derivative coefficients of order s of $A_{\mathrm{sec},d}$, and of $\nabla_\epsilon A_{\mathrm{sec},d}$, with the output fixed or with any one coarse input fixed, are bounded by C_s with the weight $e^{a_s \mathsf{t}}$ for some $a_s > 0$; in the sums with a coarse input fixed, the fine outputs are summed with the weight ϵ^3. The constants C_s and a_s depend only on s and on the radii and decay rates, as in the convention of Section 9.1.

3. Coordinates reducing the constraint to its linear part. *There exist $r_{\mathrm{st}}, r_D > 0$ with $r_{\mathrm{st}} < r_*/4$ such that, for every fine field w with $\|w\|_\infty < r_{\mathrm{st}}$, there is a unique coarse correction $\mathscr{D}_d(w)$ with $\|\mathscr{D}_d(w)\|_\infty < r_D$ satisfying*

$$\mathscr{D}_d(w) = \mathscr{E}_d^{\mathrm{av}}\big(w - H_d\mathscr{D}_d(w)\big).$$

   It is holomorphic in w, and $\Xi_d(w) = w - H_d\mathscr{D}_d(w)$ satisfies

$$\mathsf{F}_d(\Xi_d(w)) = Q_d w.$$

   Further, $\|\mathscr{D}_d(w)\|_\infty \le C\|w\|_\infty^2$, the row norm of $D\mathscr{D}_d(w)$ is at most $C\|w\|_\infty$, and its counting column norm is at most $C\epsilon^3\|w\|_\infty$. For every fixed $s \ge 2$, the derivatives of order

s of $\mathscr{D}_d$ have row sums at most C_s and counting column sums, with any one input fixed, at most $C_s\epsilon^3$, with a weight $e^{a_s \mathsf{t}}$, $a_s > 0$. Even if w has no control of its differences,

$$\|\Xi_d(w) - w\|_\infty + \|\nabla_\epsilon(\Xi_d(w) - w)\|_\infty \le C\|w\|_\infty^2.$$

4. Coordinates on the fibers. *There exists $0 < r_{\mathrm{fib}} < r_{\mathrm{st}}$, independent of d and n, such that every fine field A with $\|A\|_\infty < r_{\mathrm{fib}}$ and $\mathsf{F}_d(A) = \theta$, $\|\theta\|_\infty < \theta_*$, can be written uniquely as*

$$A = \Xi_d(a + H_d\theta), \qquad a \in \ker Q_d,$$

namely with $a = (I - H_dQ_d)A$, and then $\|a + H_d\theta\|_\infty < r_{\mathrm{st}}$. Conversely, $\mathsf{F}_d(\Xi_d(a + H_d\theta)) = \theta$ for every $a \in \ker Q_d$ with $\|a + H_d\theta\|_\infty < r_{\mathrm{st}}$. Moreover $\mathsf{P}_d \operatorname{div}_\epsilon \Xi_d(a + H_d\theta) = \mathsf{P}_d \operatorname{div}_\epsilon a$, so restricting a to $\mathcal{V}_d$ gives exactly the fields of this form that satisfy $\mathsf{P}_d \operatorname{div}_\epsilon A = 0$.

The configuration with prescribed image under T_M^d obtained from $A_{\mathrm{sec},d}$, and its action, are described in Corollary 9.10.

The following list summarizes the roles of the radii in Theorem 9.6; it does not replace the inequalities in the statement.

Radius	Domain or role
r_*	Fine input ball on which F_d is holomorphic and the remainder bounds of part (1) hold.
θ_*, $2\theta_*$	Coarse target ball, and coarse ball in which $q_d(\theta)$ is the unique fixed point.
r_{st}, r_D	Fine parameter ball on which Ξ_d is defined, and coarse ball in which $\mathscr{D}_d(w)$ is the unique correction.
r_{fib}	Fine ball of solutions of $\mathsf{F}_d(A) = \theta$ covered by the coordinates of part (4); their parameters lie in the ball of radius r_{st}, but the image of that whole parameter ball is not claimed to lie in the ball of radius r_{fib}.

Proof. We first extract the quadratic remainder of F_d from Lemma 8.11, then solve the two coarse fixed-point equations by Lemma 9.5, and finally prove the bounds for derivatives of higher order by induction over the order.

Step 1: The remainder. We apply Lemma 8.10 with background connection $U_0 = I$, and denote the intermediate potentials by A_j. Since $\epsilon_d = 1$, the last potential is $\mathsf{F}_d(A)$. At the identity every background curvature vanishes, and the transported segment averages K_j are the averages K_M/M of physical potentials, whose product is Q_d by Lemma 8.1. Also

$$\sum_{j<d} \epsilon_{j+1}\|A_j\|_\infty \le 2\|A\|_\infty \frac{M}{M-1}.$$

Using the telescope of Lemma 8.11 with $j = d$, we obtain

$$\|D\mathsf{F}_d(A) - Q_d\|_{\mathrm{row}} \le C\|A\|_\infty, \qquad \|D\mathsf{F}_d(A) - Q_d\|_{\text{counting col}} \le C\epsilon^3\|A\|_\infty. \tag{9.13}$$

All terms have a dependence radius at most C_M, and a fixed exponential weight multiplies their coefficients by at most a fixed factor. We shrink the complex ball once and call its radius r_*. Integrating $D\mathsf{F}_d(tA) - Q_d$ against A for $0 \le t \le 1$ gives the quadratic bound for $\mathscr{E}_d^{\mathrm{av}} = \mathsf{F}_d - Q_d$ and its two vanishing Taylor coefficients. By Lemma 8.11, every derivative of fixed order of this remainder has a bounded row sum and a counting column sum with a fixed input at most $C_s\epsilon^3$; subtracting the linear part affects only the first order.

Step 2: The coarse remainder. Fix a spatial rate smaller than the rate of the kernel of H_d. Let B_H be a common upper bound for $\|H_d\|_{\infty\to\infty}$ and for the weighted row and volume-normalized column norms of H_d given by Theorem 9.3, and set $r(q) = \mathscr{E}_d^{\mathrm{av}}(H_d q)$. Composing, with a further fixed reduction of the rate if necessary, we obtain

$$\|r(q)\|_\infty \le C_r\|q\|_\infty^2, \qquad \|Dr(q)\|_{\mathrm{row}} + \|Dr(q)\|_{\mathrm{col}} \le C_r\|q\|_\infty, \tag{9.14}$$

where here and below the norms in derivative estimates may carry the spatial weight. The column composition is explicit: with $E = D\mathscr{E}_d^{\mathrm{av}}(H_d q)$,

$$\sum_c \|(EH_d)(c,b)\| \le \sum_e \Big(\sum_c \|E(c,e)\|\Big)\|H_d(e,b)\| \le C\epsilon^3\|q\|_\infty \sum_e \|H_d(e,b)\| \le C\|q\|_\infty.$$

The row composition uses the two row bounds. In the weighted version, $\mathrm{dist}(c,b) \le \mathrm{dist}(c,e) + \mathrm{dist}(e,b)$, and the same calculation applies. No power of the fine volume remains.

Step 3: The analytic right inverse. We enlarge C_r so that it controls both weighted norms, and choose θ_* so small that

$$2B_H\theta_* < r_*, \qquad 2C_r\theta_* \le \tfrac{1}{4}.$$

The map $q \mapsto \theta - r(q)$ sends the closed ball $\|q\|_\infty \le 2\theta_*$ into itself, since $\|r(q)\|_\infty \le 4C_r\theta_*^2 \le \theta_*/2$, and it is a contraction with constant at most $1/4$. By Lemma 9.5, there exists a unique fixed point, which is holomorphic and real for real θ. Since $r(0) = 0$, the derivative bound implies that $\|q\|_\infty \le \|\theta\|_\infty + \|q\|_\infty/4$, which gives $\|q\|_\infty \le 2\|\theta\|_\infty$.

In both the weighted row norm and the weighted column norm on the coarse lattice,

$$U^{-1} = (I + Dr(q))^{-1} = \sum_{k\ge 0}(-Dr(q))^k, \qquad \|U^{-1}\| \le \tfrac{4}{3},$$

by submultiplicativity (Lemma 5.3). Differentiating the fixed-point equation, we find $D_\theta q = U^{-1}$. Lemma 9.1, applied with counting measure on both coarse lattices, bounds its ℓ^2 operator norm by $4/3$. Integrating along $t\theta$ with $q(0) = 0$, we obtain $\|q(\theta)\|_2 \le C\|\theta\|_2$. The identity $\mathsf{F}_d(A_{\mathrm{sec},d}) = Q_d H_d q + r(q) = \theta$ follows from $Q_d H_d = I$ and the fixed-point equation, and the bounds for $A_{\mathrm{sec},d}$ and its first differences follow from the row bounds of the extension.

Step 4: Derivatives of higher order of the right inverse. For each fixed order s, we compose a remainder tensor of order $p \le s$ with p copies of H_d. With the output fixed, all copies use rows. With a coarse input fixed, the copy on the branch of that input has counting column sum at most $C\epsilon^{-3}$, which is canceled by the counting column sum $C_p\epsilon^3$ of the remainder tensor with a fine input fixed. All other branches use rows. The union of the connecting networks of the components connects all external locations, and the weight of a shortest connecting network is bounded by the product of the weights of the components, as in Lemma 5.3. We obtain finite bounds for $D^p r$, for $1 \le p \le s$, with any index fixed, at a common positive rate. For $s \ge 2$, differentiating the equation for q, we obtain

$$U\, D^s q[h_1, \dots, h_s] = - \sum_{\substack{\pi \text{ a partition of } \{1,\dots,s\} \\ |\pi| \ge 2}} D^{|\pi|} r(q) \Big[D^{|B|} q[h_i : i \in B] : B \in \pi \Big], \tag{9.15}$$

and every block in the sum has size smaller than s. Starting from the bound for Dq, multiplication by U^{-1} and induction on s give the bounds with the output or any coarse input fixed. The number of partitions and the constants up to order s depend only on s and on the radii and decay rates fixed above. A final composition with H_d, or with $\nabla_\epsilon H_d$, proves the bounds for the section; with a coarse input fixed and fine outputs, this last column uses $\epsilon^3 \sum_e$.

Step 5: The coordinates Ξ_d. We now construct Ξ_d without any assumption on the differences of w. Let C_E dominate the quadratic and derivative constants of Step 1 on a smaller ball. We choose $r_{\mathrm{st}} < r_*/4$ and set $r_D = 8C_E r_{\mathrm{st}}^2$, decreasing r_{st} until

$$B_H r_D \le r_{\mathrm{st}}, \qquad 2C_E B_H r_{\mathrm{st}} \le \tfrac{1}{4}.$$

For $\|w\|_\infty < r_{\mathrm{st}}$ and $\|\mathscr{D}\|_\infty \le r_D$ we have $\|w - H_d\mathscr{D}\|_\infty \le 2r_{\mathrm{st}}$. Therefore the map $\mathscr{D} \mapsto \mathscr{E}_d^{\mathrm{av}}(w - H_d\mathscr{D})$ sends the closed ball of radius r_D into the concentric ball of radius $r_D/2$ and is a contraction with constant at most $1/4$. Lemma 9.5 constructs $\mathscr{D}_d(w)$, unique in that ball. Comparing its equation with the value at $\mathscr{D} = 0$, we find

$$\|\mathscr{D}_d(w)\|_\infty \le C_E \|w\|_\infty^2 + \tfrac{1}{4}\|\mathscr{D}_d(w)\|_\infty, \tag{9.16}$$

and absorbing the last term gives the quadratic bound. Using $Q_d H_d = I$ in the defining equation, we obtain

$$\mathsf{F}_d\big(w - H_d\mathscr{D}_d(w)\big) = Q_d w - \mathscr{D}_d(w) + \mathscr{E}_d^{\mathrm{av}}\big(w - H_d\mathscr{D}_d(w)\big) = Q_d w.$$

For the derivative bounds, write $X = \Xi_d(w)$, $E_1 = D\mathscr{E}_d^{\mathrm{av}}(X)$, and $W = I + E_1 H_d$. The coarse weighted row and column norms of $E_1 H_d$ are $O(\|w\|_\infty)$, and a Neumann series bounds W^{-1} uniformly. Differentiating, we obtain

$$D\mathscr{D}_d = W^{-1} E_1, \qquad D\Xi_d = I - H_d D\mathscr{D}_d. \tag{9.17}$$

The right factor E_1 has counting column sum at most $C\epsilon^3\|w\|_\infty$, which the first formula keeps, and its row sum is at most $C\|w\|_\infty$. The second formula has bounded rows and columns from fine fields to fine fields: in the column composition, the factor ϵ^{-3} from H_d cancels against the factor ϵ^3 from $D\mathscr{D}_d$. For $s \geq 2$,

$$W\, D^s \mathscr{D}_d[h_1, \dots, h_s] = \sum_{\substack{\pi \text{ a partition of } \{1,\dots,s\} \\ |\pi| \geq 2}} D^{|\pi|} \mathscr{E}_d^{\mathrm{av}}(X) \Big[D^{|B|} \Xi_d[h_i : i \in B] : B \in \pi \Big], \quad (9.18)$$

where $D^t \Xi_d = -H_d D^t \mathscr{D}_d$ for $t \geq 2$. By induction, these tensors from fine fields to fine fields have bounded rows and columns. With an external fine input fixed in a term of (9.18), we follow its branch: the tensor $D\Xi_d$ or $D^t\Xi_d$ on that branch uses its column, and the remainder tensor then uses its column with a fine input fixed, which supplies one factor ϵ^3. All other branches use rows. The coarse inverse W^{-1} preserves this factor. By the symmetry of derivatives any input may be the fixed one. This proves, by induction, the bounds C_s for rows and $C_s\epsilon^3$ for counting columns, with positive rates.

Step 6: Coordinates on the fibers. Let $r_{\mathrm{fib}} > 0$ be so small that

$$r_{\mathrm{fib}} < r_{\mathrm{st}}/2, \qquad r_{\mathrm{fib}} + B_H C_E r_{\mathrm{fib}}^2 < r_{\mathrm{st}}, \qquad C_E r_{\mathrm{fib}}^2 < r_D.$$

If $\mathsf{F}_d(A) = \theta$, set $a = (I - H_d Q_d)A$. Then $Q_d a = 0$ and

$$w = a + H_d\theta = A + H_d \mathscr{E}_d^{\mathrm{av}}(A).$$

By these inequalities, w lies in the ball of radius r_{st} and $\mathscr{E}_d^{\mathrm{av}}(A)$ in the ball of radius r_D in which the correction is unique. Since $w - H_d\mathscr{E}_d^{\mathrm{av}}(A) = A$, the field $\mathscr{E}_d^{\mathrm{av}}(A)$ solves the correction equation at w, and uniqueness implies that $\mathscr{D}_d(w) = \mathscr{E}_d^{\mathrm{av}}(A)$ and $\Xi_d(w) = A$. Conversely, $Q_d(a + H_d\theta) = \theta$, and the identity of part (3) yields the constraint for every such parameter. Applying $I - H_d Q_d$ to $\Xi_d(a + H_d\theta) = a + H_d\theta - H_d\mathscr{D}_d(a + H_d\theta)$ recovers a, which proves uniqueness of the parameter. Since $\mathsf{P}_d \operatorname{div}_\epsilon H_d = 0$,

$$\mathsf{P}_d \operatorname{div}_\epsilon \Xi_d(a + H_d\theta) = \mathsf{P}_d \operatorname{div}_\epsilon a,$$

which proves the statement about $\mathcal{V}_d$. Finally $\Xi_d(w) - w = -H_d\mathscr{D}_d(w)$. Using the row bounds of H_d and $\nabla_\epsilon H_d$ and (9.16), we obtain the bound for the correction even when w has no controlled differences. □

9.6 The constrained Wilson Hessian

We now show that the Wilson action, written in the coordinates $a \in \mathcal{V}_d$ of Theorem 9.6, has a Hessian comparable to the curl form. The domain is controlled by the supremum norms of the field and of its curl only, so that fields without control of all first differences

are allowed. The Hessian of the composition contains, besides the Hessian of the action in the direction of the tangent map, the first variation of the action applied to the second derivative of the coordinate map; this second term must be kept.

Theorem 9.7. *In the setting of Theorem 9.6, let*

$$\mathscr{S}_\epsilon(A) = 4\epsilon^{-1}\sum_p q\big((e^{\epsilon A})_p\big), \qquad \mathcal{S}_{d,\theta}(a) = \mathscr{S}_\epsilon\big(\Xi_d(a + H_d\theta)\big).$$

There exist $r_0, C_*, C > 0$ such that the following holds with the constant c_0 of Theorem 9.3. Let $0 < r_{\mathrm{ph}} \le r_0$, let θ be a real coarse field with $\|\theta\|_\infty < r_{\mathrm{ph}}/C_*$, and let $a \in \mathcal{V}_d$ be real with

$$\|a\|_\infty + \|\mathrm{d}_\epsilon a\|_\infty < r_{\mathrm{ph}}.$$

1. *The field $A = \Xi_d(a + H_d\theta)$ satisfies $\|A\|_\infty + \|\mathrm{d}_\epsilon A\|_\infty \le C r_{\mathrm{ph}}$.*
2. *For every $v \in \mathcal{V}_d$,*
$$\frac{c_0}{2}\|v\|^2_{H^1_\epsilon} \le D^2_a\mathcal{S}_{d,\theta}(a)[v,v] \le C\|v\|^2_{H^1_\epsilon}.$$
3. *With $w = a + H_d\theta$ and $T = D\Xi_d(w) = I - H_d D\mathscr{D}_d(w)$, the Hessian is*
$$D^2_a\mathcal{S}_{d,\theta}(a)[v,v] = D^2\mathscr{S}_\epsilon(A)[Tv,Tv] - D\mathscr{S}_\epsilon(A)\big[H_d D^2\mathscr{D}_d(w)[v,v]\big].$$
4. *The following bounds hold, where e_c denotes a unit coarse link-color vector:*
$$\big|D^2\mathscr{S}_\epsilon(A)[z,z] - \|\mathrm{d}_\epsilon z\|^2_\epsilon\big| \le C r_{\mathrm{ph}}\|z\|^2_{H^1_\epsilon},$$
$$\sup_c |D\mathscr{S}_\epsilon(A)[H_d e_c]| \le C r_{\mathrm{ph}}, \qquad \sum_c |D^2\mathscr{D}_{d,c}(w)[v,v]| \le C\|v\|^2_\epsilon.$$

The same conclusions hold, after a fixed adjustment of the constants, when the hypothesis on $\|\mathrm{d}_\epsilon a\|_\infty$ is replaced by the same hypothesis on $\|\nabla_\epsilon a\|_\infty$. The domain of a described above is convex. If it contains a critical point $a_*(\theta)$ of $\mathcal{S}_{d,\theta}$ on $\mathcal{V}_d$, then a_* is the only critical point in the domain, and for every a in the domain

$$\mathcal{S}_{d,\theta}(a) \ge \mathcal{S}_{d,\theta}(a_*) + \frac{c_0}{4}\|a - a_*\|^2_{H^1_\epsilon}.$$

For the Wilson action at coarse coupling g_n, every energy and Hessian in these statements is multiplied by g_n^{-2}. The constants do not depend on r_{ph}, d, n, L, γ, g_n, or J.

The bound on $D\mathscr{S}_\epsilon(A)[H_d e_c]$ concerns the first variation tested against the extensions of unit coarse fields; no bound on the first variation at individual fine links is used.

Proof. We first bound the Hessian and the tested first variation of $\mathscr{S}_\epsilon$ near the identity, then control the two terms of the chain rule separately, and finally deduce the convexity statements.

Step 1: The Hessian of the Wilson action. Suppose that $\|A\|_\infty + \|\mathrm{d}_\epsilon A\|_\infty \le \rho \le \rho_0$ with a fixed small ρ_0, and use the notation of Lemma 9.4. By (9.10) and the triangle inequality, $|X_p(A)| \le C\epsilon^2\rho$. Let $b_p = (\mathrm{d}_\epsilon z)_p$ and $E_p = DX_p(A)[z] - \epsilon^2 b_p$. The second derivative of the term of p in $\mathscr{S}_\epsilon$ is

$$\frac{4}{\epsilon}\Big(D^2\varphi(X_p)\big[\epsilon^2 b_p + E_p, \epsilon^2 b_p + E_p\big] + D\varphi(X_p)\big[D^2X_p(A)[z,z]\big]\Big).$$

Since $D^2\varphi = I/4 + O(|X|^2)$, its leading term is exactly $\epsilon^3|b_p|^2$. By (9.11), the cross term and the square of E_p are bounded by $C\epsilon^3\rho(|b_p|^2 + Z_p^2)$, since $\rho \le \rho_0$. The error in $D^2\varphi$ is bounded by the same expression, since $\epsilon \le 1$ and $|X_p| \le C\epsilon^2\rho$. By (9.12) and $|D\varphi(X_p)| \le C|X_p|$, the last term, the first variation applied to the second variation of X_p, is bounded by $C\epsilon^3\rho Z_p^2$. Summing over plaquettes, using the fixed overlap of links and plaquettes, $\|\mathrm{d}_\epsilon z\|_\epsilon \le C\|\nabla_\epsilon z\|_\epsilon$, and $\epsilon^3\sum_p Z_p^2 \le C\|z\|_\epsilon^2$, we obtain

$$\big|D^2\mathscr{S}_\epsilon(A)[z,z] - \|\mathrm{d}_\epsilon z\|_\epsilon^2\big| \le C\rho\|z\|_{H^1_\epsilon}^2. \tag{9.19}$$

In particular $D^2\mathscr{S}_\epsilon(0)[z,z] = \|\mathrm{d}_\epsilon z\|_\epsilon^2$.

Step 2: The first variation tested against the extension. Let $z = H_d e_c$. Using the same first-variation formula, $|D\varphi(X_p)| \le C\epsilon^2\rho$, and (9.11), we obtain

$$|D\mathscr{S}_\epsilon(A)[H_d e_c]| \le C\rho\,\epsilon^3 \sum_p \Big(|(\mathrm{d}_\epsilon H_d e_c)_p| + \rho \sum_{e\in\partial p} |H_d(e,c)|\Big) \le C\rho.$$

In the last step we used the column bounds with the factor ϵ^3 for the kernels of H_d and $\nabla_\epsilon H_d$ in Theorem 9.3, and the fixed overlap of plaquettes. The bound is uniform in the coarse link c.

Step 3: The size of the chart. Let B_0 and B_1 bound the rows of the kernels of H_d and $\nabla_\epsilon H_d$. For $w = a + H_d\theta$, the hypotheses imply that

$$\|w\|_\infty \le r_{\mathrm{ph}} + B_0 r_{\mathrm{ph}}/C_*, \qquad \|\mathrm{d}_\epsilon w\|_\infty \le r_{\mathrm{ph}} + CB_1 r_{\mathrm{ph}}/C_*.$$

We take $C_* > 4(1 + B_0 + CB_1)$ and r_0 so that these fields lie in the ball of radius r_{st} of Theorem 9.6 and their images lie in the potential ball of Step 1. By the bound for $\Xi_d(w) - w$ in that theorem, we have

$$\|A\|_\infty + \|\mathrm{d}_\epsilon A\|_\infty \le C_1 r_{\mathrm{ph}} = \rho, \tag{9.20}$$

with constants fixed before r_{ph}. If the hypothesis is instead the bound on $\|\nabla_\epsilon a\|_\infty$, the inequality $\|\mathrm{d}_\epsilon a\|_\infty \le C\|\nabla_\epsilon a\|_\infty$ gives the same estimate after enlarging C_1 by this dimensional factor. We choose r_0 below with the enlarged constant; the Hessian bounds then hold under both hypotheses.

Step 4: The term with the tangent map. Let $D_1 = D\mathscr{D}_d(w)$ and $T = I - H_d D_1$. By Theorem 9.6, the row sum of D_1 is at most Cr_{ph} and its counting column sum is at most $C\epsilon^3 r_{\mathrm{ph}}$. By Lemma 9.1 and the H^1_ϵ bound for the extension, we have

$$\|D_1 v\|_2 \le Cr_{\mathrm{ph}}\|v\|_\epsilon, \qquad \|Tv - v\|_{H^1_\epsilon} \le Cr_{\mathrm{ph}}\|v\|_\epsilon. \tag{9.21}$$

Applying (9.19) to Tv and expanding the difference of the two curl squares, we obtain

$$\left|D^2\mathscr{S}_\epsilon(A)[Tv, Tv] - \|\mathrm{d}_\epsilon v\|^2_\epsilon\right| \le C_2 r_{\mathrm{ph}}\|v\|^2_{H^1_\epsilon}. \tag{9.22}$$

Step 5: The term with the second derivative of the coordinates. This term requires an ℓ^1 bound on a tensor. Let $B_{c;e,f}$ denote the color block of the second derivative of $\mathscr{D}_{d,c}$ at w with respect to the fine inputs e, f. By part (3) of Theorem 9.6 with $s = 2$,

$$\sup_e \sum_{c,f} \|B_{c;e,f}\| \le C\epsilon^3.$$

Since the tensor is symmetric in its two fine inputs, we have

$$\begin{aligned}\sum_c |D^2\mathscr{D}_{d,c}(w)[v,v]| &\le \sum_{c,e,f} \|B_{c;e,f}\||v_e||v_f| \le \frac{1}{2}\sum_{c,e,f}\|B_{c;e,f}\|\left(|v_e|^2 + |v_f|^2\right)\\ &\le C\epsilon^3 \sum_e |v_e|^2 = C\|v\|^2_\epsilon.\end{aligned} \tag{9.23}$$

Combining this with Step 2, we obtain

$$\left|D\mathscr{S}_\epsilon(A)\left[H_d D^2\mathscr{D}_d(w)[v,v]\right]\right| \le C_3 r_{\mathrm{ph}}\|v\|^2_\epsilon. \tag{9.24}$$

No norm of the first variation summed over the coarse lattice enters this pairing.

Step 6: The chain rule and the conclusion. With θ fixed, $D_a A = T$ and $D^2_a A[v,v] = -H_d D^2\mathscr{D}_d(w)[v,v]$, and the second-order chain rule gives the formula of part (3). By (9.22) and (9.24), the Hessian differs from $\|\mathrm{d}_\epsilon v\|^2_\epsilon$ by at most $C_4 r_{\mathrm{ph}}\|v\|^2_{H^1_\epsilon}$. We shrink r_0 so that $C_4 r_0 \le c_0/2$. For $v \in \mathcal{V}_d$, the lower bound of part (2) follows from the coercivity of the curl in Theorem 9.3, and the componentwise bound $\|\mathrm{d}_\epsilon v\|_\epsilon \le C\|\nabla_\epsilon v\|_\epsilon$ implies the upper bound. This also proves the bounds of part (4), with $\rho = C_1 r_{\mathrm{ph}}$ absorbed into the constants.

The domain of a is the intersection of the linear space $\mathcal{V}_d$ with the open ball for the sum of a norm and a seminorm, which is convex. If a_* is a critical point in the domain and $h = a - a_*$, then the derivative at a_* vanishes on $h \in \mathcal{V}_d$, and by Taylor's formula along the segment we have

$$\mathcal{S}_{d,\theta}(a) - \mathcal{S}_{d,\theta}(a_*) = \int_0^1 (1-t) D^2_a \mathcal{S}_{d,\theta}(a_* + th)[h,h]\, dt \ge \frac{c_0}{4}\|h\|^2_{H^1_\epsilon}.$$

If there were two critical points, integrating the Hessian along the segment between them and pairing the difference of their derivatives with their difference would give a positive number and also zero, so they coincide. Finally, since the fine coupling satisfies $g_0^2 = g_n^2 \epsilon$, the Wilson action at coarse coupling g_n equals $g_n^{-2} \mathscr{S}_\epsilon$, and energies and derivatives are multiplied by g_n^{-2}. □

9.7 A scalar constrained inverse including constant modes

The linearization of the gauge-fixing problem of Section 9.8 is the scalar system $(\mathsf{P}_d \mathscr{L}_\epsilon \lambda, Q_d' \lambda) = (f, b)$. The following lemma inverts it, with estimates for λ, its first differences, and its Laplacian. Bounds on all second differences of λ are not needed and are not proved; the Laplacian is controlled through exact identities.

Lemma 9.8. *In the geometry of Theorem 9.3, let $Q = Q_d'$ and $\mathscr{L} = \mathscr{L}_\epsilon$, and define, with the adjoints of Section 9.1,*

$$G = (\mathscr{L} + Q^\sharp Q)^{-1}, \qquad T = QG^2Q^\sharp, \qquad \mathsf{P}_d = I - GQ^\sharp T^{-1} QG,$$
$$\mathscr{B} = G - G^2 Q^\sharp T^{-1} QG, \qquad \mathscr{E} = G^2 Q^\sharp T^{-1} + \mathscr{B} Q^\sharp.$$

Then the following statements hold.

1. *G is defined, T is positive definite, and the formula above for P_d is the orthogonal projection onto $\mathscr{L} \ker Q$.*
2. *We have*

$$Q\mathscr{B} = 0, \quad \mathscr{L}\mathscr{B} = \mathsf{P}_d, \quad Q\mathscr{E} = I, \quad \mathsf{P}_d \mathscr{L}\mathscr{E} = 0, \quad \mathscr{L}\mathscr{E} = GQ^\sharp T^{-1}(I - QGQ^\sharp).$$

3. *For every fine scalar field $f \in \operatorname{Ran} \mathsf{P}_d$ and every coarse scalar color field b, the unique solution of*

$$(\mathsf{P}_d \mathscr{L} \lambda, Q\lambda) = (f, b)$$

is $\lambda = \mathscr{B} f + \mathscr{E} b$, and in the norm

$$\|\lambda\|_{\mathsf{Y}} = \|\lambda\|_\infty + \|\nabla_\epsilon \lambda\|_\infty + \|\mathscr{L}\lambda\|_\infty$$

it satisfies $\|\lambda\|_{\mathsf{Y}} \le C(\|f\|_\infty + \|b\|_\infty)$.

4. *The maps $\mathscr{B}$ and $\mathscr{E}$, their left first differences, and $\mathscr{L}\mathscr{B}$ and $\mathscr{L}\mathscr{E}$ have absolute row sums bounded with a positive exponential weight in the distance between coarse blocks.*
5. *For a constant coarse field b, $\mathscr{E} b = b$; the constant scalar mode is fixed by the coarse datum, not removed.*

The constants depend only on M, the localization size M_{loc} of Lemma 9.2, and the decay rates and radii, as in the convention of Section 9.1; they do not depend on d, n, L, γ, or J.

The algebra in parts (1) and (2) is the scalar algebra of [10, (1.43)–(1.45), pp. 25–26] and the projection of [11, (2.17), p. 225], and the analytic input is [13, Theorems 3.1 and 3.2]; see Table 9.1. We give the finite-dimensional proof with our adjoints.

Proof. We first prove the finite-dimensional identities, then transfer the cited estimates for penalty α_d from the cover to the torus of side n, convert them to penalty one, and compose.

Step 1: Algebra. The centered scalar blocks partition the fine sites, and

$$(Qf)(Y) = \epsilon^3 \sum_{x \in \mathsf{B}_m(Y)} f(x), \qquad (Q^\sharp b)(x) = b(Y) \quad (x \in \mathsf{B}_m(Y)),$$

where $\mathsf{B}_m(Y)$ is the block of Y. Then $QQ^\sharp = I$, Q is onto, and $Q^\sharp$ is injective. If the nonnegative form of $\mathscr{L} + Q^\sharp Q$ vanishes at u, then $\nabla_\epsilon u = 0$ and $Qu = 0$; a periodic function with zero gradient is constant, and its block average is that constant, so $u = 0$. This shows that G exists for all finite d and n. Further, $\langle b, Tb\rangle = \|GQ^\sharp b\|_\epsilon^2 > 0$ for $b \neq 0$, and T is positive definite.

Let $Y = GQ^\sharp$, whose adjoint is $Y^\sharp = QG$. Then $Y^\sharp Y = T$, and $YT^{-1}Y^\sharp$ is a self-adjoint idempotent with range $\operatorname{Ran} Y$. We identify the orthogonal complement of this range. For $u \in \ker Q$,

$$\langle \mathscr{L}u, GQ^\sharp b\rangle_\epsilon = \langle u, (I - Q^\sharp QG)Q^\sharp b\rangle_\epsilon = 0,$$

where we used $\mathscr{L}G = I - Q^\sharp QG$; both terms of the second expression vanish since $Qu = 0$. The restriction of $\mathscr{L}$ to $\ker Q$ is injective, since its null vectors would be constants with zero block average. Its image has codimension equal to the number of coarse scalar variables, which is the dimension of the range of the injective map Y. Together with the orthogonality just proved, this implies that $(\operatorname{Ran} Y)^\perp = \mathscr{L} \ker Q$, which proves part (1).

Multiplying in the stated order, we find $Q\mathscr{B} = QG - (QG^2Q^\sharp)T^{-1}QG = 0$, and hence

$$\mathscr{L}\mathscr{B} = (G^{-1} - Q^\sharp Q)\mathscr{B} = I - GQ^\sharp T^{-1}QG = \mathsf{P}_d. \tag{9.25}$$

Let $Z = G^2Q^\sharp T^{-1}$. Then $QZ = I$ and $\mathscr{L}Z = GQ^\sharp T^{-1} - Q^\sharp$, which gives $Q\mathscr{E} = I$ and

$$\mathscr{L}\mathscr{E} = GQ^\sharp T^{-1} - Q^\sharp + \mathsf{P}_d Q^\sharp = GQ^\sharp T^{-1}(I - QGQ^\sharp).$$

Since $\mathsf{P}_d GQ^\sharp = 0$, this implies that $\mathsf{P}_d \mathscr{L}\mathscr{E} = 0$, which completes part (2). In particular, $\lambda = \mathscr{B}f + \mathscr{E}b$ solves the two equations for every $f \in \operatorname{Ran} \mathsf{P}_d$. For a solution of the homogeneous system, $Q\lambda = 0$ implies $\mathscr{L}\lambda \in \operatorname{Ran} \mathsf{P}_d$, the projected equation gives $\mathscr{L}\lambda = 0$, and λ is a constant with zero block average, hence zero. This proves uniqueness. If b is constant, the constant fine field equal to b solves the system with $f = 0$, and by uniqueness $\mathscr{E}b = b$.

At $d = 0$, substituting $Q = I$, we find $T = G^2$, $\mathsf{P}_0 = 0$, $\mathscr{B} = 0$, and $\mathscr{E} = I$. The unit-mesh first difference and Laplacian have finite stencils with bounded absolute rows, and all estimates hold directly, with $f = 0$. In the rest of the proof we assume $d \geq 1$.

Step 2: The cited estimates and the penalty. The uniform estimates are [13, Theorem 3.1, the potential and first-gradient entries of (3.42), p. 397, and the global bounds (3.47), p. 398]. Further, [13, Theorem 3.2, (3.48), p. 398] gives the exponential decay of the kernel of the corresponding coarse inverse, which is $\widehat{T}^{-1}$ in the notation introduced below, and (3.49), p. 399, gives the kernel of the complementary projection. For a source supported in one coarse block of unit size, the two entries of (3.42) bound the potential and its first physical gradient in another coarse block by $Ce^{-a\,\mathrm{dist(blocks)}}$ times the supremum of the source, and the coarse inverse in (3.48) has the same exponential bound. All scale factors are one in this whole-torus specialization with unit coarse spacing. We apply these estimates on the cover of side kn of Lemma 9.2, in the specialization described after that lemma. The local gauge transformations in [13, (3.35)–(3.36), p. 396] are the identity with potential zero, and the scalar average is the lower-corner average translated by T_d as in (9.5) and (9.6). Conjugation by T_d translates the scalar inverse and the kernels of the projection and preserves the coarse Schur operator. The fine measure is ϵ^3, and coarse kernels are summed with counting measure.

In the whole-torus convention of [13, (3.24), p. 394], the parameter $a = 1$ gives a coarse penalty coefficient α_d with

$$\alpha_0 = 1, \qquad \alpha_d = \frac{1 - M^{-2}}{1 - M^{-2d}} \quad (d \geq 1), \qquad 1 - M^{-2} \leq \alpha_d \leq 1.$$

Indeed, the recurrence $a_{j+1} = a_j/(M^{-2} + a_j)$ with $a_1 = 1$ is solved by taking reciprocals and summing the geometric progression. The operators to which the cited estimates apply directly are

$$\widehat{G} = (\mathscr{L} + \alpha_d Q^\sharp Q)^{-1}, \qquad \widehat{T} = Q\widehat{G}^2 Q^\sharp.$$

The estimates hold for $\widehat{G}^{(kn)}$ and $(\widehat{T}^{(kn)})^{-1}$ on the cover, uniformly in d and n. We next transfer them to the torus of side n and then convert to penalty one.

Step 3: Transfer to the torus of side n. For every $\alpha > 0$, on either torus, the form $\|\nabla_\epsilon \lambda\|_\epsilon^2 + \alpha\|Q\lambda\|_2^2$ is positive at $\lambda \neq 0$, since a field with zero gradient is constant and Q preserves constants. Hence $\mathscr{L} + \alpha Q^\sharp Q$ is invertible. The operators $\mathscr{L}$, Q, and $Q^\sharp$ commute with π^*, and α_d is the same on both tori. Applying the positive operator to both sides gives the first identity below; the second follows by composition, and the third by positivity and uniqueness of the coarse inverse:

$$\widehat{G}^{(kn)}\pi^* = \pi^*\widehat{G}^{(n)}, \qquad \widehat{T}^{(kn)}\pi^* = \pi^*\widehat{T}^{(n)}, \qquad (\widehat{T}^{(kn)})^{-1}\pi^* = \pi^*(\widehat{T}^{(n)})^{-1}. \tag{9.26}$$

Here $\langle b, \widehat{T}b\rangle = \|\widehat{G}Q^\sharp b\|_\epsilon^2 > 0$ for $b \neq 0$, since $Q^\sharp$ is injective. The nonlocal constraint is also the same on both tori: by Lemma 9.2, $\mathsf{P}_d^{(kn)}\pi^* = \pi^*\mathsf{P}_d^{(n)}$, where both are the

projections onto the corresponding $\mathscr{L}\ker Q$. These checks justify the scalar applications of that lemma. Their matrices in the coordinate bases and the first output differences satisfy its formulas, weighted rows descend without the factor k^3, and an estimate for a source in one coarse block descends with at most the factor $k^3 = (6M_{\mathrm{loc}})^3$. We conclude that all cited estimates hold on the torus of side n.

At the identity connection these scalar kernels act separately and identically on the colors. At a fixed output site and output component, choosing the signs of a real source in one source block identifies the supremum operator norm with the absolute row sum of the kernel over that block. Hence the estimates for sources in one block bound the absolute row sums, also for each component of $\nabla_\epsilon \widehat{G}$. Summing the exponential block estimates over the coarse unit blocks and using (9.9), we obtain bounds for the rows of $\widehat{G}$, $\nabla_\epsilon \widehat{G}$, and $\widehat{T}^{-1}$, and for their weighted block rows at a smaller fixed rate. Both Q and $Q^\sharp$ have rows of norm one and bounded dependence radius.

Step 4: Conversion to penalty one. We set $\delta = 1 - \alpha_d$, $S = Q\widehat{G}Q^\sharp$, and $K = I + \delta S$. The coarse matrix S is self-adjoint and nonnegative. Its exponentially weighted rows are bounded by the composition bounds above, and so are its columns, by self-adjointness. Since $0 \le \delta \le M^{-2}$, we have $K \ge I$ and the weighted off-diagonal row and column sums of K are bounded. The coarse lattice has unit mesh and polynomial counting growth independent of n. By the inverse estimate of Lemma 5.3 with lower bound one, we obtain bounded weighted rows and columns of K^{-1} at a smaller positive rate, independent of d and n. By direct multiplication, we have

$$G = \widehat{G} - \delta \widehat{G} Q^\sharp K^{-1} Q \widehat{G}, \qquad GQ^\sharp = \widehat{G} Q^\sharp K^{-1}, \qquad T = K^{-1}\widehat{T}K^{-1}, \qquad T^{-1} = K\widehat{T}^{-1}K. \tag{9.27}$$

For example, multiplying the first expression by $\mathscr{L} + Q^\sharp Q = \widehat{G}^{-1} + \delta Q^\sharp Q$ leaves the extra terms $\delta Q^\sharp Q\widehat{G} - \delta Q^\sharp K K^{-1} Q\widehat{G} = 0$. Its product with $Q^\sharp$ is the second expression, since $I - \delta K^{-1} S = K^{-1}$. Taking the adjoint and forming $(GQ^\sharp)^\sharp(GQ^\sharp)$ gives the formula for T, and inverting it, we obtain the last one. These identities transfer the bounds for the potential and first gradient from $\widehat{G}$ to G, and the bounds for the coarse inverse from $\widehat{T}^{-1}$ to T^{-1}, with one further fixed reduction of the rate. A left gradient in the first identity acts only on the leftmost factor $\widehat{G}$.

Step 5: The solution maps and the Laplacian. In each term of $\mathscr{B}$ and $\mathscr{E}$, these operators are composed in the displayed order. Row sums are submultiplicative, and for a left gradient only the leftmost factor G is differentiated. Therefore $\mathscr{B}$, $\mathscr{E}$, and their left first differences have bounded rows and bounded exponentially weighted block rows. For example, the left gradient of the second term of $\mathscr{B}$ is $(\nabla_\epsilon G)GQ^\sharp T^{-1}QG$, all of whose factors have the required rows; the triangle inequality for block distances gives the weighted version. For the Laplacian we use (9.25) and the formula for $\mathscr{L}\mathscr{E}$ in part (2). The projection $\mathsf{P}_d = I - GQ^\sharp T^{-1}QG$ has a bounded weighted block row, including its

identity part, and $\mathscr{L}\mathscr{E}$ is a composition of operators whose rows are already bounded. Adding the bounds for the potential, the first differences, and the Laplacian proves part (3), and the block rows prove part (4). No estimate for the first differences of the identity part of P_d applied to a general source is used. □

9.8 Local gauge fixing with prescribed coarse gauge

We now bring a small fine field into the chart of Theorem 9.7 by a small fine gauge transformation. The transformation is fixed by two conditions: the projected divergence of the transformed field vanishes, and the composed coarse gauge transformation of the gauge-corrected averaging, multiplied by the coarse values of the fine gauge transformation, is a prescribed coarse gauge transformation e^c. The divergence of a gauge-transformed field involves the Laplacian of the gauge parameter, and a direct estimate would require bounds on all second differences of the parameter. We avoid this by an exact formula on each link in which the inverse lattice spacing cancels. We measure the gauge parameter in the norm $\|\cdot\|_{\mathsf{Y}}$ of Lemma 9.8, which controls the Laplacian but not the individual second differences. The map $\mathscr{H}_d$ below is not related to the linear extension H_d.

Theorem 9.9. *Use the geometry of Theorem 9.3 at the identity connection, and set*

$$\|A\|_{\mathsf{X}} = \|A\|_\infty + \|\mathrm{div}_\epsilon A\|_\infty, \qquad \|\lambda\|_{\mathsf{Y}} = \|\lambda\|_\infty + \|\nabla_\epsilon \lambda\|_\infty + \|\mathscr{L}_\epsilon \lambda\|_\infty.$$

Let $\mathsf{G}_d(A)$ be the composed gauge transformation of Lemma 8.10 with background connection $U_0 = I$, applied to the fine field $e^{\epsilon A}$. There exist $r_1, C > 0$, independent of d and n, such that the following statements hold.

1. *On the complex balls $\|A\|_{\mathsf{X}} < 2r_1$ and $\|\lambda\|_{\mathsf{Y}} < 2r_1$, the maps*

$$A^{e^\lambda}_{xy} = \epsilon^{-1} \operatorname{Log}\bigl(e^{\lambda_x} e^{\epsilon A_{xy}} e^{-\lambda_y}\bigr), \qquad \mathscr{H}_d(A,\lambda) = \operatorname{Log}\bigl[\mathsf{G}_d(A^{e^\lambda})\, e^{\lambda|_{\mathrm{roots}}}\bigr]$$

are holomorphic, with bounds on their operator derivatives of each fixed order on smaller balls. They satisfy

$$\begin{aligned} \mathrm{div}_\epsilon A^{e^\lambda} &= \mathrm{div}_\epsilon A - \mathscr{L}_\epsilon \lambda + \mathscr{R}_D(A,\lambda), \\ \mathscr{H}_d(A,\lambda) &= \operatorname{Log} \mathsf{G}_d(A) + Q_d' \lambda + \mathscr{R}_H(A,\lambda), \end{aligned}$$

where both remainders vanish at $\lambda = 0$, and for $0 < r_{\mathrm{loc}} \le r_1$ and $\|A\|_{\mathsf{X}}, \|\lambda\|_{\mathsf{Y}}, \|\lambda'\|_{\mathsf{Y}} \le r_{\mathrm{loc}}$,

$$\|\mathscr{R}_D(A,\lambda) - \mathscr{R}_D(A,\lambda')\|_\infty + \|\mathscr{R}_H(A,\lambda) - \mathscr{R}_H(A,\lambda')\|_\infty \le C r_{\mathrm{loc}} \|\lambda - \lambda'\|_{\mathsf{Y}}.$$

In particular $D_\lambda \mathscr{H}_d(0,0) = Q_d'$, including the constants and across the periodic seams. The order of the factors in $\mathscr{H}_d$ follows from $(U^k)^l = U^{lk}$.

2. *There exist $0 < r_{\mathsf{Y}}, r_{\mathsf{X}}, r_c < r_1$, independent of d and n, such that for every fine field A with $\|A\|_{\mathsf{X}} < r_{\mathsf{X}}$ and every coarse field c with $\|c\|_\infty < r_c$ there is a unique λ with $\|\lambda\|_{\mathsf{Y}} < r_{\mathsf{Y}}$ satisfying*
$$\mathsf{P}_d \operatorname{div}_\epsilon A^{e^\lambda} = 0, \qquad \mathsf{G}_d(A^{e^\lambda})\, e^{\lambda|_{\mathrm{roots}}} = e^c.$$
This solution depends holomorphically on (A, c) on smaller balls, is real for real data, and satisfies $\|\lambda(A,c)\|_{\mathsf{Y}} \le C(\|A\|_{\mathsf{X}} + \|c\|_\infty)$. If A_* lies in these domains, $\mathsf{P}_d \operatorname{div}_\epsilon A_* = 0$, and $c = \operatorname{Log} \mathsf{G}_d(A_*)$, then $\lambda(A_*, c) = 0$.
3. *With $b = T_M^d(e^{\epsilon A})$, the gauge-corrected output of the transformed field is $V_d(A^{e^\lambda}) = b^{e^c}$.*
4. *For real data the transformation preserves the plaquette distances ρ_G, and*
$$\|A^{e^\lambda}\|_\infty + \|\mathrm{d}_\epsilon A^{e^\lambda}\|_\infty \le C\big(\|A\|_{\mathsf{X}} + \|c\|_\infty + \|\mathrm{d}_\epsilon A\|_\infty\big).$$
Further, for every fixed $r_{\mathrm{ph}} \le r_0$, if the supremum norms of A, of $\operatorname{div}_\epsilon A$, of $\mathrm{d}_\epsilon A$, and of c are smaller than r_{ph} divided by a sufficiently large constant, then $A' = A^{e^\lambda}$ lies in the domain of Theorem 9.7: $A' = \Xi_d(a + H_d\theta)$ with $a \in \mathcal{V}_d$, $\|a\|_\infty + \|\mathrm{d}_\epsilon a\|_\infty < r_{\mathrm{ph}}$, and $\|\theta\|_\infty < r_{\mathrm{ph}}/C_*$.

The constants depend only on M, the localization size M_{loc} of Lemma 9.8, and the radii of the balls in the statement and the larger balls containing them; they do not depend on d, n, L, γ, or J. A bound on all first differences of the output is not required.

We also summarize the remaining radii of Theorems 9.7 and 9.9.

Radius	Domain or role
r_0, C_*	Upper bound on the radius r_{ph} of the convex chart in Theorem 9.7, and the factor in the target condition $\|\theta\|_\infty < r_{\mathrm{ph}}/C_*$.
$2r_1$, r_{loc}	Complex input radii for the gauge maps $A \mapsto A^{e^\lambda}$ and $\mathscr{H}_d$ in the norms $\|\cdot\|_{\mathsf{X}}$ and $\|\cdot\|_{\mathsf{Y}}$, and radius $r_{\mathrm{loc}} \le r_1$ for the Lipschitz bounds of the remainders.
r_{X}, r_c, r_{Y}	Fine input radius in $\|\cdot\|_{\mathsf{X}}$, radius of the prescribed coarse gauge c, and radius of the ball in $\|\cdot\|_{\mathsf{Y}}$ in which the gauge parameter λ is unique.

Proof. We first derive an exact formula for the gauge transformation on one link, then expand the divergence and the coarse gauge to first order in λ, and finally solve the two equations by a contraction in the norm $\|\cdot\|_{\mathsf{Y}}$.

Step 1: The gauge transformation on one link. For a positive link $e = (x, x + \epsilon e_i)$ set
$$u = \lambda_x, \qquad v = \nabla_{\epsilon,i}\lambda(x), \qquad a = A_i(x), \qquad F_\epsilon(u,v,a) = \epsilon^{-1} \operatorname{Log}\big(e^u e^{\epsilon a} e^{-u-\epsilon v}\big).$$

The product inside the logarithm is the identity at $\epsilon = 0$. Its logarithm is a holomorphic function vanishing there, and the quotient by ϵ therefore has a removable analytic extension. Differentiating at $\epsilon = 0$, we obtain

$$F_\epsilon(u,v,a) = C(u)a - J(u)v + \epsilon R_\epsilon(u,v,a), \qquad C(u) = \operatorname{Ad}(e^u), \quad J(u)v = \int_0^1 \operatorname{Ad}(e^{su})v\,ds. \tag{9.28}$$

For example, the derivative of $e^{-u-\epsilon v}$ at $\epsilon = 0$, multiplied on the left by e^u, is $-J(u)v$, which fixes the sign and the order of the adjoints. On fixed small complex balls of (u,v,a) the products stay in the identity chart for $0 \le \epsilon \le 1$, and the analytic extension has bounded Taylor coefficients and derivatives, uniformly in ϵ. Its terms linear in (a,v) are exactly $C(u)a - J(u)v$, independently of ϵ, and R_ϵ starts at degree two in (a,v). Further, conjugation shows that $F_\epsilon(u,0,a) = C(u)a$ exactly, and $R_\epsilon(u,0,a) = 0$. Using its convergent Taylor series on a smaller ball, we obtain

$$|R_\epsilon(u,v,a)| \le C|v|\big(|a| + |v|\big), \tag{9.29}$$

with derivatives in (a,v) bounded by $C(|a| + |v|)$ and derivative in u bounded by $C|v|(|a| + |v|)$. In particular $\|A^{e^\lambda}\|_\infty \le C(\|A\|_\infty + \|\nabla_\epsilon \lambda\|_\infty)$.

Step 2: The divergence. We abbreviate $C_x = C(\lambda_x)$, $J_x = J(\lambda_x)$, $v_i(x) = \nabla_{\epsilon,i}\lambda(x)$, and $R_i(x) = R_\epsilon(\lambda_x, v_i(x), A_i(x))$. Substituting (9.28) into the backward divergence of Section 9.1 and freezing the coefficients at x, we obtain

$$\begin{aligned} \operatorname{div}_\epsilon A^{e^\lambda}(x) = {} & C_x \operatorname{div}_\epsilon A(x) - J_x \mathscr{L}_\epsilon \lambda(x) \\ & + \sum_i \frac{C_{x-\epsilon e_i} - C_x}{\epsilon} A_i(x - \epsilon e_i) - \sum_i \frac{J_{x-\epsilon e_i} - J_x}{\epsilon} v_i(x - \epsilon e_i) \\ & + \sum_i \big(R_i(x - \epsilon e_i) - R_i(x)\big). \end{aligned} \tag{9.30}$$

The last line has no factor ϵ^{-1}: the factor ϵ in (9.28) has canceled it. Its size is bounded by the two values in (9.29), and no difference of A is needed. For the differences of the coefficients, the integral formula along the segment from λ_x to $\lambda_{x-\epsilon e_i}$ gives a bound $C\|\nabla_\epsilon \lambda\|_\infty$; also $\|C_x - I\| + \|J_x - I\| \le C\|\lambda\|_\infty$. It follows that the difference between the first line of (9.30) and $\operatorname{div}_\epsilon A - \mathscr{L}_\epsilon \lambda$, together with the other two lines, defines a holomorphic remainder $\mathscr{R}_D$ that vanishes at $\lambda = 0$.

For the Lipschitz bound, take λ, λ' with $\|\lambda\|_Y, \|\lambda'\|_Y \le r_{\mathrm{loc}}$ and set $\delta\lambda = \lambda - \lambda'$. In $(C - I)\operatorname{div}_\epsilon A$, the change is at most $C\|\operatorname{div}_\epsilon A\|_\infty \|\delta\lambda\|_\infty$. In $(J - I)\mathscr{L}_\epsilon \lambda$, the product rule for differences bounds the change by

$$C\big(\|\lambda\|_\infty \|\mathscr{L}_\epsilon \delta\lambda\|_\infty + \|\mathscr{L}_\epsilon \lambda'\|_\infty \|\delta\lambda\|_\infty\big).$$

In the second line of (9.30), the same integral formula and the bounded second derivatives of C and J bound the changes of the difference quotients by $C(\|\nabla_\epsilon \delta\lambda\|_\infty + r_{\mathrm{loc}}\|\delta\lambda\|_\infty)$.

Their other factors have norm at most r_{loc}, and changing v_i in the second sum gives one more product of the same type. The derivative bounds following (9.29) bound the change of the last line by $Cr_{\mathrm{loc}}\|\delta\lambda\|_{\mathsf{Y}}$. These estimates prove the Lipschitz bound for $\mathscr{R}_D$, as well as holomorphy and bounds on the operator derivatives of fixed order of the divergence map from $\mathsf{X}\times\mathsf{Y}$ to the supremum norm on smaller balls. Only the scalar Laplacian, not the individual second differences, was used. Applying P_d preserves these estimates, since P_d has bounded rows by Lemma 9.8.

Step 3: The composed coarse gauge transformation. By Lemma 8.10, $\operatorname{Log}\mathsf{G}_d(A)$ is holomorphic and bounded on a fixed complex ball in the supremum norm, since the sizes of its factors are at most $C_M\epsilon_j\|A_j\|_\infty$, whose sum over j is a geometric sum. After a fixed decrease of r_1, the bound on A^{e^λ} in Step 1 puts A^{e^λ} inside that ball, and $\lambda|_{\mathrm{roots}}$ has supremum norm at most $\|\lambda\|_{\mathsf{Y}}$. The product defining $\mathscr{H}_d$ lies in a fixed identity chart and is a bounded holomorphic function. Its operator derivatives of fixed order are bounded independently of the dimension. To see this, we restrict the bounded holomorphic map to $x+\sum_{i=1}^s z_ih_i$ with $\|h_i\|\le 1$ and $|z_i|<\delta/s$ at distance at least δ from the boundary of the ball on which the map is bounded. Cauchy's formula then bounds the mixed derivative by $C(s/\delta)^s$. This bounds an operator norm; it does not sum absolute coefficients.

We compute the derivative in λ at $(0,0)$. At $A=0$, take the pure fine gauge transformation $\Omega_x=e^{t\lambda_x}$. At one level, each path transport is $\Omega_v\Omega_x^{-1}$, and the infinitesimal logarithm of the endpoint gauge transformation at the coarse vertex v is

$$-M^{-3}\sum_{x\in\mathsf{B}_M(v)}(\lambda_v-\lambda_x)=-\lambda_v+M^{-3}\sum_{x\in\mathsf{B}_M(v)}\lambda_x,$$

and the pure gauge transformation itself contributes $+\lambda_v$ at that vertex. Their sum is the centered scalar block average of λ. Iterating this calculation composes the scalar block averages, whose composition is Q'_d by Lemma 8.1. Every intermediate vertex of the paths cancels, also for paths across the periodic seams, and a constant is averaged to itself. For $d=0$ the composed gauge transformation is the identity and the restriction to the roots is $Q'_0=I$. In all cases

$$D_\lambda\mathscr{H}_d(0,0)=Q'_d. \tag{9.31}$$

The order of the factors follows from $(U^k)^l=U^{lk}$: the fine gauge transformation is applied first and $\mathsf{G}_d(A^{e^\lambda})$ second, and at the coarse vertices their product is $\mathsf{G}_d(A^{e^\lambda})e^{\lambda|_{\mathrm{roots}}}$.

We define $\mathscr{R}_H=\mathscr{H}_d(A,\lambda)-\mathscr{H}_d(A,0)-Q'_d\lambda$, which vanishes at $\lambda=0$; note $\mathscr{H}_d(A,0)=\operatorname{Log}\mathsf{G}_d(A)$. By the bounds on the second operator derivatives and (9.31), we have

$$\|D_\lambda\mathscr{H}_d(A,\lambda)-Q'_d\|\le C\big(\|A\|_{\mathsf{X}}+\|\lambda\|_{\mathsf{Y}}\big),$$

and integrating along the segment from λ' to λ gives the Lipschitz bound for $\mathscr{R}_H$. Together with Step 2 this proves part (1).

Step 4: Solving the two equations. On $\operatorname{Ran}\mathsf{P}_d \times \{\text{coarse scalar fields}\}$ we use the product supremum norm and define $\mathcal{L}\lambda = (-\mathsf{P}_d\mathscr{L}_\epsilon\lambda, Q_d'\lambda)$. By Lemma 9.8, its inverse is $\mathcal{L}^{-1}(f,b) = -\mathscr{B}f + \mathscr{E}b$, with norm at most C_I into Y. We set

$$\mathsf{d}(A,c) = \big(\mathsf{P}_d \operatorname{div}_\epsilon A,\ \operatorname{Log}\mathsf{G}_d(A) - c\big), \qquad R(A,\lambda) = \big(\mathsf{P}_d\mathscr{R}_D(A,\lambda),\ \mathscr{R}_H(A,\lambda)\big).$$

By part (1), the two equations of part (2) are equivalent to

$$\lambda = -\mathcal{L}^{-1}\big(\mathsf{d}(A,c) + R(A,\lambda)\big), \tag{9.32}$$

where the first component of the argument lies in $\operatorname{Ran}\mathsf{P}_d$, so that $\mathcal{L}^{-1}$ is applied within its domain. Let C_R dominate the Lipschitz constants of the remainders, including the row bound of P_d, and choose $0 < r_\mathsf{Y} < r_1/2$ with $C_I C_R r_\mathsf{Y} \le 1/4$. The composed gauge transformation is the identity at $A = 0$ and has a bounded first operator derivative, and $\|\mathsf{d}(A,c)\| \le C_d(\|A\|_\mathsf{X} + \|c\|_\infty)$. Let $r_\mathsf{X}, r_c < r_\mathsf{Y}$ satisfy $C_I C_d(r_\mathsf{X} + r_c) < r_\mathsf{Y}/4$. Since $R(A,0) = 0$, the right side of (9.32) maps the closed ball of radius r_Y in Y into the concentric ball of radius $r_\mathsf{Y}/2$ and has Lipschitz constant at most $1/4$. By Lemma 9.5, the solution exists, is unique in the ball, depends holomorphically on the data on smaller balls, and is real for real data. Absorbing the Lipschitz term, we obtain

$$\|\lambda(A,c)\|_\mathsf{Y} \le \tfrac{4}{3} C_I C_d\big(\|A\|_\mathsf{X} + \|c\|_\infty\big).$$

If $\mathsf{P}_d \operatorname{div}_\epsilon A_* = 0$ and $c = \operatorname{Log}\mathsf{G}_d(A_*)$, then $\lambda = 0$ solves (9.32), and by uniqueness $\lambda(A_*, c) = 0$. The logarithm and the exponential are inverse to each other in the chart, so the logarithmic equation for the coarse gauge is equivalent to the group equation in part (2).

Step 5: The gauge-corrected output. By part (3) of Lemma 8.10 with background connection $U_0 = I$, we have

$$V_d(A^{e^\lambda}) = \big[T_M^d\big((e^{\epsilon A})^{e^\lambda}\big)\big]^{\mathsf{G}_d(A^{e^\lambda})} = \big[b^{e^\lambda|_{\text{roots}}}\big]^{\mathsf{G}_d(A^{e^\lambda})} = b^{\mathsf{G}_d(A^{e^\lambda})e^\lambda|_{\text{roots}}} = b^{e^c}.$$

The second equality is the gauge covariance of T_M, which follows from the cancellation of the gauge transformations at the interior vertices of the paths in its definition. The small relative logarithms in the complex charts transform analytically under conjugation, so the calculation also holds on the holomorphic domains; for real data it is the gauge covariance for $\mathrm{SU}(2)$-valued gauge transformations.

Step 6: Real data and the chart. Let the data be real and set $A' = A^{e^\lambda}$. Plaquette transports transform by conjugation, so $\rho_G((e^{\epsilon A'})_p) = \rho_G((e^{\epsilon A})_p)$. Since both potentials are small, their plaquette transports lie in the same real identity chart, where the logarithms

are related by an adjoint at the base point of the plaquette. Hence $|X_p(A')| = |X_p(A)|$. Using (9.10) for A' with the reverse triangle inequality and for A with the triangle inequality, we obtain

$$\begin{aligned} \epsilon^2 |(\mathrm{d}_\epsilon A')_p| &\le |X_p(A')| + C\epsilon^2 \sum_{e\in\partial p} |A'_e|^2 = |X_p(A)| + C\epsilon^2 \sum_{e\in\partial p} |A'_e|^2 \\ &\le \epsilon^2 |(\mathrm{d}_\epsilon A)_p| + C\epsilon^2 \sum_{e\in\partial p} \big(|A_e|^2 + |A'_e|^2\big). \end{aligned} \tag{9.33}$$

Dividing by ϵ^2 and taking the supremum over plaquettes, we obtain

$$\|\mathrm{d}_\epsilon A'\|_\infty \le \|\mathrm{d}_\epsilon A\|_\infty + C\big(\|A\|_\infty^2 + \|A'\|_\infty^2\big).$$

The bound on A^{e^λ} from Step 1 and the bound on λ from Step 4 imply that $\|A'\|_\infty \le C(\|A\|_{\mathsf{X}} + \|c\|_\infty)$. Since these quantities lie in a fixed small ball, the squares can be absorbed into a linear bound, which proves the estimate of part (4).

To verify the statement about the chart, take the data so small that $\|A'\|_\infty < r_{\mathrm{fib}}$, and set

$$\theta = \mathsf{F}_d(A'), \qquad a = (I - H_d Q_d)A'.$$

Then $Q_d a = 0$, and $\mathsf{P}_d \operatorname{div}_\epsilon a = 0$ by the solved gauge equation and $\mathsf{P}_d \operatorname{div}_\epsilon H_d = 0$. By part (4) of Theorem 9.6, we have $A' = \Xi_d(a + H_d\theta)$. The row bound for the average and the quadratic bound for its remainder imply that $\|\theta\|_\infty \le C\|A'\|_\infty$, and by the row bounds of H_d and $\nabla_\epsilon H_d$, we have

$$\|a\|_\infty + \|\mathrm{d}_\epsilon a\|_\infty \le C\|A'\|_\infty + \|\mathrm{d}_\epsilon A'\|_\infty.$$

For any fixed $r_{\mathrm{ph}} \le r_0$, if the input potential, divergence, curl, and coarse gauge are smaller than r_{ph} divided by a sufficiently large constant, both conditions of Theorem 9.7 hold, including $\|\theta\|_\infty < r_{\mathrm{ph}}/C_*$. All radii depend only on M, the localization data, and the radii and decay rates fixed above. □

9.9 A trial configuration with prescribed coarse field

The analytic right inverse of Theorem 9.6 produces, after a gauge transformation, a fine configuration with prescribed image under T_M^d and Wilson action at most $C g_n^{-2}\|\theta\|_2^2$, where e^θ is the prescribed coarse field.

Corollary 9.10. *In the setting of Theorem 9.6, after a fixed decrease of θ_*, let θ be a real coarse field with $\|\theta\|_\infty < \theta_*$, let $A_{\mathrm{sec}} = A_{\mathrm{sec},d}(\theta)$, and let $U = e^{\epsilon A_{\mathrm{sec}}}$. Let k be any periodic* SU(2)*-valued gauge transformation on the fine lattice whose values at the coarse vertices are those of the composed gauge transformation $\mathsf{G}_d(A_{\mathrm{sec}})$ of Lemma 8.10 with background connection $U_0 = I$, and set $U_{\mathrm{sec}} = U^k$. Then the following statements hold.*

1. *$T_M^d U_{\mathrm{sec}} = e^\theta$, the plaquette distances of U_{sec} equal those of U, and for every coarse coupling $g_n > 0$*
$$4g_n^{-2}\epsilon^{-1}\sum_p q\big((U_{\mathrm{sec}})_p\big) \le C g_n^{-2}\|\theta\|_2^2.$$
2. *Let $\epsilon_j = M^{j-d}$ and $g_j = g_n\sqrt{\epsilon_j}$, so that the fine coupling is $g_0 = g_n\sqrt{\epsilon}$. For $0 \le j < d$, let z_j be the free logarithmic coordinates of $T_M^j U_{\mathrm{sec}}$ relative to $T_M^{j+1}U_{\mathrm{sec}}$ in the block axial gauge, given by the inverse branch of Lemma 6.3 for one averaging step. Then*
$$\|z_j/g_j\|_\infty \le C\frac{\|\theta\|_\infty}{g_n}\epsilon_j^{3/2} \qquad (0 \le j < d).$$
3. *Let $p_j > 0$ satisfy*
$$C\frac{\|\theta\|_\infty}{g_n}\epsilon_j^{3/2} \le p_j/2, \qquad g_j p_j < r_M \qquad (0 \le j < d),$$
where r_M is the radius of Lemma 6.3. Then the inverse branches are defined on the whole products $\prod_e\{|z_{j,e}| \le g_j p_j\}$, and the coordinates of U_{sec} lie in the interior of the product $\prod_{j,e}\{|z_{j,e}/g_j| \le p_j\}$, in its concentric half. For a common radius $p_j = p$, the condition $\|\theta\|_\infty \le c g_n p$ suffices, together with $\|\theta\|_\infty < \theta_*$ and $g_j p < r_M$.
4. *The infimum of the Wilson action $4g_n^{-2}\epsilon^{-1}\sum_p q(U_p)$ over any set of configurations that contains U_{sec} lies between 0 and $C g_n^{-2}\|\theta\|_2^2$.*

The gauge transformation k may be rough; the derivative bounds of Theorem 9.6 refer to A_{sec}, before the gauge transformation. The constants do not depend on d, n, L, γ, g_n, or J.

Proof. We first verify the image under T_M^d, then the bounds on the coordinates, and finally the bound on the action.

Step 1: The image under T_M^d. Since $\mathsf{F}_d(A_{\mathrm{sec}}) = \theta$, part (3) of Lemma 8.10 with background connection $U_0 = I$ reads
$$e^\theta = (T_M^d U)^{\mathsf{G}_d(A_{\mathrm{sec}})}.$$
One choice of k assigns to each fine vertex the value of this gauge transformation at the center of its block on the coarse lattice. This is a periodic fine gauge transformation with the required values. For any such k, the gauge covariance of T_M implies that $T_M^d(U^k) = (T_M^d U)^{k|_{\mathrm{roots}}} = e^\theta$, where $k|_{\mathrm{roots}}$ is the restriction to the coarse vertices.

Step 2: The choice of k does not affect the coordinates. In a block with center v, the block axial gauge uses the path transports $k_x^{\mathrm{ax}} = U(\sigma_{v,x})$. Under a real fine gauge transformation l, this transport becomes $l_v U(\sigma_{v,x}) l_x^{-1}$, and the two gauge-fixed fields differ by the gauge transformation equal to l_v on the whole block. Since the coarse-field

lift of the target transforms by the same blockwise constant gauge transformation, the relative logarithms transform as $X_e \mapsto \mathrm{Ad}(l_v)X_e$, and their norms are unchanged. The same calculation applies at each level, with the restriction of l to the vertices of that level. All the coordinates z_j of U and U^k have the same norms.

Step 3: The coordinates. By (9.10) and the bound $\|A_{\mathrm{sec}}\|_\infty + \|\nabla_\epsilon A_{\mathrm{sec}}\|_\infty \le C\|\theta\|_\infty$,

$$\delta(U) \le C\epsilon^2\|\theta\|_\infty. \tag{9.34}$$

We apply part (2) of Lemma 8.10, now regarding the real configuration U as the background. Its curvature hypothesis holds with $\varepsilon = C\|\theta\|_\infty$ after a fixed decrease of θ_*, and it yields for the iterates

$$\delta(T_M^j U) \le C\epsilon_j^2\|\theta\|_\infty \qquad (0 \le j \le d).$$

We decrease θ_* once more so that all these curvatures lie below the threshold of Lemma 7.2. We use its clause for one averaging step under a curvature hypothesis at each $j < d$, not its clause for J consecutive steps under a bound on the links. The lattice sides at this use are

$$n_j = M^{d-j}n = Mn_{j+1}, \qquad n_{j+1} = M^{d-j-1}n \ge n \ge 4, \tag{9.35}$$

so the local patches have the contractible lifts required there. That lemma identifies the relative coordinates in the block axial gauge with the inverse branch for one averaging step and bounds their free components by $C\epsilon_j^2\|\theta\|_\infty$. Dividing by $g_j = g_n\sqrt{\epsilon_j}$, we obtain part (2) for U, and Step 2 transfers it to U_{sec}.

The inequalities with $p_j/2$ imply strict membership in the product. For the statement about the whole product, the target $b = T_M^{j+1}U_{\mathrm{sec}}$ is $\mathrm{SU}(2)$-valued, and Lemma 6.3 defines Γ_b at every free input with $\max_e|z_e| < r_M$, uniformly in the target. The condition $g_j p_j < r_M$ puts the closed product $\prod_e\{|z_e| \le g_j p_j\}$ strictly inside this domain, and the coordinates of U_{sec} lie in the concentric half product. For a common radius we have $\epsilon_j^{3/2} \le 1$, and choosing the constant c small enough gives the sufficient condition in part (3). At depth zero there are no coordinates to check.

Step 4: The action. On the ball of the section, Lemma 9.4 implies that

$$q(U_p) \le C\epsilon^4\Big(|(\mathrm{d}_\epsilon A)_p|^2 + \|A\|_\infty^2 \sum_{e\in\partial p}|A_e|^2\Big), \qquad A = A_{\mathrm{sec}}. \tag{9.36}$$

Indeed, the linear term of $X_p(A)$ is exactly $\epsilon^2(\mathrm{d}_\epsilon A)_p$, $q(e^X) \le C|X|^2$, and the square of the remainder is bounded using $(\sum_{e\in\partial p}|A_e|^2)^2 \le 4\|A\|_\infty^2\sum_{e\in\partial p}|A_e|^2$. Each positive link belongs to a fixed number of plaquette boundaries, and $\|\mathrm{d}_\epsilon A\|_\epsilon \le C\|\nabla_\epsilon A\|_\epsilon$. We obtain

$$4\epsilon^{-1}\sum_p q(U_p) \le C\big(\|\nabla_\epsilon A\|_\epsilon^2 + \|A\|_\infty^2\|A\|_\epsilon^2\big) \le C\|q_d(\theta)\|_2^2 \le C\|\theta\|_2^2. \tag{9.37}$$

In the middle inequality we used the H^1_ϵ bound for the extension and the supremum bound on the ball of the section, and in the last one part (2) of Theorem 9.6. Since gauge transformations preserve the group distance of each plaquette, and hence its value of q, the same bound holds for U_{sec}. Since the fine coupling satisfies $g_0^2 = g_n^2 \epsilon$, multiplication by g_n^{-2} gives part (1). Since the Wilson action of an SU(2)-valued configuration is nonnegative, every infimum over a set containing U_{sec} lies between zero and this bound, which proves part (4). □

SECTION 10

Classical background fields and analytic estimates

In this section we construct the classical background field on the periodic torus and prove the analytic estimates for it that the renormalization group analysis uses. Fix a coarse lattice of side $n \geq 4$ and a depth $d \geq 0$, and consider the fine lattice of side nM^d, so that d averaging steps lead from the fine lattice to the coarse one. For a coarse configuration e^θ close to the identity, we minimize the Wilson action, rescaled to coarse lattice units, in a local gauge-fixed constraint chart. A gauge transform of the resulting field is a local minimum of the action on the fiber $\{U : T_M^d U = e^\theta\}$, modulo gauge transformations. Following Bałaban [16], we call the minimizer the classical background field. Its action is the effective classical action $E_d(e^\theta)$; divided by the square of the coupling, it is the classical part of the effective densities of Sections 13 and 14.

We prove four results. Theorem 10.6 constructs the background field in a gauge-fixed chart and shows that it depends analytically on θ and that its response to a change of θ decays exponentially. It also proves the local minimality on the fiber $\{U : T_M^d U = e^\theta\}$ described above. Lemma 10.8 shows that E_d is invariant under small coarse gauge transformations, lattice translations, the spatial inversion, and constant color rotations. Theorem 10.10 proves the nested minimization identity

$$E_{d+1}(c) = M \min_{\|z\|_\infty \leq r_z} E_d(b(c,z)),$$

where $b(c,z)$, for $\|z\|_\infty \leq r_z$, parametrizes a local branch of the fiber $\{b : T_M b = c\}$ on the intermediate lattice, in block axial gauge. The minimizer $z_d^*(c)$ is an interior point, it is analytic in c, and the Hessian in z has a positive lower bound that does not depend on d. The factor M is the change of units in three dimensions: with $g_+^2 = Mg^2$ the identity reads $E_{d+1}(c)/g_+^2 = g^{-2} \min_z E_d(b(c,z))$. Finally, Theorem 10.11 proves factorial bounds, in weighted row and column norms of the derivative tensors, for E_d, the background field, its block averages at every intermediate scale (in explicitly given gauges), and its plaquette logarithms divided by the square of the mesh. In all these statements the radii, decay rates, and constants are the same for every d and n.

The background field and the conditional constrained minimizer z^* center the fluctuation coordinates of Section 12, and the constrained Hessian normalizes them. The uniform estimates are the classical input to the contraction estimates of Section 11, and they are used throughout the later parts of the paper, from the analysis on block regions in Section 18 to the weak-coupling analysis in Section 36.

The inputs are the block averaging map of Definition 4.3 and the coefficient norms of Definition 4.6, the estimates for weighted absolute Taylor coefficients in Lemma 5.3, and the effective Maxwell quadratic form of Theorem 8.3. From Section 9 we use the linear constrained extension (Theorem 9.3), the nonlinear constraint parametrization (Theorem 9.6), the convexity of the constrained action (Theorem 9.7), the gauge slice with prescribed coarse gauge (Theorem 9.9), and the transfer of kernels from periodic covers (Lemma 9.2). The only other input from the literature is Bałaban's estimate for the constrained Green operator at the identity background [13, Theorem 3.13, p. 426].

There are two main ideas. The first is to invert the constrained linear curl form from the supremum norm to the C^1 norm, using Bałaban's estimate, and to solve the Euler equation in the constraint coordinates by a contraction argument. The strict convexity proved in Theorem 9.7 then identifies the solution as the minimum. The second concerns the derivative bounds. At the linear level, one averaging step has row sums one and column sums M^{-3}. Its nonlinear part at mesh $\epsilon_j = M^{j-d}$ carries a factor ϵ_j, and these factors are summable over j. Composing nonnegative majorant series with these linear masses, we obtain bounds in which no radius and no decay rate is lost at any scale.

The construction follows Bałaban's treatment of the variational problem in [16]. There the minimizing configuration with prescribed averages is constructed in a projected Landau gauge [16, Theorem 1, p. 279], and its analytic dependence on the averages and the exponential localization of its derivative are studied in [16, Section G, pp. 305–309, and Proposition 9, p. 309]. Our averaging map, coordinate domains, and coefficient norms differ from those of [16], and we give the proofs in full. Uniform regularity and decay of lattice Green functions go back to [9].

After the notation of Section 10.1, the proof proceeds through the constrained Green operator (Section 10.2), the block maps and constraint coordinates (Section 10.3), the minimization (Sections 10.4 to 10.7), and the estimates at intermediate scales (Section 10.8).

10.1 Rescaled fields, scalar products, and norms

Units and constants. Throughout this section $M \geq 3$ is a fixed odd integer, $n \geq 4$ is the side of the coarse lattice, and $d \geq 0$ is the depth. We measure lengths in coarse lattice units, in which the coarse lattice spacing is one. The fine lattice then has side nM^d and mesh $\varepsilon_d = M^{-d}$, and all distances are periodic distances in these units. On the torus of side L the coarse spacing is $a_n = L/n$, and the physical length of the fine mesh is $a_n \varepsilon_d$. The coupling plays no role in this section; in particular ε_d is unrelated to g_n^2.

All constants, radii, and decay rates in this section depend only on M, on fixed larger complex and real coordinate domains and the ratios of their radii, and on finitely many spatial decay rates chosen in the proofs, as in item (2) of Definition 4.14. In particular, they do not depend on d, n, L, or γ. The integer J of a renormalization group step does

not enter the constructions of this section, and the constants are also independent of J. A constant that carries a derivative order s as an index may depend on s. In proofs, K denotes a constant of this kind whose value may change from line to line. The auxiliary localization size used in Lemma 10.2 is a fixed function of M.

We identify $\mathfrak{su}(2)$ with $\mathbb{R}^3$ as in Section 4. A color block, that is, an element of $\mathfrak{su}(2)$ or a multilinear map between copies of $\mathfrak{su}(2)$, has its Euclidean norm. Complex fields take values in the complexification of $\mathfrak{su}(2)$, and the scalar products below are extended bilinearly to them. For a field and its first differences in the three coordinate directions we use the maximum of the norms of the four components. This maximum and the C^1_ε norm below are equivalent up to a fixed factor, which enters only at the beginning and at the end of an estimate.

Fields and scalar products. The operators Q_d, $\mathsf{P}_d^{\mathrm{div}}$, H_d, and D_d of the following definition are constructed in Section 9; here we only name them.

Definition 10.1. Fix $n \geq 4$ and $d \geq 0$, and put $\varepsilon = \varepsilon_d = M^{-d}$. A rescaled lattice connection is a function A on the positive links of the fine lattice of side nM^d, with values in $\mathfrak{su}(2)$ or its complexification; it determines the configuration $e^{\varepsilon A}$, $(e^{\varepsilon A})_e = \exp(\varepsilon A_e)$. Let ∇_ε be the collection of all componentwise forward differences divided by ε, and let d_ε be the lattice exterior derivative (the curl) divided by ε. Set

$$\mathscr{S}_\varepsilon(A) = 4\varepsilon^{-1} \sum_p q((e^{\varepsilon A})_p), \qquad \langle A, B\rangle_\varepsilon = \varepsilon^3 \sum_e \langle A_e, B_e\rangle, \qquad \|A\|_{C^1_\varepsilon} = \|A\|_\infty + \|\nabla_\varepsilon A\|_\infty,$$

where p runs over the positive fine plaquettes and e over the positive fine links. We also write $\mathscr{S}_\varepsilon(U)$ for the same sum $4\varepsilon^{-1}\sum_p q(U_p)$ at a fine configuration U. On coarse fields we use the counting scalar product $\sum_c \langle \theta_c, \eta_c\rangle$, where c runs over the positive coarse links.

Let Q_d be the centered linear block average, $\mathsf{P}_d^{\mathrm{div}}$ the orthogonal projection onto $\mathscr{L}_\varepsilon \ker Q'_d$, where Q'_d is the scalar centered box average and $\mathscr{L}_\varepsilon$ the positive scalar Laplacian, and H_d the linear constrained extension, all as in Theorem 9.3, where they are denoted Q_d, P_d, and H_d. Thus

$$\mathsf{Q}_d \mathsf{H}_d = I, \qquad \mathsf{P}_d^{\mathrm{div}} \operatorname{div}_\varepsilon \mathsf{H}_d = 0.$$

Write

$$\mathcal{V}_d = \ker \mathsf{Q}_d \cap \ker(\mathsf{P}_d^{\mathrm{div}} \operatorname{div}_\varepsilon).$$

The constrained Green operator C_d is defined by the conditions $\mathsf{C}_d f \in \mathcal{V}_d$ and

$$\langle d_\varepsilon v, d_\varepsilon \mathsf{C}_d f\rangle_\varepsilon = \langle v, f\rangle_\varepsilon \qquad (v \in \mathcal{V}_d);$$

its existence is proved in Lemma 10.2. Let D_d be the coarse correction and $\mathsf{P}_d^{\mathrm{cl}}$ the nonlinear constraint parametrization of Theorem 9.6, where they are denoted $\mathscr{D}_d$ and Ξ_d:

$$\mathsf{P}_d^{\mathrm{cl}}(w) = w - \mathsf{H}_d \mathsf{D}_d(w), \qquad w = v + \mathsf{H}_d\theta, \quad v \in \mathcal{V}_d.$$

Here $\mathsf{D}_d(0) = D\mathsf{D}_d(0) = 0$, and the field $\mathsf{P}_d^{\mathrm{cl}}(w)$ has gauge-corrected block average e^θ and projected divergence $\mathsf{P}_d^{\mathrm{div}} \operatorname{div}_\varepsilon \mathsf{P}_d^{\mathrm{cl}}(w) = 0$; the gauge-corrected block average is defined by the recursion (10.9) below. A superscript $\sharp$ denotes the adjoint with respect to the fine and coarse scalar products just defined, with the bilinear transpose on complexifications. In particular

$$((D\mathsf{D}_d(w))^\sharp u)_e = \varepsilon^{-3} \sum_c (D_{w_e} \mathsf{D}_{d,c}(w))^T u_c.$$

None of these objects removes the constant (harmonic) part of the coarse field θ.

The letter d denotes the depth, and d_ε the exterior derivative. The constrained Green operator is C_d, while in Section 10.7 the symbol $\mathsf{C}_{c'}$, indexed by a coarse link c', denotes the block averaging constraint of Definition 4.3. In Sections 10.3 and 10.8 we write $\epsilon_j = M^{j-d}$ for the mesh of the lattice reached after j averaging steps from the fine lattice; thus $\epsilon_0 = \varepsilon_d$ is the fine mesh, and the coarse mesh is $\epsilon_d = 1$. The variable w of Definition 10.1 is a fine field; it is not one of the normalized fluctuation variables of later sections, which do not occur here.

Coefficient norms. We use the weighted absolute coefficient norms of Definition 4.6. Let T be a tensor with one output index x and input indices $y_1, \dots, y_s$. Typically T is the derivative of order s, at a given point, of a map between spaces of fields, and an index consists of a link of some lattice, a color, and, where relevant, a component type. Each index has a spatial location. Let $\mathsf{t}(x; y_1, \dots, y_s)$ be the length, in coarse lattice units, of a shortest connected network containing the locations of all the indices; internal vertices are allowed. For $a \geq 0$ the output row and the counting input column of T are

$$\|T\|_{a,\mathrm{out}} = \sup_x \sum_{y_1,\dots,y_s} e^{a\mathsf{t}} |T(x; y_1, \dots, y_s)|,$$
$$\|T\|_{a,\mathrm{input,count}} = \sup_{y_1} \sum_x \sum_{y_2,\dots,y_s} e^{a\mathsf{t}} |T(x; y_1, \dots, y_s)|,$$

where $|\cdot|$ is the norm of the color block and $\mathsf{t} = \mathsf{t}(x; y_1, \dots, y_s)$. A derivative tensor is symmetric in its inputs, so fixing y_1 is the same as fixing any one input. If the output lives on a lattice of mesh a_{out} and the inputs on a lattice of mesh a_{in}, the volume-normalized input column of Definition 4.6 is $(a_{\mathrm{out}}/a_{\mathrm{in}})^3$ times the counting column. For a tensor with coarse inputs and outputs at mesh ε we write $\|T\|_{a,\mathrm{input};\varepsilon^3}$ for the volume-normalized column, which is ε^3 times the counting column. For a scalar function E of a coarse field, $\|D^s E\|_{a,\mathrm{root}}$ is the supremum over one argument of the weighted sum of $|D^s E|$ over the remaining arguments; by symmetry every argument may serve as the fixed one. For a matrix T, $\|T\|_{a,\mathrm{row+col}}$ is the sum of the output row and the counting input column. For matrices whose input and output indices have the same mesh, counting and volume-normalized columns coincide. For these matrices, and with the same spatial weights, the sum used here lies between the maximum used in Sections 4, 14, and 31 and

twice that maximum. The bounds imported from Theorem 8.3 use the same sum. The matrices measured in this sum in Lemma 10.9 and Theorem 10.10 have their input and output indices on one lattice, and their upper bounds therefore imply the corresponding maximum-norm bounds in Section 14 with unchanged constants. For matrices between different meshes, the column measures must first be related by the factor $(a_{\mathrm{out}}/a_{\mathrm{in}})^3$. We omit a from the notation when $a = 0$. These norms are sums of absolute Taylor coefficients. A bound on directional derivatives, or on the values of an analytic map, does not control them, which is why several proofs below work with majorant series for the coefficients.

For example, $D_\theta^2 A(\theta)$, for a map $\theta \mapsto A(\theta)$ from coarse fields to fine fields, has a fine output link e and coarse input links c_1, c_2. Its output row is $\sup_e \sum_{c_1,c_2} e^{a\mathsf{t}(e;c_1,c_2)} |D_\theta^2 A(\theta)(e;c_1,c_2)|$, and its volume-normalized input column is

$$\sup_{c_1} \varepsilon^3 \sum_e \sum_{c_2} e^{a\mathsf{t}(e;c_1,c_2)} |D_\theta^2 A(\theta)(e;c_1,c_2)|.$$

There are of order ε^{-3} fine links within distance one of c_1, and the factor ε^3 makes their contribution of order one. Since $\mathsf{t}(e;c_1,c_2)$ is at least each of the distances $\mathrm{dist}(e,c_1)$, $\mathrm{dist}(e,c_2)$, and $\mathrm{dist}(c_1,c_2)$, bounds on these norms give exponential decay in all three distances.

Normalizations. The following factors occur repeatedly.

1. The fine scalar product carries the factor ε^3 and the coarse one does not. For a linear map L from fine to coarse fields with kernel $L(c,e)$, the adjoint is $(L^\sharp u)_e = \varepsilon^{-3} \sum_c L(c,e)^T u_c$, and for a linear map L from coarse to fine fields, $(L^\sharp f)_c = \varepsilon^3 \sum_e L(e,c)^T f_e$.
2. By Theorem 9.3, the kernels of H_d and $\nabla_\varepsilon \mathsf{H}_d$ have bounded weighted rows and bounded volume-normalized columns

$$\sup_c \varepsilon^3 \sum_e e^{a\,\mathrm{dist}(e,c)} \big(|\mathsf{H}_d(e,c)| + |\nabla_\varepsilon \mathsf{H}_d(e,c)| \big) \le C_a;$$

   their counting columns are of order ε^{-3}.
3. The derivatives of D_d have bounded output rows, and their counting columns with a fine input fixed carry the factor ε^3 (Theorem 9.6 and Lemma 10.4 below). When H_d and a derivative of D_d are contracted over a fine index, the factors ε^{-3} and ε^3 cancel. In the adjoint $(D\mathsf{D}_d)^\sharp$, the factor ε^{-3} of item (1) cancels the factor ε^3 of the column.
4. The fine lattice at depth d over a coarse lattice of side Mm is also the fine lattice at depth $d+1$ over the coarse lattice of side m. In the new coarse units the fine mesh is ε/M. The rescaled connection of a fixed configuration is multiplied by M, its first differences by M^2, and $\mathscr{S}_{\varepsilon/M} = M\mathscr{S}_\varepsilon$. With the couplings $g_+^2 = Mg^2$, the action divided by the square of the coupling is unchanged.

10.2 The constrained Green operator

We invert the Euler equation of the variational problem with the operator C_d of Definition 10.1. A bound on C_d from the supremum norm to the supremum norm of the field and its first differences, uniform in d and n, does not follow from the coercivity of the curl form on $\mathcal{V}_d$. We obtain it from Bałaban's estimate for the constrained Green operator. A unit block below is a cube of side one in coarse lattice units, and $\|u\|_{C^1_\varepsilon(x)}$ is the supremum of $|u|$ and $|\nabla_\varepsilon u|$ over the fine links in the unit block x.

Lemma 10.2. *The operator C_d of Definition 10.1 exists, is real, and is self-adjoint with respect to $\langle\cdot,\cdot\rangle_\varepsilon$. There exist $b, K > 0$ such that the counting kernels of C_d and of $\nabla_{\varepsilon_d}\mathsf{C}_d$ satisfy*

$$\sup_e \sum_f e^{b\,\mathrm{dist}(e,f)} \big(|\mathsf{C}_d(e,f)| + |\nabla_{\varepsilon_d}\mathsf{C}_d(e,f)|\big) \le K. \tag{10.1}$$

Further, there exist $a, C > 0$ such that, for every fine field f,

$$\|\mathsf{C}_d f\|_{C^1_{\varepsilon_d}} \le C\|f\|_\infty,$$

and, if f is supported in one unit block y, then for every unit block x

$$\|\mathsf{C}_d f\|_{C^1_{\varepsilon_d}(x)} \le C e^{-a\,\mathrm{dist}(x,y)}\|f\|_\infty.$$

The counting kernel is defined by $(\mathsf{C}_d f)_e = \sum_f \mathsf{C}_d(e,f) f_f$; since the variational definition uses $\langle\cdot,\cdot\rangle_\varepsilon$, it already contains the factor ε^3 of the source. The first bound in the lemma follows from (10.1).

Proof of Lemma 10.2. Existence and self-adjointness are finite-dimensional linear algebra (Step 1). The estimates come from [13, Theorem 3.13, p. 426], which applies to periodic tori whose sides satisfy divisibility conditions relative to fixed auxiliary localization sizes. We first work on a finite periodic cover of side kn which satisfies these conditions (Step 2), identify C_d on the cover with Bałaban's constrained Green operator (Step 3), apply his estimate (Step 4), and convert it into absolute row bounds (Step 5). Finally we restrict the cover operator to fields invariant under the deck translations (Step 6) and transfer the estimates to side n (Step 7). Throughout, $\varepsilon = \varepsilon_d$.

Step 1: finite solvability. On a torus of any finite side $s \ge 4$, the curl coercivity of Theorem 9.3 makes the form $\langle d_\varepsilon u, d_\varepsilon v\rangle_\varepsilon$ positive definite on $\mathcal{V}_d^{(s)}$, the space $\mathcal{V}_d$ on that torus. Inverting this form after restricting the source pairing $v \mapsto \langle v, f\rangle_\varepsilon$ to $\mathcal{V}_d^{(s)}$, we obtain a unique operator $\mathsf{C}_d^{(s)}$ with the variational definition, and it is real and self-adjoint. If $d = 0$, then $\mathsf{Q}_0 = I$, $\mathcal{V}_0 = \{0\}$, and $\mathsf{C}_0 = 0$, and all assertions hold. We assume $d \ge 1$ from now on.

Step 2: a cover satisfying the conditions of the literature. Fix the admissible auxiliary integers $R_0, M_0, K_{\mathrm{loc}}$ of Lemma 9.2, and define

$$M_{\mathrm{loc}} = K_{\mathrm{loc}} R_0 M_0 \geq M_1(3, M), \qquad k = 6M_{\mathrm{loc}}, \qquad s = kn.$$

These integers depend only on M, not on n or d. At mesh ε the cover has fine side knM^d. The periodic torus of [10, Section A, pp. 17–18] has sides $2L_\mu$ with general side parameters; we take $2L_\mu = kn$ in coarse units, which is possible since k is even. For the scale domains of [11, (2.1)–(2.2), p. 224] we take every domain to be the whole cover. Since their complements are empty, the separation condition imposes no boundary restriction. At scale j the side of the cover, in the lattice units of that scale, is knM^{d-j}, which is divisible by M_{loc}. Both endpoints of the symmetric fundamental interval are boundaries of auxiliary blocks, since $knM^{d-j}/2 = 3M_{\mathrm{loc}} nM^{d-j}$. Hence the auxiliary blocks tile every scale domain.

The domain condition in [13, Section A, p. 393] is the same. The subdivisions there use the auxiliary sizes R_0, M_0, and $K_{\mathrm{loc}} R_0 M_0$. The local regularity step of [13, Section C, pp. 408–409] uses enlarged localization cubes $\widetilde{\square}^5$ of side $12M_{\mathrm{loc}}$ in the units of their own scale. Their side in coarse units is at most $12M_{\mathrm{loc}}$. Since $kn \geq 24M_{\mathrm{loc}}$, these cubes have embedded lifts in the cover. This verifies the subdivision, divisibility, and size requirements and the empty boundary condition, which are the geometric conclusions recorded in Lemma 9.2. A lower bound on n alone would not give these requirements on the torus of side n; this is why we pass to the cover.

Step 3: identification of the operator on the cover. We use the identity background $U = I$, zero background force, and zero local background potentials. Both regularity conditions (3.35)–(3.36) of [13, pp. 396–397] then have vanishing left sides. The dimension is 3, the blocking factor is our odd M, and the auxiliary localization size is M_{loc}. The constrained Gaussian covariance is defined in [13, (3.148), p. 425] and represented in [13, (3.153), p. 426]; at this background the additional background quadratic terms vanish.

The constraints match ours. By Theorem 9.3, the centered translation T_d conjugates the published vector average to Q_d, that is, $\mathsf{Q}_d = Q_d^{\mathrm{pub}} \mathsf{T}_d$. The scalar centered box average Q'_d is obtained from the published scalar average by the same fine translation. Since the translation is orthogonal and commutes with the scalar Laplacian, it also conjugates the orthogonal projection onto $\mathscr{L}_\varepsilon \ker Q_d'^{\mathrm{pub}}$ to $\mathsf{P}_d^{\mathrm{div}}$. The two constraints become $\mathsf{Q}_d v = 0$ and $\mathsf{P}_d^{\mathrm{div}} \operatorname{div}_\varepsilon v = 0$. The translation has bounded length in coarse units and preserves the fine scalar product. It changes localization distances and block assignments by at most a fixed collar, which is absorbed into the constants.

The penalty used in [13] does not change the operator on $\mathcal{V}_d$. For a penalty $\alpha > 0$, we define

$$\mathscr{D}^0_{d,\alpha} = d_\varepsilon^* d_\varepsilon + \nabla_\varepsilon \mathsf{P}_d^{\mathrm{div}} \operatorname{div}_\varepsilon + \alpha \mathsf{Q}_d^\sharp \mathsf{Q}_d.$$

For $u, v \in \mathcal{V}_d$ its pairing is $\langle d_\varepsilon v, d_\varepsilon u\rangle_\varepsilon$, since the last two terms vanish by the two constraints. In particular the covariance on $\mathcal{V}_d$ is the same whether the positive homogeneous penalty of [13], with its parameter equal to one, or the penalty $\alpha = 1$ is used. The Gaussian quadratic form is $\|d_\varepsilon v\|_\varepsilon^2/2$, with the source pairing $\langle v, f\rangle_\varepsilon$. No constant mode has to be removed separately: a constant field with zero block average is zero. By uniqueness of this finite variational problem, the translated published covariance on the cover equals $\widehat{\mathsf{C}}_d = \mathsf{C}_d^{(kn)}$.

Step 4: Bałaban's estimate on the cover. We use a special case. On a periodic torus satisfying the conditions verified in Step 2, at the identity background with zero background force and zero local background potentials, [13, Theorem 3.13, p. 426] transfers [13, Theorem 3.3, p. 399] to the constrained covariance (3.148). We use only the entries of [13, (3.42), p. 397] for the potential and its first differences, in their global form [13, (3.47), p. 398]. The scale in these entries is $M^d\varepsilon = 1$, so both scale factors equal one. With the hypotheses checked in Steps 2 and 3, the result on the cover is: there exist $K_0, b_0 > 0$ such that

$$\|\widehat{\mathsf{C}}_d f\|_{C^1_{\hat\varepsilon}(\hat x)} \le K_0 e^{-b_0 \operatorname{dist}_{kn}(\hat x,\hat y)} \|f\|_\infty \quad \text{if } \operatorname{supp} f \text{ is contained in the unit block } \hat y. \tag{10.2}$$

The entry for the covariant Laplacian, which is excepted in Theorem 3.13, is not used.

Step 5: absolute rows on the cover. Fix one scalar output component at a fine link $\hat e$ and one source unit block, and let each scalar source coordinate in that block be the sign of the real kernel coefficient of that output. The supremum norm of this source is bounded by a fixed color factor, and its output at $\hat e$ is the sum of the absolute values of the coefficients in the block. Applying (10.2) to this source, and repeating for the finitely many color components and first-difference outputs, we find that the sum of the absolute kernel coefficients over a unit block $\hat y$ is at most $K_0' e^{-b_0 \operatorname{dist}_{kn}(\hat x,\hat y)}$, where $\hat x$ is the unit block containing $\hat e$. For $0 < b < b_0$, summing over source blocks, we obtain

$$\sup_{\hat e} \sum_{\hat f} e^{b \operatorname{dist}_{kn}(\hat e,\hat f)} \left(|\widehat{\mathsf{C}}_d(\hat e,\hat f)| + |\nabla_\varepsilon \widehat{\mathsf{C}}_d(\hat e,\hat f)|\right) \le K_1. \tag{10.3}$$

In the summation we used that the number of unit blocks in a shell of radius R and thickness one is at most $K(1+R)^2$, uniformly on periodic tori, and that the remaining exponential is summable. The counting kernel already contains the factor ε^3 of the source, and the choice of signs introduces no factor that counts the fine source coordinates.

Step 6: restriction to deck-invariant fields. Let π^* repeat fields from side n to side kn, and let $\mathcal{D} = (\mathbb{Z}/k\mathbb{Z})^3$ act on the cover by the translations by $n\eta$, $\eta \in \mathcal{D}$, in coarse units. These translations are integer multiples of every lattice spacing M^{j-d}, $0 \le j \le d$, so they preserve the centered blocks, their patterns at all scales, and the fine translation T_d. The

vector and scalar averages, the differences, and the adjoints therefore intertwine π^*. Both the fine and the coarse scalar products satisfy

$$\langle \pi^* u, \pi^* v \rangle_{kn} = k^3 \langle u, v \rangle_n. \tag{10.4}$$

The scalar projection needs an additional argument, since it is not a local operator. We write $\mathcal{S}^{(s)} = \mathscr{L}_\varepsilon \ker Q_d'^{(s)}$; the cover space $\mathcal{S}^{(kn)}$ is invariant under $\mathcal{D}$. Let $g = \mathscr{L}_\varepsilon \lambda$ be an element of $\mathcal{S}^{(kn)}$ invariant under $\mathcal{D}$. The average $\overline{\lambda}$ of λ over $\mathcal{D}$ is of the form $\pi^* \lambda_0$, it still has zero scalar average, and $\mathscr{L}_\varepsilon \overline{\lambda} = g$. Since π^* is injective and $\pi^* Q_d'^{(n)} \lambda_0 = Q_d'^{(kn)} \pi^* \lambda_0 = 0$, we have $Q_d'^{(n)} \lambda_0 = 0$. Conversely, the repetition of every element of $\mathcal{S}^{(n)}$ is an invariant element of $\mathcal{S}^{(kn)}$. We conclude that

$$\mathcal{S}^{(kn)} \cap \operatorname{Fix} \mathcal{D} = \pi^* \mathcal{S}^{(n)}.$$

Let g_0 be an arbitrary scalar field on the torus of side n. Since the orthogonal projection onto $\mathcal{S}^{(kn)}$ commutes with the unitary action of $\mathcal{D}$, the projection of $\pi^* g_0$ is invariant. It is therefore $\pi^* h$ for some $h \in \mathcal{S}^{(n)}$, and $\pi^*(g_0 - h)$ is orthogonal to $\pi^* \mathcal{S}^{(n)}$. By (10.4), $g_0 - h$ is orthogonal to $\mathcal{S}^{(n)}$, that is, $h = \mathsf{P}_d^{\mathrm{div},(n)} g_0$. Combining this with the identities for the averages and the divergence, we obtain

$$\begin{aligned} \mathsf{P}_d^{\mathrm{div},(kn)} \pi^* &= \pi^* \mathsf{P}_d^{\mathrm{div},(n)}, \\ \mathcal{V}_d^{(kn)} \cap \operatorname{Fix} \mathcal{D} &= \pi^* \mathcal{V}_d^{(n)}. \end{aligned} \tag{10.5}$$

This verifies the nonlocal constraint in Lemma 9.2.

Let f be a field on the torus of side n, and let $\widehat{u} = \widehat{\mathsf{C}}_d \pi^* f$. A deck translation preserves $\mathcal{V}_d^{(kn)}$, the curl form, and the source $\pi^* f$, so it maps $\widehat{u}$ to a solution of the same variational problem on the cover. By uniqueness, $\widehat{u} = \pi^* u_0$ for some u_0, and (10.5) implies that $u_0 \in \mathcal{V}_d^{(n)}$. Testing the equation on the cover against $\pi^* v$, $v \in \mathcal{V}_d^{(n)}$, and using (10.4), we have

$$k^3 \langle d_\varepsilon v, d_\varepsilon u_0 \rangle_{\varepsilon,n} = k^3 \langle v, f \rangle_{\varepsilon,n}.$$

Canceling k^3, we see that u_0 solves the variational problem on the torus of side n. By uniqueness,

$$\widehat{\mathsf{C}}_d \pi^* = \pi^* \mathsf{C}_d^{(n)}. \tag{10.6}$$

This establishes the hypotheses of the constrained curl case of Lemma 9.2.

Evaluating (10.6) on a coordinate source, we obtain for any lifts $\widetilde{e}, \widetilde{f}$ the identity of counting kernels

$$\mathsf{C}_d^{(n)}(e, f) = \sum_{\eta \in \mathcal{D}} \widehat{\mathsf{C}}_d(\widetilde{e}, \widetilde{f} + n\eta). \tag{10.7}$$

It also holds after a first difference in the output: differences commute with repetition, also across periodic seams, where the neighboring output is taken at a neighboring lift. There is no factor k^{-3}, because repetition repeats a source rather than averaging it.

Step 7: the estimates on the torus of side n. For every image of the source, $\mathrm{dist}_n(e,f) \le \mathrm{dist}_{kn}(\widetilde{e},\widetilde{f}+n\eta)$. By the triangle inequality in (10.7) and summation over f and η, the weighted row in (10.1) is bounded by the left side of (10.3), since the images $\widetilde{f}+n\eta$ run over the positive source links of the cover exactly once. The identity for first differences gives the same bound for $\nabla_\varepsilon \mathsf{C}_d^{(n)}$. This proves (10.1), without a multiplicity factor, and the bound from the supremum norm to C^1_ε follows.

If f is supported in one unit block y, then $\pi^* f$ is the sum of the sources in the k^3 image blocks of y. At a lift $\widetilde{x}$ of x, using (10.2) and $\mathrm{dist}_{kn}(\widetilde{x},\widetilde{y}+n\eta) \ge \mathrm{dist}_n(x,y)$, we obtain

$$\|\mathsf{C}_d^{(n)} f\|_{C^1_\varepsilon(x)} \le K_0 \sum_{\eta\in\mathcal{D}} e^{-b_0\,\mathrm{dist}_{kn}(\widetilde{x},\widetilde{y}+n\eta)} \|f\|_\infty \le k^3 K_0 e^{-b_0\,\mathrm{dist}_n(x,y)} \|f\|_\infty .$$

Since the factor k^3 is a fixed function of M, this is the bound for sources in one unit block, for every $n \ge 4$. Taking the smaller of the decay rates and the larger of the constants proves all assertions for real sources. Complex sources follow by splitting into real and imaginary parts. □

10.3 Analytic block maps and constraint coordinates

In this section we prove coefficient bounds for the composition of d gauge-corrected averaging steps and for the coarse correction D_d, with one radius and one decay rate for all derivative orders and all depths. These bounds strengthen the fixed-order estimates of Lemma 8.10 and Theorem 9.6 to convergent majorant series. We first isolate the composition argument, since it is used again in Section 10.8.

Let $d \ge 1$ and $\epsilon_j = M^{j-d}$. By level j we mean the lattice of mesh ϵ_j, that is, of side nM^{d-j}. A label at level j is a pair consisting of a positive link of this lattice and a component type from a fixed finite set (which may consist of one element); a field at level j is a function on the labels at level j with values in the complexification of $\mathfrak{su}(2)$, and $\|A\|_\infty$ is the maximum of $|A|$ over the labels. The norms below are those of Section 10.1, with the component type as part of the index.

Lemma 10.3. *Let $d \ge 1$, and for $0 \le j < d$ let Φ_j be a holomorphic map from the complex fields A at level j with $\|A\|_\infty < \rho$ to the fields at level $j+1$. Let $K \ge 1$ and $0 < R < \rho/2$, and assume that for $0 \le j < d$, for every complex field A at level j with $\|A\|_\infty \le 2R$, and for every $s \ge 2$, the following hold:*

1. $\|\Phi_j(A)\|_\infty \le \|A\|_\infty + K\epsilon_j \|A\|_\infty^2$;
2. $\|D\Phi_j(A)\|_{\mathrm{out}} \le 1 + K\epsilon_j R$ *and* $\|D\Phi_j(A)\|_{\mathrm{input,count}} \le M^{-3}(1+K\epsilon_j R)$;
3. $\|D^s\Phi_j(A)\|_{\mathrm{out}} \le s! K^s \epsilon_j$ *and* $\|D^s\Phi_j(A)\|_{\mathrm{input,count}} \le M^{-3} s! K^s \epsilon_j$;
4. *each output label of Φ_j depends only on the input labels at distance at most $K\epsilon_j$ from it.*

Put $S = 1/(M-1)$ and assume that $8KSR < 1$. For a complex field A at level 0 with $\|A\|_\infty \le R$ let $A_0 = A$ and $A_{j+1} = \Phi_j(A_j)$. Then A_j is defined and

$$\|A_j\|_\infty \le \frac{\|A\|_\infty}{1 - KS\|A\|_\infty} \le 2\|A\|_\infty \qquad (0 \le j \le d).$$

Further, for every $b \ge 0$ there exists K_1, depending only on K, M, R, and b, such that for all such A, all $0 \le j \le d$, and all $s \ge 1$, the derivatives of the map $A \mapsto A_j$ at A satisfy

$$\|D^s A_j\|_{b,\mathrm{out}} \le K_1^{s+1} s!, \qquad \|D^s A_j\|_{b,\mathrm{input,count}} \le (\epsilon_0/\epsilon_j)^3 K_1^{s+1} s!.$$

Each output label of $A \mapsto A_j$ depends only on the labels at level 0 at distance at most $K\epsilon_j/(M-1)$ from it.

Proof of Lemma 10.3. We begin with the values. Let $a_j = \|A_j\|_\infty$. If some a_j vanishes, then by hypothesis (1) every later a_l vanishes, and their bounds are immediate. We may therefore assume that the iterates under consideration are nonzero when we take reciprocals. As long as $a_j \le 2R$, hypothesis (1) implies $a_{j+1} \le a_j + K\epsilon_j a_j^2$, and hence, if $a_{j+1} > 0$,

$$\frac{1}{a_{j+1}} \ge \frac{1}{a_j(1 + K\epsilon_j a_j)} \ge \frac{1}{a_j} - K\epsilon_j.$$

Since $\sum_{l<d} \epsilon_l = (1 - M^{-d})/(M-1) \le S$, by induction on j we have $1/a_j \ge 1/a_0 - KS$, that is, $a_j \le a_0/(1 - KSa_0)$. As $KSa_0 \le KSR < 1/8$, this is at most $2a_0 \le 2R$, which keeps the induction going.

Next we bound the rows. Fix A with $\|A\|_\infty \le R$, let $R_s(j)$ be the unweighted output row of $D^s A_j$ at A, and let $F_j(t) = \sum_{s \ge 1} R_s(j) t^s/s!$, a power series with nonnegative coefficients. Then $F_0(t) = t$, since $A_0 = A$. We write $F \preceq G$ if every coefficient of $G - F$ is nonnegative. By the chain rule, $D^s(\Phi_j \circ A_j)$ is the sum, over all partitions of $\{1, \dots, s\}$ into blocks $B_1, \dots, B_k$, of $D^k\Phi_j(A_j)[D^{|B_1|}A_j, \dots, D^{|B_k|}A_j]$. By Lemma 5.3, with output rows on all factors, the output row of each term is at most $\|D^k\Phi_j(A_j)\|_{\mathrm{out}} \prod_i R_{|B_i|}(j)$. The sum over partitions with k blocks has generating function $F_j^k/k!$. Since $\|A_j\|_\infty \le 2R$, hypotheses (2) and (3) give

$$F_{j+1} \preceq (1 + K\epsilon_j R)F_j + K^2\epsilon_j \frac{F_j^2}{1 - KF_j}, \tag{10.8}$$

where we used $\sum_{k \ge 2} K^k \epsilon_j F_j^k = K^2\epsilon_j F_j^2/(1 - KF_j)$. Let $P_j = \prod_{l<j}(1 + K\epsilon_l R)$, so that $P_j \le P = \exp(KRS)$, and let $f_j = F_j/P_j$. At a fixed $t > 0$ with $KF_j(t) \le 1/2$, (10.8) implies

$$f_{j+1}(t) \le f_j(t) + 2K^2 P \epsilon_j f_j(t)^2,$$

because $P_j^2/P_{j+1} \le P$. Fix $t_0 > 0$ with $4KPt_0 \le 1$ and $8K^2PSt_0 \le 1$. By the reciprocal inequality used for the values and induction on j, we have $1/f_j(t_0) \ge 1/t_0 - 2K^2PS \ge$

$3/(4t_0)$. In particular, $f_j(t_0) \le 2t_0$ and $F_j(t_0) \le 2Pt_0 \le 1/(2K)$, which keeps the induction going. Since the coefficients are nonnegative, $R_s(j) \le s!\, t_0^{-s} F_j(t_0) \le 2Pt_0\, s!\, t_0^{-s}$.

For the columns, let $C_s(j)$ be the unweighted counting column of $D^s A_j$ at A, with one input at level 0 fixed, and define $\widehat{C}_s(j) = (\epsilon_j/\epsilon_0)^3 C_s(j)$ and $H_j(t) = \sum_{s\ge 1} \widehat{C}_s(j) t^{s-1}/(s-1)!$. Then $H_0 = 1$. In the chain rule, the block containing the fixed input contributes the counting column of $D^{|B|}A_j$, the corresponding slot of $D^k\Phi_j$ contributes the counting column of $D^k\Phi_j$, and all other blocks contribute output rows; this is the contraction rule of Lemma 5.3 with the column on the branch containing the fixed index. The factor M^{-3} in hypotheses (2) and (3) cancels the change from $(\epsilon_j/\epsilon_0)^3$ to $(\epsilon_{j+1}/\epsilon_0)^3 = M^3(\epsilon_j/\epsilon_0)^3$. With $\psi(z) = Kz^2/(1-Kz)$ we obtain

$$H_{j+1} \preceq \big[1 + K\epsilon_j R + K\epsilon_j \psi'(F_j)\big] H_j.$$

At t_0 we have $KF_j(t_0) \le 1/2$ and $\psi'(F_j(t_0)) \le 4$, and therefore $H_j(t_0) \le \exp(KS(R+4))$. Since the coefficients are nonnegative, $C_s(j) \le (\epsilon_0/\epsilon_j)^3 (s-1)!\, t_0^{1-s} H_j(t_0)$.

Finally we add the spatial weights. By hypothesis (4) and induction, each output label of A_j depends only on labels at level 0 at distance at most $\sum_{l<j} K\epsilon_l \le K\epsilon_j/(M-1)$. A nonzero coefficient of $D^s A_j$ therefore has connecting length $\mathrm{t} \le sK\epsilon_j \le sK$, and the weight $e^{b\mathrm{t}}$ is at most e^{bKs}. Combining this with the unweighted bounds and enlarging the constant, we obtain the claim. □

We now apply this lemma to the gauge-corrected block averages. They are defined by the explicit path products of the following lemma, which also gives the gauge transformation relating them to the iterates of T_M.

Lemma 10.4. *Let $d \ge 0$ and $\epsilon_j = M^{j-d}$. For a field A on the lattice of mesh ϵ, with $V = e^{\epsilon A}$, and for a vertex r of the next coarser lattice, set*

$$\begin{aligned} k_\epsilon(A)_r &= \exp\Big\{-M^{-3} \sum_{x \in \mathsf{B}_M(r)} \operatorname{Log} V(\sigma_{r,x})\Big\}, \\ (\mathcal{M}_\epsilon(V))_{rs} &= k_\epsilon(A)_r (T_M V)_{rs} k_\epsilon(A)_s^{-1}, \\ \Psi_\epsilon(A) &= (M\epsilon)^{-1} \operatorname{Log} \mathcal{M}_\epsilon(e^{\epsilon A}), \qquad A_{j+1} = \Psi_{\epsilon_j}(A_j), \quad A_0 = A. \end{aligned} \tag{10.9}$$

The block $\mathsf{B}_M(r)$, the paths $\sigma_{r,x}$, and the coarse link (r,s) are those of Definition 4.3, at the current fine mesh. This is the gauge-corrected averaging step of Lemma 8.10 at the identity background, and e^{A_d} is the gauge-corrected block average of $e^{\epsilon_0 A}$; in the notation of Theorem 9.6, $A_d = \mathsf{F}_d(A)$. There exist $R, R', b, K > 0$ such that the following hold for every complex fine field A with $\|A\|_\infty \le R$.

1. *For $0 \le j \le d$ and $s \ge 1$, the map $A \mapsto A_j$ satisfies $\|D^s A_j\|_{b,\mathrm{out}} \le K^{s+1} s!$ and $\|D^s A_j\|_{b,\mathrm{input,count}} \le (\epsilon_0/\epsilon_j)^3 K^{s+1} s!$.*

2. *The nonlinear remainder* $\mathscr{E}_d^{\mathrm{av}}(A) = A_d - \mathsf{Q}_d A$ *of Theorem 9.6 has no constant or linear term. Its first derivative has output row at most* $K\|A\|_\infty$ *and counting input column at most* $\epsilon_0^3 K\|A\|_\infty$*, and its derivatives of order* $s \geq 2$ *have counting input columns at most* $\epsilon_0^3 K^{s+1} s!$*.*
3. *For the coarse correction* D_d*, which has fine inputs and coarse outputs, let* $\|\cdot\|_{b,\mathrm{input,count}}$ *be the counting sum over the coarse output and all remaining fine inputs with one fine input fixed. Since* $\epsilon_0 = \varepsilon_d$*, the volume-normalized column is* ϵ_0^{-3} *times this sum. For complex fine fields* w *with* $\|w\|_\infty \leq R'$*,*

$$\begin{aligned} \|D^s \mathsf{D}_d\|_{b,\mathrm{out}} &\leq K^s s!, \qquad \|D^s \mathsf{D}_d\|_{b,\mathrm{input,count}} \leq \epsilon_0^3 K^s s! \quad (s \geq 2), \\ \|D\mathsf{D}_d(w)\|_{b,\mathrm{out}} &\leq K\|w\|_\infty, \quad \|D\mathsf{D}_d(w)\|_{b,\mathrm{input,count}} \leq \epsilon_0^3 K\|w\|_\infty. \end{aligned} \tag{10.10}$$

4. *There is a gauge transformation* G_j *at the vertices of level* j*, holomorphic in* A*, such that*

$$e^{\epsilon_j A_j} = (T_M^j e^{\epsilon_0 A})^{G_j}, \qquad G_0 = I, \quad G_{j+1} = k_{\epsilon_j}(A_j)\, G_j|_{\text{next roots}}, \tag{10.11}$$

where $G_j|_{\text{next roots}}$ *is the restriction of* G_j *to the vertices of level* $j+1$*. Its final logarithm satisfies* $\|\mathrm{Log}\, G_d\|_\infty \leq K\|A\|_\infty$*.*

For $d = 0$ *the recursion is empty,* $G_0 = I$*, and* $\mathsf{D}_0 = 0$*.*

We write $G_d(A)$ for the gauge transformation G_d of (10.11) determined by the fine field A; it is the composed gauge transformation denoted $\mathsf{G}_d(A)$ in Theorem 9.9. The definition (10.9) fixes the representatives used later. They are not the iterates of the block averaging map, to which they are related through (10.11).

Proof of Lemma 10.4. For $d = 0$ there is nothing to prove, so let $d \geq 1$. We first prove bounds for one step (Steps 1–3), then apply Lemma 10.3 (Step 4), identify the linear part of the composition and the remainder (Step 5), solve the equation for D_d (Step 6), and finally prove the gauge identity (Steps 7 and 8).

Step 1: local analyticity. Every expression in (10.9) for one output involves at most q_M distinct link variables and paths of length at most q_M, for an integer q_M depending only on M. We shrink a complex polydisc of link angles until every exponential, relative logarithm, and final logarithm in (10.9) is holomorphic there. Cauchy estimates on smaller closed polydiscs and the geometric series for the matrix logarithm give a bound depending only on q_M and the ratio of the radii. Cauchy's formula in these $3q_M$ scalar variables bounds the sum of the absolute values of the derivatives of order s by $s!K_M^s$. The factor from counting the local variables is exponential in s and does not depend on the size of the lattice.

Step 2: the linear part at zero. Before composing the steps, we compute the linear masses exactly. At zero, the derivative of $\mathrm{Log}\, T_M V$ is the average of the sums of A along the paths $F_{c,x}$. The derivative of the reference path enters each relative logarithm with a

negative sign and cancels the derivative of the final reference factor. The derivative of k_ϵ cancels the averaged sums along the initial root paths, and the derivative of its inverse at the other endpoint cancels the averaged sums along the final root paths. After division by $M\epsilon$ there remains the positive operator

$$(QA)_{(r,r+Me_i)} = M^{-4} \sum_{x \in \mathsf{B}_M(r)} \sum_{l=0}^{M-1} A_i(x + le_i). \tag{10.12}$$

Its row mass is 1. A fixed positive fine link $(y, y + e_i)$ of orientation i occurs for the M starting points $x = y - le_i$, $0 \le l < M$, each of which lies in exactly one centered block. Its counting column mass is $M \cdot M^{-4} = M^{-3}$. The starting points are distinct on every input lattice of side at least $4M$, and the same count holds across periodic seams.

Step 3: bounds for one step. We write $\Psi_\epsilon(A) = (M\epsilon)^{-1} P(\epsilon A)$, where P is the fixed local analytic expression of Step 1. Its linear part is Q, and its derivatives of order $s \ge 2$ carry the factor ϵ^{s-1}/M. Together with Steps 1 and 2, this gives, on $\|A\|_\infty \le 2R$,

$$\begin{aligned} &\|D\Psi_\epsilon(A)\|_{\text{out}} \le 1 + K_M\epsilon R, \quad \|D\Psi_\epsilon(A)\|_{\text{input,count}} \le M^{-3}(1 + K_M\epsilon R), \\ &\|D^s\Psi_\epsilon(A)\|_{\text{out}} \le s!K_M^s\epsilon, \qquad \|D^s\Psi_\epsilon(A)\|_{\text{input,count}} \le M^{-3}s!K_M^s\epsilon \quad (s \ge 2). \end{aligned} \tag{10.13}$$

For the columns of the nonlinear part, we note that a fixed input lies in at most q'_M output stencils. Bounding each such coefficient by the row bound and absorbing $M^3 q'_M$ into K_M, we obtain the column bounds. This counting of incidences is applied only to the nonlinear part; the leading factor M^{-3} is the count of Step 2. Since Q has nonnegative scalar coefficients and row mass one, $\|QA\|_\infty \le \|A\|_\infty$. Using this, the Taylor series of $\Psi_\epsilon - Q$ at zero, and (10.13), we obtain, after enlarging K_M,

$$\|\Psi_\epsilon(A)\|_\infty \le \|A\|_\infty + K_M\epsilon\|A\|_\infty^2.$$

Each output of Ψ_ϵ depends only on the fine links in the two blocks of its coarse link, that is, on labels within distance $K_M\epsilon$.

Step 4: composition. By Step 3, the maps $\Phi_j = \Psi_{\epsilon_j}$ satisfy the hypotheses of Lemma 10.3 with $K = K_M$. We choose R so that $8K_MSR < 1$ and the polydisc of Step 1 contains the ball of radius $2R$. By the lemma, the recursion is defined on the common complex ball $\|A\|_\infty \le R$, with $\|A_j\|_\infty \le 2\|A\|_\infty$, and assertion (1) holds at a fixed exponent $b > 0$. Every composed expression depends only on initial inputs within distance $K_M\epsilon_j$ of its output. Its connecting length is therefore at most $K_M s\epsilon_j$ at order s, and the spatial weight does not reduce the rate at any scale or order.

Step 5: the linear map at level d and the remainder. At $j = d$ the linear part of $A \mapsto A_d$ is the product of the kernels (10.12), and it equals Q_d. The centered sums of the base-M

digits give the centered box, and the segment sums give its convolution in the direction of the link. This is also the linear map of Theorem 9.6. Subtracting it, we obtain $\mathscr{E}_d^{\mathrm{av}}$, which has no constant or linear term. Its derivatives of order $s \geq 2$ are those of $A \mapsto A_d$, and assertion (1) at $j = d$, where $\epsilon_d = 1$, gives the factor ϵ_0^3 in their counting columns. Integrating the second derivative from zero, we find that the first derivative of $\mathscr{E}_d^{\mathrm{av}}$ has row $O(\|A\|_\infty)$ and counting input column $O(\epsilon_0^3 \|A\|_\infty)$. This proves assertion (2).

Step 6: the coarse correction. By Theorem 9.6, D_d is the unique small solution of

$$\mathsf{D}_d(w) = \mathscr{E}_d^{\mathrm{av}}(w - \mathsf{H}_d \mathsf{D}_d(w)).$$

The rows of H_d and its volume-normalized columns are bounded by Theorem 9.3. When H_d is contracted with $\mathscr{E}_d^{\mathrm{av}}$ over a fine index, the counting column $O(\epsilon_0^{-3})$ of H_d cancels the counting input column $O(\epsilon_0^3)$ of $\mathscr{E}_d^{\mathrm{av}}$. In a tensor whose fixed input is a fine input w_e, the factor ϵ_0^3 of $\mathscr{E}_d^{\mathrm{av}}$ is kept instead. The weighted tensor composition inequality of Lemma 5.3 applies at a rate below the decay rate of H_d. It shows that all output rows and all columns with a fixed fine input are majorized by the solution of the scalar equation

$$x = K \frac{(t + Kx)^2}{1 - K(t + Kx)}.$$

This is the implicit-series assertion of Lemma 5.3, with zero linear coefficient in x, and it gives (10.10) at $w = 0$, including the factor ϵ_0^3 at a fixed fine input. To pass to a nonzero point w of a smaller ball of radius r, we translate the series: a series with coefficients bounded by K^{s+1} acquires the binomial sum $\sum_{l \geq 0} \binom{s+l}{l} (Kr)^l = (1 - Kr)^{-s-1}$. Contracting the additional slots with the fixed point w does not increase the connecting length of the external indices. One smaller ball and one rate therefore suffice for all the bounds in (10.10). By the uniqueness statement of Theorem 9.6, the solution of the majorized system is D_d. This proves assertion (3).

Step 7: gauge covariance of the block averaging map. For real configurations and compact gauge transformations, the gauge covariance below, including the Borel extension at the logarithm singularity, is stated in Proposition 6.2(3). We recall the argument, since we also need its holomorphic version. Let ω be a periodic vertex gauge transformation and $P = e_1 \cdots e_l$ a path from r to s. When we multiply the transformation laws of the links, the adjacent factors $\omega_x^{-1} \omega_x$ cancel, and we obtain

$$(U^\omega)(P) = \omega_r U(P) \omega_s^{-1}.$$

This also covers reversed links, whose transports are the inverses of the transports of the corresponding positive links. Since both $F_{c,x}$ and C_c run from r to s, their relative product transforms by conjugation:

$$(U^\omega)(F_{c,x})(U^\omega)(C_c)^{-1} = \omega_r \big[U(F_{c,x}) U(C_c)^{-1} \big] \omega_r^{-1}.$$

On the identity chart of the logarithm, conjugation commutes with Log, as one sees by conjugating each term of the power series of $\mathrm{Log}(I+X)$; it also commutes with the exponential. For compact real gauge transformations, the principal real logarithm away from $-I$ has the same property: the conjugated logarithm exponentiates to the conjugated group element and has the same norm, less than 2π, so it is the principal logarithm of that element. The mean logarithm in the definition of T_M is then conjugated at r, and the final reference factor transforms from r to s. This proves

$$T_M(U^\omega) = (T_M U)^{\omega|_{\mathrm{roots}}}, \tag{10.14}$$

where $\omega|_{\mathrm{roots}}$ is the restriction to the vertices of the coarser lattice. The exceptional case is preserved as well: a relative product equals $-I$ if and only if its conjugate does. In that case both sides use the reference path, for which covariance was just proved. The identity (10.14) therefore holds for the block averaging map with its Borel extension. For complex gauge transformations it holds on the domains where the logarithms before and after the transformation exist, and the power series argument gives its holomorphic version.

Step 8: the composed gauge transformation. Let $V_j = e^{\epsilon_j A_j}$, and suppose that $V_j = (T_M^j V_0)^{G_j}$, which holds for $j=0$ with $G_0 = I$. By (10.14), $T_M V_j = (T_M^{j+1} V_0)^{G_j|_{\text{next roots}}}$. The definition (10.9) applies the gauge transformation $k_{\epsilon_j}(A_j)$ to this field. Since $(U^a)^b = U^{ba}$, the new gauge transformation is $G_{j+1} = k_{\epsilon_j}(A_j) G_j|_{\text{next roots}}$. This proves (10.11), with the displayed order of the factors, and its holomorphic continuation.

Each $\mathrm{Log}\, k_{\epsilon_j}(A_j)$ has norm at most $K_M \epsilon_j \|A_j\|_\infty \le 2K_M \epsilon_j \|A\|_\infty$, and the sum of these bounds is at most $K\|A\|_\infty$. After reducing R, products of factors this close to the identity stay in a fixed ball of the logarithm. The power series of the product and of its logarithm give the holomorphy and the bound on $\mathrm{Log}\, G_d$, uniformly in j, d, and n. □

10.4 The Euler equation in constraint coordinates

We now write the condition for a critical point of $v \mapsto \mathscr{S}_\varepsilon(\mathsf{P}_d^{\mathrm{cl}}(v + \mathsf{H}_d\theta))$, $v \in \mathcal{V}_d$, as a fixed point equation that can be solved by contraction.

We begin with a heuristic. If A is the restriction to the lattice of a smooth connection, then the logarithm of the plaquette variable is $\varepsilon^2(\partial_i A_j - \partial_j A_i + [A_i, A_j]) + O(\varepsilon^3)$. Since $q(e^X) = |X|^2/8 + O(|X|^4)$, the action $\mathscr{S}_\varepsilon(A)$ is a Riemann sum for one half of $\sum_{i<j}\int |F_{ij}|^2$, and its gradient should be $d_\varepsilon^* d_\varepsilon A$ plus terms of the form $A\nabla A$ and A^3. However, a direct expansion of the lattice gradient produces a quadratic term with the prefactor ε^{-1}, which is of size $\varepsilon^{-1}|A|^2$ unless it cancels. The first part of the following lemma shows that this term vanishes on fields that are constant in each direction, and hence is of order $\|A\|_\infty \|\nabla_\varepsilon A\|_\infty$. The second part records the gradient of the action in the constraint coordinates. Differentiating these coordinates produces the term $(D\mathsf{D}_d)^\sharp \mathsf{J}_d$ below, which must be kept.

Lemma 10.5. *There exist $r_0, a_0, C > 0$ with the following properties for every $d \geq 0$ and $n \geq 4$, with $\varepsilon = \varepsilon_d$.*

1. *Define the gradient $G_\varepsilon(A)$ of the action by $D\mathscr{S}_\varepsilon(A)[v] = \langle G_\varepsilon(A), v\rangle_\varepsilon$. Then*

$$G_\varepsilon(A) = d_\varepsilon^* d_\varepsilon A + N_\varepsilon(A),$$

where d_ε^* is the adjoint of d_ε with respect to the fine scalar products. On the complex C^1_ε ball of radius r_0 the map N_ε is holomorphic, and for $0 < r \leq r_0$,

$$\|N_\varepsilon(A)\|_\infty \leq C\|A\|^2_{C^1_\varepsilon}, \qquad \|N_\varepsilon(A) - N_\varepsilon(B)\|_\infty \leq Cr\|A - B\|_{C^1_\varepsilon} \quad (\|A\|_{C^1_\varepsilon}, \|B\|_{C^1_\varepsilon} \leq r).$$

2. *There is a holomorphic function $\widetilde{N}_\varepsilon(A, G)$ of a fine field A and a triple $G = (G_\mu)_{\mu=1,2,3}$ of independent fine fields, defined on a fixed complex ball, with $\widetilde{N}_\varepsilon(A, \nabla_\varepsilon A) = N_\varepsilon(A)$, where $G_{i,\mu}$ takes the place of $\nabla_{\varepsilon,\mu} A_i$. It vanishes to second order at the origin, and its derivatives of order $s \geq 2$ have output rows and counting input columns at most $C^{s+1}s!$ at the exponent a_0. Each output of $\widetilde{N}_\varepsilon$ depends only on inputs at distance at most $C_M\varepsilon$.*
3. *For $w = v + \mathsf{H}_d\theta$ with $v \in \mathcal{V}_d$, and $A = \mathsf{P}^{\mathrm{cl}}_d(w)$, put*

$$\Delta_d = \mathsf{H}_d^\sharp d_\varepsilon^* d_\varepsilon \mathsf{H}_d, \qquad \mathsf{J}_d(w) = \Delta_d[\theta - \mathsf{D}_d(w)] + \mathsf{H}_d^\sharp N_\varepsilon(A).$$

If $\|v\|_{C^1_\varepsilon} + \|\theta\|_\infty \leq r \leq r_0$, then

$$\|\mathsf{J}_d(w)\|_\infty \leq C(\|\theta\|_\infty + r^2), \qquad \|(D\mathsf{D}_d(w))^\sharp\|_{\infty\to\infty} \leq Cr.$$

The second bound follows from $\sup_e \sum_c e^{a_0 \operatorname{dist}(e,c)} |D_{w_e}\mathsf{D}_{d,c}(w)| \leq C\varepsilon^3 r$. At fixed θ, the maps $v \mapsto N_\varepsilon(A)$ and $v \mapsto (D\mathsf{D}_d(w))^\sharp \mathsf{J}_d(w)$ are Lipschitz from the C^1_ε norm to the supremum norm, with constant Cr.
4. *For every $u \in \mathcal{V}_d$,*

$$D_v\mathscr{S}_\varepsilon(\mathsf{P}^{\mathrm{cl}}_d(w))[u] = \langle d_\varepsilon u, d_\varepsilon v\rangle_\varepsilon + \langle u, N_\varepsilon(A) - (D\mathsf{D}_d(w))^\sharp \mathsf{J}_d(w)\rangle_\varepsilon.$$

Consequently $D_v\mathscr{S}_\varepsilon(\mathsf{P}^{\mathrm{cl}}_d(w))[u] = 0$ for all $u \in \mathcal{V}_d$ if and only if

$$v = -\mathsf{C}_d\big\{N_\varepsilon(A) - (D\mathsf{D}_d(w))^\sharp \mathsf{J}_d(w)\big\}.$$

In the proof we show that $\mathsf{J}_d(w) = \mathsf{H}_d^\sharp G_\varepsilon(A)$: it is the gradient of the action pulled back to the coarse variables. The bounds of the lemma concern local rows and volume-normalized columns. The sum of $|\mathsf{J}_d(w)|$ over all coarse links is not bounded independently of the volume, and it is not used.

Proof of Lemma 10.5. Parts (1) and (2) are proved in Steps 1–4, part (3) in Steps 5 and 6, and part (4) in Step 7.

Step 1: expansion of the gradient. Fix a positive fine link. Differentiating the finitely many plaquette variables containing it, in the link angles $X_e = \varepsilon A_e$, we see that the gradient $G_\varepsilon(A)$ at that link is $4\varepsilon^{-3}$ times the angle derivative of $\sum_p q$. The common power series of these local expressions has no constant term. Its linear part is $d_\varepsilon^* d_\varepsilon A$, because the quadratic part of the action is $\varepsilon^3 \sum_p |d_\varepsilon A(p)|^2/2$, by $q(e^X) = |X|^2/8 + O(|X|^4)$. A term of degree k in A in the gradient carries the factor ε^{k-3}. After the linear part is subtracted, only the quadratic term can carry a negative power of ε; we write it as $\varepsilon^{-1} P_e(A)$, where P_e is a quadratic polynomial in the values of A near e.

Step 2: the quadratic term vanishes on constant fields. Let $A_i(x) = a_i$ on the whole lattice, for constants a_1, a_2, a_3. A plaquette variable is then the group commutator of $e^{\varepsilon a_i}$ and $e^{\varepsilon a_j}$. Its logarithm begins at degree two, so its value of q begins at degree four, and the cubic part of the action vanishes identically on such fields. At a constant field, translation invariance makes the gradient of the cubic part of the action the same at all links of a given orientation. Differentiating the vanishing cubic polynomial in a_i shows that the number of links of orientation i times this common coefficient is zero. We conclude that $P_e(a) = 0$ for every link e.

Step 3: the nonlinear bounds. Fix a vertex near e as base point, and replace each value $A_i(x)$ in the stencil of P_e by the value $a_i = A_i(\text{base point})$. The differences $A_i(x) - a_i$ are sums of at most K_M first differences times ε. Subtracting the two quadratic polynomials and using $P_e(a) = 0$, we obtain

$$|P_e(A)| \le K\varepsilon \|A\|_\infty \|\nabla_\varepsilon A\|_\infty,$$

and the differential of P_e at A in the direction v is bounded by

$$K\varepsilon\big(\|A\|_\infty \|\nabla_\varepsilon v\|_\infty + \|\nabla_\varepsilon A\|_\infty \|v\|_\infty\big).$$

These identities cancel the apparent inverse power of the mesh before any norm is taken. All terms of degree at least three in the gradient carry nonnegative powers of ε and are given by a uniformly convergent local series; their value and differential are bounded by $K\|A\|_\infty^3$ and $K\|A\|_\infty^2 \|v\|_\infty$. Integrating along the segment from B to A, we obtain the two inequalities of part (1).

Step 4: a version for independent value and difference variables. In the difference of the two quadratic polynomials used in Step 3, we change the arguments one at a time. Every resulting term contains a factor

$$A_i(x) - a_i = \varepsilon \sum_l \pm G_{i,\mu_l}(x_l),$$

a sum of first differences along a path from the base point to x. Treating the remaining local values of A and these variables G as independent, we obtain a polynomial extension

of $\varepsilon^{-1}P_e$ which is quadratic in (A, G). Adding the terms of degree at least three, which are local analytic functions of A, defines $\widetilde{N}_\varepsilon(A, G)$. It agrees with $N_\varepsilon(A)$ when $G = \nabla_\varepsilon A$. Cauchy estimates on a fixed smaller polydisc in finitely many variables bound each absolute derivative tensor of order s by $K^{s+1}s!$. Since a fixed input belongs to a bounded number of stencils, this bound holds with any input fixed as well as with the output fixed. Since the stencils have radius $K_M\varepsilon$, a spatial weight contributes a factor at most $e^{a_0 K_M s}$. Since these arguments use polynomial identities and convergent power series, they hold on the complex balls. This proves part (2).

Step 5: the coarse gradient. We use H_d and its minimizing property from Theorem 9.3: $\langle d_\varepsilon \mathsf{H}_d \eta, d_\varepsilon v\rangle_\varepsilon = 0$ for every coarse field η and every $v \in \mathcal{V}_d$. The kernel of Δ_d is $\Delta_d(c, c') = \varepsilon^3 \sum_p (d_\varepsilon \mathsf{H}_d)(p, c)^T (d_\varepsilon \mathsf{H}_d)(p, c')$, the pairing with the fine measure of two curl kernels of H_d. Since each curl kernel is controlled by the bounds of Theorem 9.3 on first differences, Δ_d has bounded weighted rows and columns. The same volume-normalized column bound implies $\|\mathsf{H}_d^\sharp f\|_\infty \le K\|f\|_\infty$. Since $A = v + \mathsf{H}_d[\theta - \mathsf{D}_d(w)]$, the minimizing property gives the identity

$$\mathsf{H}_d^\sharp G_\varepsilon(A) = \Delta_d[\theta - \mathsf{D}_d(w)] + \mathsf{H}_d^\sharp N_\varepsilon(A) = \mathsf{J}_d(w).$$

The bounds on H_d and on D_d (Theorems 9.3 and 9.6) place A in a C^1_ε ball of radius Kr and give $\|\mathsf{D}_d(w)\|_\infty \le Kr^2$. Together with part (1), this proves $\|\mathsf{J}_d(w)\|_\infty \le K(\|\theta\|_\infty + r^2)$.

Step 6: the adjoint of the derivative of the correction. By (10.10), the counting column of $D\mathsf{D}_d(w)$ with a fine input fixed is at most $K\varepsilon^3 r$, and the same holds with the exponential weight. Taking the adjoint multiplies this column by exactly ε^{-3} (item (1) of the normalizations in Section 10.1), which proves $\|(D\mathsf{D}_d(w))^\sharp\|_{\infty\to\infty} \le Kr$, together with its weighted version. The column bound for the second derivative of D_d bounds the difference of these adjoints at w and $w' = v' + \mathsf{H}_d\theta$ by $K\|v - v'\|_{C^1_\varepsilon}$. At fixed θ, the parametrized fields $\mathsf{P}_d^{\mathrm{cl}}(w)$ and $\mathsf{P}_d^{\mathrm{cl}}(w')$ differ by at most $K\|v - v'\|_{C^1_\varepsilon}$ in C^1_ε, the nonlinear terms N_ε by at most $Kr\|v - v'\|_{C^1_\varepsilon}$ by part (1), and J_d by the same amount. By the product rule and $\|\theta\|_\infty \le r$, the difference of $(D\mathsf{D}_d)^\sharp \mathsf{J}_d$ at w and w' is at most $Kr\|v - v'\|_{C^1_\varepsilon}$. This proves part (3).

Step 7: the tested equation. For $u \in \mathcal{V}_d$, the derivative of $v \mapsto \mathsf{P}_d^{\mathrm{cl}}(v + \mathsf{H}_d\theta)$ in the direction u is $u - \mathsf{H}_d D\mathsf{D}_d(w)u$. Testing the derivative of the action against it and using the adjoints, we have

$$\langle u, G_\varepsilon(A)\rangle_\varepsilon - \sum_c \langle (D\mathsf{D}_d(w)u)_c, \mathsf{J}_d(w)_c\rangle = \langle d_\varepsilon u, d_\varepsilon v\rangle_\varepsilon + \langle u, N_\varepsilon(A) - (D\mathsf{D}_d(w))^\sharp \mathsf{J}_d(w)\rangle_\varepsilon.$$

Here we used $\langle u, d_\varepsilon^* d_\varepsilon A\rangle_\varepsilon = \langle d_\varepsilon u, d_\varepsilon v\rangle_\varepsilon$, which follows from the minimizing property of H_d; only the linear contribution of the extension is removed by this property. By the

defining identity of C_d, the right side vanishes for every $u \in \mathcal{V}_d$ if and only if v satisfies the displayed fixed point equation; uniqueness follows from the coercivity of the curl form on $\mathcal{V}_d$. We decrease r_0 and a_0 to the minima of the finitely many radii and rates used above, and take C larger than the corresponding constants. □

10.5 The classical background field and local minimality

The two descriptions of the constraint. The renormalization group prescribes the block average $T_M^d U$ of a fine configuration. The coordinates of Section 9 prescribe its gauge-corrected block average instead. For a fine field A the gauge-corrected block average is $e^{\mathsf{F}_d(A)}$, where $\mathsf{F}_d(A)$ is the d-th iterate in (10.9). Taking $j = d$ in (10.11), we obtain

$$e^{\mathsf{F}_d(A)} = (T_M^d e^{\varepsilon A})^{G_d(A)}, \qquad \text{that is,} \qquad T_M^d e^{\varepsilon A} = \big(e^{\mathsf{F}_d(A)}\big)^{G_d(A)^{-1}}.$$

Thus a field A with gauge-corrected block average e^θ lies in the fiber of T_M^d over $(e^\theta)^{G_d(A)^{-1}}$. Let Ω be any fine gauge transformation whose values at the coarse vertices are $G_d(A)$. Applying (10.14) d times and using $(U^k)^l = U^{lk}$, we have

$$T_M^d\big((e^{\varepsilon A})^\Omega\big) = \big((e^\theta)^{G_d(A)^{-1}}\big)^{G_d(A)} = e^\theta, \qquad \mathscr{S}_\varepsilon\big((e^{\varepsilon A})^\Omega\big) = \mathscr{S}_\varepsilon(A).$$

We construct the background field in the chart $\{\mathsf{P}_d^{\mathrm{cl}}(v + \mathsf{H}_d\theta) : v \in \mathcal{V}_d\}$. All points of this chart have gauge-corrected block average e^θ and projected divergence zero, and we transfer the conclusions to the fiber $\{U : T_M^d U = e^\theta\}$ with such a gauge transformation. In the opposite direction, we use Theorem 9.9 to move a field near the fiber into the chart by a gauge transformation, in part (6) of the next theorem and in Lemma 10.7.

By Lemma 10.5, the critical points in the chart are the fixed points of the map

$$\mathcal{T}_\theta(v) = -\mathsf{C}_d\big\{N_\varepsilon(A) - (D\mathsf{D}_d(w))^\sharp \mathsf{J}_d(w)\big\}, \qquad w = v + \mathsf{H}_d\theta, \quad A = \mathsf{P}_d^{\mathrm{cl}}(w).$$

In the following theorem, r_{ph} and C_* denote the constants of Theorem 9.7, and $\mathcal{T}$ is called the Euler map.

Theorem 10.6. *There exist $r_v, r_\theta, a, C > 0$ such that the following hold for every $d \geq 0$ and $n \geq 4$, with $\varepsilon = \varepsilon_d$.*

1. *For every complex coarse field θ with $\|\theta\|_\infty < r_\theta$, the Euler map $\mathcal{T}_\theta$ maps the closed complex ball $\{v \in \mathcal{V}_d : \|v\|_{C_\varepsilon^1} \leq r_v\}$ strictly into itself and is a contraction with factor at most $1/2$. Its unique fixed point $v_d^*(\theta)$ is holomorphic in θ and real for real θ, and*

$$\|v_d^*(\theta)\|_{C_\varepsilon^1} \leq C\|\theta\|_\infty^2, \qquad A_d(\theta) = \mathsf{P}_d^{\mathrm{cl}}(v_d^*(\theta) + \mathsf{H}_d\theta),$$
$$\|A_d(\theta)\|_{C_\varepsilon^1} \leq C\|\theta\|_\infty, \qquad DA_d(0) = \mathsf{H}_d.$$

We call $A_d(\theta)$ the classical background field with coarse field e^θ.

2. *For real θ with $\|\theta\|_\infty < r_\theta$, the point $v_d^*(\theta)$ is the unique minimum of $v \mapsto \mathscr{S}_\varepsilon(\mathsf{P}_d^{\mathrm{cl}}(v + \mathsf{H}_d\theta))$ on the closed ball $\{v \in \mathcal{V}_d : \|v\|_{C_\varepsilon^1} \le r_v\}$. It is also the unique minimum of this function on the convex set $\{v \in \mathcal{V}_d : \|v\|_\infty + \|d_\varepsilon v\|_\infty < r_{\mathrm{ph}}\}$, for every r_{ph} allowed in Theorem 9.7 with $\|\theta\|_\infty < r_{\mathrm{ph}}/C_*$.*
3. *For a fine output link e and a coarse input link c, and $\|\theta\|_\infty < r_\theta$,*

$$|D_{\theta_c} A_d(\theta)_e| + |\nabla_\varepsilon D_{\theta_c} A_d(\theta)_e| \le C e^{-a\,\mathrm{dist}(e,c)}.$$

4. *For every integer $s \ge 1$ there exist $a_s, C_s > 0$, depending on s, such that on $\|\theta\|_\infty < r_\theta/2$,*

$$\|D_\theta^s(A_d, \nabla_\varepsilon A_d)\|_{a_s,\mathrm{out}} + \|D_\theta^s(A_d, \nabla_\varepsilon A_d)\|_{a_s,\mathrm{input};\varepsilon^3} \le C_s.$$

5. *Define the effective classical action by*

$$E_d(e^\theta) = \mathscr{S}_\varepsilon(A_d(\theta)), \qquad E_0 = S_W.$$

It is holomorphic on a common ball, nonnegative for real θ, and $E_d(I) = DE_d(I) = 0$. With $w = v_d^*(\theta) + \mathsf{H}_d\theta$, its gradient in θ is

$$\nabla_\theta E_d = (I - D\mathsf{D}_d(w)\mathsf{H}_d)^T \mathsf{J}_d(w).$$

For each $s \ge 2$ there exist $a_s, C_s > 0$ such that $\|D^s E_d\|_{a_s,\mathrm{root}} \le C_s$. For $g > 0$ let $W_{d,g}(B) = g^{-2} E_d(e^{gB})$. If $\|gB\|_\infty < r_\theta/2$, then

$$\|D_B^s W_{d,g}\|_{a_s,\mathrm{root}} \le C_s g^{s-2} \quad (s \ge 2), \qquad \|D_B W_{d,g}\|_\infty \le C\|B\|_\infty.$$

6. *Let θ be real with $\|\theta\|_\infty < r_\theta$, and let Ω_* be a fine gauge transformation whose values at the coarse vertices are $G_d(A_d(\theta))$. Then $U_* = (e^{\varepsilon A_d(\theta)})^{\Omega_*}$ satisfies $T_M^d U_* = e^\theta$, and U_* is a local minimum of $\mathscr{S}_\varepsilon$ on the fiber $\{U : T_M^d U = e^\theta\}$ modulo fine gauge transformations. More precisely, there is a neighborhood of U_* in this fiber on which $\mathscr{S}_\varepsilon(U) \ge \mathscr{S}_\varepsilon(U_*)$, with equality only if $U = U_*^h$ for a fine gauge transformation h whose values at the coarse vertices leave e^θ fixed. Every tangent vector to the fiber at U_* has zero first variation. The neighborhood may depend on the fine lattice; the radii and constants in (1)–(5) do not.*
7. *The constrained Green operator C_d satisfies the bounds of Lemma 10.2: $\|\mathsf{C}_d f\|_{C_\varepsilon^1} \le C\|f\|_\infty$, and $\|\mathsf{C}_d f\|_{C_\varepsilon^1(x)} \le C e^{-a\,\mathrm{dist}(x,y)}\|f\|_\infty$ if f is supported in the unit block y. They give weighted absolute rows for C_d and its first differences, and they are the specialization of [13, Theorem 3.13, p. 426] described in the proof of Lemma 10.2.*

The fixed-order bounds in (4) and (5) follow from the factorial bounds (10.17) and (10.20) proved below, which are also collected in Theorem 10.11. The minimality statements in (2) and (6) concern real coarse fields; for complex θ, the field $A_d(\theta)$ and the value $E_d(e^\theta)$ are holomorphic continuations of the critical point and the critical value.

Proof of Theorem 10.6. Step 1 constructs the fixed point by contraction. Steps 2 and 3 prove factorial coefficient bounds for A_d, which give (3) and (4). Step 4 proves (2). Steps 5 and 6 treat the effective classical action, and Step 7 proves the local minimality on the fiber. Part (7) is Lemma 10.2, applied on the torus of side n. Since the geometry of the cover, both constraints, and the variational identity were checked there, no divisibility condition or additional lower bound on n enters.

Step 1: contraction. Let K be larger than the constants of the extension H_d, of the correction D_d, of the nonlinear remainder of the action gradient in Lemma 10.5, and of the Green operator in Lemma 10.2, on fixed larger domains. By Lemmas 10.2 and 10.5, for $\|v\|_{C^1_\varepsilon}, \|v'\|_{C^1_\varepsilon} \le r_v$ and $\|\theta\|_\infty \le r_\theta$,

$$\begin{aligned} \|\mathcal{T}_\theta(v)\|_{C^1_\varepsilon} &\le K(\|v\|_{C^1_\varepsilon} + \|\theta\|_\infty)^2, \\ \|\mathcal{T}_\theta(v) - \mathcal{T}_\theta(v')\|_{C^1_\varepsilon} &\le K(r_v + r_\theta)\|v - v'\|_{C^1_\varepsilon}. \end{aligned} \tag{10.15}$$

Fix $r_v > 0$ with $16Kr_v \le 1$ and so small that the closed C^1_ε ball of radius r_v in $\mathcal{V}_d$ lies inside all the larger domains. We also require that $3r_v$ is an allowed value of r_{ph} in Theorem 9.7. Since $\|d_\varepsilon v\|_\infty \le 2\|\nabla_\varepsilon v\|_\infty$, the closed C^1_ε ball of radius r_v is then contained in the convex domain $\{v \in \mathcal{V}_d : \|v\|_\infty + \|d_\varepsilon v\|_\infty < 3r_v\}$ of that theorem. Next fix $0 < r_\theta \le r_v$ so that $\mathsf{H}_d\theta$ and the correction lie in their domains with fixed margins, uniformly in d and n, and so that $r_\theta < 3r_v/C_*$ and $6Kr_\theta \le C_*$. Then (10.15) implies that $\|\mathcal{T}_\theta(v)\|_{C^1_\varepsilon} \le 4Kr_v^2 \le r_v/4$, and it gives a contraction factor at most $2Kr_v \le 1/8$. Iteration from zero converges, since successive differences are bounded by a geometric series. The limit lies in the closed linear subspace $\mathcal{V}_d$, and it is the unique fixed point $v_d^*(\theta)$ in the closed ball. Comparing the fixed point with the first iterate $\mathcal{T}_\theta(0)$, we obtain

$$\|v_d^*(\theta)\|_{C^1_\varepsilon} \le \tfrac{1}{2}\|v_d^*(\theta)\|_{C^1_\varepsilon} + K\|\theta\|_\infty^2.$$

This proves the quadratic bound $\|v_d^*(\theta)\|_{C^1_\varepsilon} \le 2K\|\theta\|_\infty^2$. Since $A_d(\theta) = v_d^*(\theta) + \mathsf{H}_d\theta - \mathsf{H}_d\mathsf{D}_d(w)$ and $\|\mathsf{D}_d(w)\|_\infty \le K\|w\|_\infty^2$, it also implies the bound on A_d and $DA_d(0) = \mathsf{H}_d$. Since the equation is preserved by complex conjugation of all fields, uniqueness shows that $v_d^*(\theta)$ is real for real θ. Holomorphy follows from Step 2.

Step 2: factorial bounds for the background field. We prove analyticity and locality through the coefficients. Let $p = (v, V_1, V_2, V_3)$ be independent variables for a fine field and its first differences in the three directions. In the nonlinear expressions we replace A and its differences by

$$\Big(v + \mathsf{H}_d[\theta - \mathsf{D}_d(w)], \quad V_\mu + \nabla_{\varepsilon,\mu}\mathsf{H}_d[\theta - \mathsf{D}_d(w)]\Big), \qquad w = v + \mathsf{H}_d\theta, \tag{10.16}$$

and we use the extension $\widetilde{N}_\varepsilon$ of Lemma 10.5. If f denotes the negative of the resulting nonlinear constrained first variation, we define the output to be the pair $(\mathsf{C}_d f, \nabla_\varepsilon \mathsf{C}_d f)$.

This is an analytic map on a product ball. Its output is a field together with its own first differences, its field component lies in $\mathcal{V}_d$, and when $V_\mu = \nabla_{\varepsilon,\mu} v$ it coincides with the Euler map.

Every factor has a majorant series with nonnegative coefficients at one rate $b > 0$: (10.10) for the correction, part (2) of Lemma 10.5 for the nonlinear remainder of the action gradient, (10.1) for the pair $(\mathsf{C}_d, \nabla_\varepsilon \mathsf{C}_d)$, and the rows and volume-normalized columns of Theorem 9.3 for H_d and $\nabla_\varepsilon \mathsf{H}_d$. The kernel Δ_d is the contraction of two curl kernels of H_d with the fine measure, as in Step 5 of the proof of Lemma 10.5, and $\mathsf{H}_d^\sharp$ carries the factor ε^3 in its sum. The only apparent inverse power of the volume is in

$$((D\mathsf{D}_d(w))^\sharp u)_e = \varepsilon^{-3} \sum_c (D_{w_e} \mathsf{D}_{d,c}(w))^T u_c.$$

An output row of this expression fixes a fine input w_e of the tensor of D_d, and the column bound in (10.10) supplies the factor ε^3 that cancels ε^{-3}. Taking s further derivatives produces a factor at most $(s+1)! K^{s+1}$; after division by $s!$, the additional factor $s + 1 \le 2^{s+1}$ changes only the constant.

Since the pair map has no constant and no linear term in (θ, p), the part of Lemma 5.3 concerning output rows majorizes the implicit solution by the solution of $x = K(t + x)^2/(1 - K(t + x))$ on a fixed small disc. The comparison can also be read off from Picard iteration: the coefficient of degree s of the solution depends only on coefficients of lower degree, and the nonnegative scalar recursion bounds all of them. The convergent series defines a holomorphic solution on every finite lattice, and the contraction of Step 1 identifies it with v_d^*. Composing with the majorants of H_d and D_d, we obtain, at $\theta = 0$ and on a smaller common ball of coarse fields,

$$\|D_\theta^s (A_d, \nabla_\varepsilon A_d)\|_{b,\mathrm{out}} \le K^{s+1} s! \qquad (s \ge 1). \tag{10.17}$$

To pass from $\theta = 0$ to the smaller ball, we use the binomial sum of Step 6 of the proof of Lemma 10.4, at the same rate.

Step 3: from rows to columns. The rows also give the volume-normalized columns. Fix a coarse input c_1 and $0 < b' < b$. For a coefficient $T_s(e; c_1, \dots, c_s)$ of order s, the connecting length satisfies $\mathsf{t} \ge \mathrm{dist}(e, c_1)$. Therefore

$$\begin{aligned} &\varepsilon^3 \sum_e \sum_{c_2,\dots,c_s} e^{b'\mathsf{t}} |T_s(e; c_1, \dots, c_s)| \\ &\qquad \le K^{s+1} s!\, \varepsilon^3 \sum_e e^{-(b-b')\,\mathrm{dist}(e,c_1)} \le K_b K^{s+1} s!. \end{aligned} \tag{10.18}$$

In the first inequality we used $e^{b'\mathsf{t}} \le e^{b\mathsf{t}} e^{-(b-b')\,\mathrm{dist}(e,c_1)}$ and (10.17). The last inequality follows by summing over fine cubes in annuli around c_1: ε^3 times the number of fine links within distance R is at most $K(1+R)^3$, on every periodic torus and for every mesh

at most one. By symmetry any c_i may be the fixed input. Taking $s = 1$ in (10.17) gives part (3). Taking $a_s = b'$ and enlarging C_s, we obtain part (4), with no loss of exponent depending on the order.

Step 4: minimality in the chart. Let θ be real. The fixed point $v_d^*(\theta)$ is an interior point of the convex domain $\{v \in \mathcal{V}_d : \|v\|_\infty + \|d_\varepsilon v\|_\infty < 3r_v\}$, and its tested Euler equation vanishes by Lemma 10.5. The formula for the Hessian and the stability inequality of Theorem 9.7 then show that $v_d^*(\theta)$ is the unique critical point and the unique minimum throughout this domain, and in particular on the closed C^1_ε ball of radius r_v. Now let r_{ph} be any value allowed in Theorem 9.7 with $\|\theta\|_\infty < r_{\mathrm{ph}}/C_*$. By Step 1, $\|v_d^*\|_\infty + \|d_\varepsilon v_d^*\|_\infty \le 3\|v_d^*\|_{C^1_\varepsilon} \le 6K\|\theta\|_\infty^2$, and since $6K\|\theta\|_\infty \le C_*$ this is at most $C_*\|\theta\|_\infty < r_{\mathrm{ph}}$. Thus $v_d^*(\theta)$ is an interior point of the larger domain as well, all its constrained first variations vanish, and the same stability inequality gives uniqueness and minimality there. This proves part (2).

Step 5: the effective classical action. The finite sum defining $\mathscr{S}_\varepsilon$ is holomorphic on the common ball and nonnegative for real fields. At $\theta = 0$ we have $A_d(0) = 0$ and $\mathsf{J}_d = 0$; in particular $E_d(I) = 0$, and $DE_d(I) = 0$ once the gradient formula is proved. We differentiate at fixed v before using stationarity. The derivative in θ of the parametrized field $v + \mathsf{H}_d\theta - \mathsf{H}_d\mathsf{D}_d(v + \mathsf{H}_d\theta)$ is $\mathsf{H}_d(I - D\mathsf{D}_d(w)\mathsf{H}_d)$. The contribution of Dv_d^* is a variation in $\mathcal{V}_d$, and its derivative of the action vanishes because v_d^* is critical. Using $\mathsf{J}_d(w) = \mathsf{H}_d^\sharp G_\varepsilon(A)$, we obtain

$$\nabla_\theta E_d = (I - D\mathsf{D}_d(w)\mathsf{H}_d)^T \mathsf{J}_d(w), \tag{10.19}$$

where T is the transpose for the counting scalar product on coarse fields. Note that this formula keeps the contribution of the constraint parametrization, and that it gives the derivatives of E_d without estimating the size of the total action.

Step 6: coefficient bounds for the action. We now derive coefficient bounds at one rate from (10.19). We write $(\nabla_\theta E_d)_c = \mathsf{J}_d(w)_c - \mathsf{T}_c$, where

$$\mathsf{T}_c = \sum_{c'} \sum_{e} \mathsf{H}_d(e,c)^T \big(D_{w_e}\mathsf{D}_{d,c'}(w)\big)^T \mathsf{J}_d(w)_{c'}, \qquad w = v_d^*(\theta) + \mathsf{H}_d\theta,$$

with c, c' coarse links and e a fine link. In the term $\mathsf{H}_d^\sharp N_\varepsilon$ of J_d, a fixed coarse index c sees the volume-normalized column of H_d, which is bounded. In T_c the fine index e is summed between H_d and $D\mathsf{D}_d$, and the factors ε^{-3} and ε^3 cancel. We carry out the bookkeeping for the first derivative, which shows all the mechanisms. The derivative of T_c in θ_{c_1} is $\mathsf{T}_c^{(1)}(c_1) + \mathsf{T}_c^{(2)}(c_1)$, where

$$\mathsf{T}_c^{(1)}(c_1) = \sum_{c',e} \mathsf{H}_d(e,c)^T \big(D_{w_e}\mathsf{D}_{d,c'}(w)\big)^T D_{\theta_{c_1}}\big[\mathsf{J}_d(w)_{c'}\big],$$

$$\mathsf{T}_c^{(2)}(c_1) = \sum_{c',e,e'} \mathsf{H}_d(e,c)^T \big(D^2_{w_e w_{e'}}\mathsf{D}_{d,c'}(w)\, D_{\theta_{c_1}} w_{e'}\big)^T \mathsf{J}_d(w)_{c'}.$$

Let $b'' > 0$ be smaller than all rates used, and write $\omega(x,y) = e^{b''\,\mathrm{dist}(x,y)}$. By the triangle inequality, $e^{b''\mathsf{t}(c;c_1)} = \omega(c,c_1)$ is at most the product of the weights ω along the chain c, e, c', c_1, or c, e, e', c_1. We first consider the output row, with c fixed. For $\mathsf{T}^{(1)}$ we sum in the order c_1, c', e:

$$\sum_{c_1} \omega(c,c_1)|\mathsf{T}^{(1)}_c(c_1)| \\ \leq \sum_e \omega(c,e)|\mathsf{H}_d(e,c)| \sum_{c'} \omega(e,c')|D_{w_e}\mathsf{D}_{d,c'}(w)| \sup_{c'} \sum_{c_1} \omega(c',c_1)|D_{\theta_{c_1}}\mathsf{J}_d(w)_{c'}|.$$

The first sum is a counting column of H_d, of order ε^{-3}. For each fixed fine e, the second sum is a counting column of $D\mathsf{D}_d$ with the fine input fixed, of order $\varepsilon^3 r$ by (10.10). The last factor is a row of the coarse tensor $D_\theta \mathsf{J}_d$, which is bounded by Step 2. The product is of order r, with no power of ε. For $\mathsf{T}^{(2)}$ we bound $|\mathsf{J}_d(w)_{c'}| \leq \|\mathsf{J}_d(w)\|_\infty$ and sum in the order c_1, (c', e'), e: the counting column of H_d at c, of order ε^{-3}, multiplies the counting column of $D^2\mathsf{D}_d$ with the fine input e fixed, of order ε^3, and the row of $D_\theta w = Dv^*_d + \mathsf{H}_d$, which is bounded by Step 2. Next we consider the input column, with c_1 fixed. For $\mathsf{T}^{(1)}$ the fixed input lies in $D_\theta \mathsf{J}_d$. We use its column $\sum_{c'} \omega(c',c_1)|D_{\theta_{c_1}}\mathsf{J}_d(w)_{c'}|$, and then the rows $\sup_{c'} \sum_e \omega(e,c')|D_{w_e}\mathsf{D}_{d,c'}(w)| \leq Kr$ and $\sup_e \sum_c \omega(c,e)|\mathsf{H}_d(e,c)| \leq K$; no power of ε occurs. For $\mathsf{T}^{(2)}$ the fixed input lies in $D_\theta w$, whose counting column $\sum_{e'} \omega(e',c_1)|D_{\theta_{c_1}} w_{e'}|$ is of order ε^{-3}; it multiplies the counting column of $D^2\mathsf{D}_d$ with the fine input e' fixed, of order ε^3, the row of H_d, and $\|\mathsf{J}_d(w)\|_\infty$.

The derivatives of higher order are bounded in the same way. In each term of the chain rule, the branch containing the fixed input, whether it lies in w or in J_d, uses the input column of that factor, and every other branch uses its output row; these are the contraction rules of Lemma 5.3. Every contraction over a fine index pairs a counting column of order ε^{-3}, of H_d or of $D_\theta w$, with a counting column of order ε^3 of a derivative of D_d. Together with (10.17), this gives, on a fixed smaller ball and at the rate b'',

$$\|D^s_\theta \nabla_\theta E_d\|_{b'',\mathrm{root}} \leq K^{s+1} s! \qquad (s \geq 1), \tag{10.20}$$

where the norm is the maximum of the output row and the input columns. Since the derivatives of a scalar function are symmetric, every argument may be the fixed one. This proves the bounds $\|D^s E_d\|_{a_s,\mathrm{root}} \leq C_s$ of part (5). Integrating the row of the Hessian along $t\theta$, $0 \leq t \leq 1$, and using $\nabla_\theta E_d(0) = 0$, we obtain $\|\nabla_\theta E_d\|_\infty \leq K\|\theta\|_\infty$. The substitution $\theta = gB$ contributes exactly the factor g^{s-2} at order s of $g^{-2}E_d(e^{gB})$, and its first derivative is $g^{-1}\nabla_\theta E_d(gB)$, which gives $\|D_B W_{d,g}\|_\infty \leq K\|B\|_\infty$.

Step 7: local minimality on the fiber. Let θ be real, and write $A_* = A_d(\theta)$, $G_* = G_d(A_*)$, and $c_* = \mathrm{Log}\, G_*$. Let Ω_* be a periodic fine gauge transformation with values G_* at the coarse vertices. By the discussion at the beginning of this section, $U_* = (e^{\varepsilon A_*})^{\Omega_*}$ satisfies $T^d_M U_* = e^\theta$. On the fixed finite lattice, let U be a configuration in this fiber close to U_*,

and write $U^{\Omega_*^{-1}} = e^{\varepsilon A}$. Since $A = A_*$ for $U = U_*$, continuity in finitely many variables shows that A lies in the ball of inputs of Theorem 9.9 if U is close enough to U_*. Its block average is $T_M^d e^{\varepsilon A} = (e^\theta)^{G_*^{-1}}$.

We apply Theorem 9.9 to A with prescribed coarse datum $c = c_*$. For $A = A_*$ the gauge transformation of that theorem is the identity, since $\mathsf{P}_d^{\mathrm{div}} \operatorname{div}_\varepsilon A_* = 0$ and $c_* = \operatorname{Log} G_d(A_*)$. The transformed field A' has projected divergence zero and gauge-corrected block average

$$\big[(e^\theta)^{G_*^{-1}}\big]^{G_*} = e^\theta,$$

where the order of the factors comes from $(U^k)^l = U^{lk}$. By that theorem $\|A'\|_\infty + \|d_\varepsilon A'\|_\infty$ is small, and the parametrization of all nearby solutions of the constraint in Theorem 9.6 gives

$$v' = (I - \mathsf{H}_d \mathsf{Q}_d) A' \in \mathcal{V}_d, \qquad A' = \mathsf{P}_d^{\mathrm{cl}}(v' + \mathsf{H}_d \theta).$$

By continuity and the supremum and curl bounds for $\mathsf{H}_d \mathsf{Q}_d A'$, we see that v' lies in the larger convex domain of Step 4. By the stability inequality of Theorem 9.7, we have

$$\mathscr{S}_\varepsilon(U) - \mathscr{S}_\varepsilon(U_*) \geq \frac{c_0}{4} \|v' - v_d^*(\theta)\|_{H_\varepsilon^1}^2,$$

where we used that all the gauge transformations involved preserve the action $\mathscr{S}_\varepsilon$. Equality forces $v' = v_d^*(\theta)$, hence $A' = A_*$. Undoing the two fine gauge transformations shows that U and U_* lie on the same fine gauge orbit. Since both configurations lie in the fiber over e^θ, the values of the relating gauge transformation at the coarse vertices leave e^θ fixed. The construction applies to all points of a sufficiently small neighborhood of U_* in the fiber on the given finite lattice. Applying the inequality along a differentiable curve in the fiber through U_*, for both signs of the parameter, shows that every tangent vector to the fiber has zero first variation. This proves part (6) and completes the proof. □

10.6 Gauge extensions and symmetries of the effective action

In this section we prove that E_d is invariant under small coarse gauge transformations, the lattice symmetries, and constant color rotations. A symmetry applied to the background field moves it out of the gauge slice in which it was constructed. To compare, we bring the transformed field back into the slice with Theorem 9.9 and use the uniqueness of critical points in the convex domain of Theorem 9.7. The following lemma isolates this argument; it is used here and again in the proof of the nested minimization identity.

Lemma 10.7. *There exists $r_{\mathrm{tr}} > 0$ such that the following holds for every $d \geq 0$ and $n \geq 4$, with $\varepsilon = \varepsilon_d$. Let $U = e^{\varepsilon A}$ be a real fine configuration with $\|A\|_{\mathsf{C}_\varepsilon^1} < r_{\mathrm{tr}}$, and let $b = T_M^d U$ satisfy $\|\operatorname{Log} b\|_\infty < r_{\mathrm{tr}}$. Assume that U is a critical point of $\mathscr{S}_\varepsilon$ on the fiber $\{U' : T_M^d U' = b\}$, that is, $(d/dt)\mathscr{S}_\varepsilon(U(t))|_{t=0} = 0$ for every differentiable curve $t \mapsto U(t)$ in this fiber with $U(0) = U$.*

Then, with $\theta = \operatorname{Log} b$, there is a real fine gauge transformation h such that $U^h = e^{\varepsilon A_d(\theta)}$. In particular $\mathscr{S}_\varepsilon(U) = E_d(b)$.

Proof of Lemma 10.7. If $d = 0$, the fiber is the single point $U = b$, so $A = \theta$; since $\mathcal{V}_0 = \{0\}$, $\mathsf{H}_0 = I$, and $\mathsf{D}_0 = 0$, we have $A_0(\theta) = \theta$, and $h = I$ works. Let $d \geq 1$. We choose r_{tr} so small that the following three steps are possible.

Step 1: moving U into the gauge slice. We have $\|A\|_\infty + \|\operatorname{div}_\varepsilon A\|_\infty \leq 3\|A\|_{C^1_\varepsilon}$ and $\|d_\varepsilon A\|_\infty \leq 2\|\nabla_\varepsilon A\|_\infty$. For small r_{tr}, Theorem 9.9 therefore applies to A with prescribed coarse datum 0. It gives a real fine scalar field λ such that the field $A' = A^{e^\lambda}$, defined by $e^{\varepsilon A'} = U^{e^\lambda}$, satisfies

$$\mathsf{P}_d^{\mathrm{div}} \operatorname{div}_\varepsilon A' = 0, \qquad G_d(A')\, e^{\lambda|_{\mathrm{roots}}} = I,$$

and has gauge-corrected block average b and $\|A'\|_\infty + \|d_\varepsilon A'\|_\infty \leq K r_{\mathrm{tr}}$. By the parametrization of all nearby solutions of the constraint in Theorem 9.6, $A' = \mathsf{P}_d^{\mathrm{cl}}(a' + \mathsf{H}_d\theta)$ with $a' = (I - \mathsf{H}_d\mathsf{Q}_d)A' \in \ker \mathsf{Q}_d$. Since $\mathsf{P}_d^{\mathrm{div}} \operatorname{div}_\varepsilon A' = 0$ and $\mathsf{P}_d^{\mathrm{div}} \operatorname{div}_\varepsilon \mathsf{H}_d = 0$, also $\mathsf{P}_d^{\mathrm{div}} \operatorname{div}_\varepsilon a' = 0$, that is, $a' \in \mathcal{V}_d$. The bounds on H_d give $\|a'\|_\infty + \|d_\varepsilon a'\|_\infty \leq K r_{\mathrm{tr}}$.

Step 2: criticality in the chart. Let $u \in \mathcal{V}_d$, and for small real t let $a(t) = a' + tu$ and $A(t) = \mathsf{P}_d^{\mathrm{cl}}(a(t) + \mathsf{H}_d\theta)$. Since the gauge-corrected block average of $A(t)$ is $e^\theta = b$ for all t, the relation at the beginning of Section 10.5 gives $T_M^d e^{\varepsilon A(t)} = b^{G_d(A(t))^{-1}}$. For a fine vertex x let $r(x)$ be the coarse vertex whose centered block at depth d contains x, and let $\Omega(t)_x = G_d(A(t))_{r(x)}$. Then $\Omega(t)$ has the values $G_d(A(t))$ at the coarse vertices, and it depends differentiably on t because G_d is holomorphic. The curve $U(t) = (e^{\varepsilon A(t)})^{\Omega(t)}$ lies in the fiber over b, and $\mathscr{S}_\varepsilon(U(t)) = \mathscr{S}_\varepsilon(A(t))$. At $t = 0$ we have $e^{\varepsilon A'} = U^{e^\lambda}$, so $U(0) = U^{h_0}$ with $h_0 = \Omega(0)e^\lambda$, by $(U^k)^l = U^{lk}$. The values of h_0 at the coarse vertices are $G_d(A')e^{\lambda|_{\mathrm{roots}}} = I$. Since a fine gauge transformation equal to the identity at the coarse vertices maps the fiber over b onto itself and preserves $\mathscr{S}_\varepsilon$, the configuration $U(0)$ is critical on the fiber, as U is. It follows that

$$\frac{d}{dt}\mathscr{S}_\varepsilon(A(t))\Big|_{t=0} = \frac{d}{dt}\mathscr{S}_\varepsilon(U(t))\Big|_{t=0} = 0.$$

Since $u \in \mathcal{V}_d$ was arbitrary, a' is a critical point of $a \mapsto \mathscr{S}_\varepsilon(\mathsf{P}_d^{\mathrm{cl}}(a + \mathsf{H}_d\theta))$ on $\mathcal{V}_d$.

Step 3: identification. Fix an allowed value r_{ph} of Theorem 9.7, and choose r_{tr} so that $r_{\mathrm{tr}} < r_\theta$, $K r_{\mathrm{tr}} < r_{\mathrm{ph}}$, and $r_{\mathrm{tr}} < r_{\mathrm{ph}}/C_*$. Then a' is a critical point in the interior of the convex domain $\{a \in \mathcal{V}_d : \|a\|_\infty + \|d_\varepsilon a\|_\infty < r_{\mathrm{ph}}\}$. By Theorem 10.6 and Lemma 10.5, $v_d^*(\theta)$ is also an interior critical point of this domain. By the uniqueness of interior critical points in Theorem 9.7, $a' = v_d^*(\theta)$. Hence $A' = A_d(\theta)$, that is, $U^{e^\lambda} = e^{\varepsilon A_d(\theta)}$, and $\mathscr{S}_\varepsilon(U) = \mathscr{S}_\varepsilon(A_d(\theta)) = E_d(b)$, since gauge transformations preserve the action. □

The next lemma constructs a smooth extension of coarse gauge transformations to the fine lattice by cardinal interpolation, and proves the symmetries of E_d. The first

differences of the extension are of the size of the coarse gauge transformation, not of its size divided by the mesh. For a coarse vertex field κ and a point x of the torus we write $\sum_c \chi_c(x)\kappa_c$, where c runs over the coarse vertices.

Lemma 10.8. *There exist smooth periodic functions χ_c on the torus, indexed by the coarse vertices c, such that $\sum_c \chi_c = 1$, $\chi_c(c') = \delta_{cc'}$ for all coarse vertices c', the supports of the χ_c have diameter at most $2\sqrt{3}$, and*

$$\sup_x \sum_c |\partial^j \chi_c(x)| \le C_j \qquad (0 \le j \le 3);$$

their restrictions to the fine vertices satisfy $\varepsilon_d^3 \sum_x |\partial^j \chi_c(x)| \le C_j$. There exist $r_{\mathrm{lift}}, r_{\mathrm{sym}}, \kappa_{\mathrm{sym}}, C > 0$ with $2Cr_{\mathrm{sym}} < \min(r_{\mathrm{lift}}, \kappa_{\mathrm{sym}})$, where C also bounds the constants of Theorem 10.6 and the constant in the bound on $\operatorname{Log} G_d$ in Lemma 10.4, such that the following hold for every $d \ge 0$ and $n \ge 4$, with $\varepsilon = \varepsilon_d$.

1. *Let $k_c = e^{\kappa_c}$ be a coarse gauge transformation with $\|\kappa\|_\infty < \kappa_{\mathrm{sym}}$, and let $\Omega(x) = \exp(\sum_c \chi_c(x)\kappa_c)$ at the fine vertices x. Then Ω equals k at the coarse vertices, and for fine fields A with $\|A\|_{C^1_\varepsilon} < r_{\mathrm{lift}}$,*

$$\|\varepsilon^{-1} \operatorname{Log}[(e^{\varepsilon A})^\Omega]\|_{C^1_\varepsilon} \le C(\|A\|_{C^1_\varepsilon} + \|\kappa\|_\infty).$$

   In particular, for $\|\theta\|_\infty < r_{\mathrm{sym}}$ the gauge orbit of $e^{\varepsilon A_d(\theta)}$ contains a representative U, analytic in θ, with $T^d_M U = e^\theta$ and $\|\varepsilon^{-1} \operatorname{Log} U\|_{C^1_\varepsilon} \le C\|\theta\|_\infty$.
2. *On common smaller complex domains,*

$$E_d(b^k) = E_d(b), \qquad E_d(\sigma b) = E_d(b), \qquad E_d(b^u) = E_d(b) \quad (u \in \mathrm{SU}(2) \text{ constant}),$$

   where b and b^k lie in the chart $\{\|\operatorname{Log} b\|_\infty < r_{\mathrm{sym}}\}$, $\|\operatorname{Log} k\|_\infty < \kappa_{\mathrm{sym}}$, and σ is a translation of the coarse lattice or the spatial inversion $x \mapsto -x$, which maps links to reversed links and inverts their variables. Differentiating the first identity, we obtain the infinitesimal gauge-invariance identities $(d/dt)E_d(b^{e^{t\xi}})|_{t=0} = 0$ for every field ξ on the coarse vertices with values in $\mathfrak{su}(2)$.

The representative in part (1) is used in the proof of Theorem 10.10. Part (2) concerns small gauge transformations only. Gauge transformations far from the identity are treated in Section 11.

Proof of Lemma 10.8. We construct the cardinal functions (Step 1), prove the bound on the gauge transform (Steps 2 and 3), and then prove the three identities (Steps 4–6). Step 7 fixes the radii.

Step 1: cardinal functions. Let

$$\eta(t) = \begin{cases} \exp\bigl(1 - (1-t^2)^{-1}\bigr), & |t| < 1, \\ 0, & |t| \ge 1, \end{cases}$$

and

$$D(t) = \sum_{l \in \mathbb{Z}} \eta(t-l), \qquad \phi_l(t) = \eta(t-l)/D(t).$$

The function D is positive and periodic, so its minimum on $[0,1]$ is positive. The derivatives of each fixed order of η are bounded and vanish at the endpoints of its support. At most two translates of η are nonzero at a noninteger point and only one at an integer point, and the sums of their derivatives are bounded in terms of the order. It follows that $\sum_l \phi_l = 1$ and $\phi_l(k) = \delta_{lk}$ for integers k. Taking tensor products of the ϕ_l in the three coordinates and periodizing with period n, we obtain functions χ_c whose supports have diameter at most $2\sqrt{3}$ in the metric of the torus. Since $n \geq 4$, the periodization keeps the finite overlap and the values at the coarse vertices. The bounds on the sums of derivatives follow from the product rule. For fixed c, the support of χ_c contains at most $K\varepsilon^{-3}$ fine vertices and the derivatives of χ_c are bounded, which proves the bounds with the factor ε^3. Finite differences divided by ε satisfy the same bounds, since they are averages of the corresponding derivatives over intervals of length ε.

Step 2: the gauge transform has a bounded rescaled connection. Let $\lambda(x) = \sum_c \chi_c(x)\kappa_c$, so that $\Omega = e^{\lambda}$. By Step 1, the value of λ and its first two differences divided by ε are bounded by $K\|\kappa\|_\infty$. For a fine link xy we write $u = \lambda_x$, $v = (\lambda_y - \lambda_x)/\varepsilon$, and $a = A_{xy}$. The analytic function of finitely many variables

$$\varepsilon^{-1} \operatorname{Log}\bigl(e^{u} e^{\varepsilon a} e^{-u-\varepsilon v}\bigr) = \operatorname{Ad}(e^{u})a - \Bigl(\int_0^1 \operatorname{Ad}(e^{tu})\,dt\Bigr)v + \varepsilon R_\varepsilon(u,v,a)$$

has a removable singularity at $\varepsilon = 0$, uniformly on a fixed small complex ball of (u,v,a). Indeed, the product of the three exponentials is the identity at $\varepsilon = 0$, and its first derivative in ε at $\varepsilon = 0$ gives the two displayed principal terms. The remainder R_ε and its derivatives are bounded by the convergent series in finitely many variables on a smaller ball. The difference of the first principal term involves $\nabla_\varepsilon A$ and $\nabla_\varepsilon \lambda$, and the difference of the second involves the first two differences of λ. For the last term,

$$|\nabla_\varepsilon(\varepsilon R)_e| \leq |R_{e+\varepsilon e_\mu}| + |R_e|,$$

with no inverse power of the mesh. Since the remainder vanishes at $(a,v) = 0$, after shrinking the domain its value is at most $K(|a| + |v|)$. This proves the bound of part (1), on a radius r_{lift} independent of the fine mesh.

Step 3: a representative with block average e^{θ}. By Lemma 10.4 and part (1) of Theorem 10.6, $\|\operatorname{Log} G_d(A_d(\theta))\|_\infty \leq K\|\theta\|_\infty$. We apply the cardinal extension of Step 2 with these values at the coarse vertices. By the discussion at the beginning of Section 10.5, the resulting field U satisfies $T_M^d U = e^{\theta}$, and Step 2 implies that $\|\varepsilon^{-1}\operatorname{Log} U\|_{C^1_\varepsilon} \leq K\|\theta\|_\infty$. The formulas in finitely many variables and the holomorphic maps already constructed show that U is analytic in θ. The radii and the bound are the same for all d and n. This proves part (1).

Step 4: gauge invariance. We first let b and k be real with $\|\operatorname{Log} b\|_\infty$ and $\|\operatorname{Log} k\|_\infty$ small, and write $b = e^\theta$ and $G = G_d(A_d(\theta))$. Using the local logarithm of kG, we apply the cardinal extension of Step 2 to the coarse gauge transformation kG, and we apply the resulting fine gauge transformation to $e^{\varepsilon A_d(\theta)}$. Since $T_M^d e^{\varepsilon A_d(\theta)} = b^{G^{-1}}$, the transformed field U_k satisfies $T_M^d U_k = (b^{G^{-1}})^{kG} = b^k$. By Step 2 its rescaled connection has C^1_ε norm at most $K(\|\theta\|_\infty + \|\operatorname{Log} k\|_\infty)$. The field U_k is obtained from the configuration U_* of part (6) of Theorem 10.6 by a fine gauge transformation, which maps the fiber over b onto the fiber over b^k and preserves $\mathscr{S}_\varepsilon$. Since U_* is critical on its fiber, U_k is critical on the fiber over b^k. By Lemma 10.7, $\mathscr{S}_\varepsilon(U_k) = E_d(b^k)$. Since all the transformations used preserve the action, we conclude that $E_d(b^k) = \mathscr{S}_\varepsilon(e^{\varepsilon A_d(\theta)}) = E_d(b)$.

Step 5: translations, inversion, and constant color rotations. Translations of the coarse lattice preserve the centered blocks and their coordinate-ordered paths. They lift to translations of the fine lattice and commute with the block averaging map. For the inversion, let $c = (r, r + Me_i)$, let $c' = (-r - Me_i, -r)$, and let $y = -x - Me_i$. The inversion maps the paths as follows: $\sigma_{r,x} \mapsto \sigma_{-r,-x}$, $F_{c,x} \mapsto F^{-1}_{c',y}$, and $C_c \mapsto C^{-1}_{c'}$. For group elements F, C in the domain of the logarithm,

$$\operatorname{Log}(F^{-1}C) = -\operatorname{Ad}(C^{-1}) \operatorname{Log}(FC^{-1}).$$

Inserting this identity into the exponential average defining T_M, we find that the averaged reversed link is the inverse of the averaged link. The same holds for the Borel extension when a ratio equals $-I$, although that case does not occur in the present chart. The inversion therefore also commutes with the block averaging map. A translation preserves the C^1_ε norm of the rescaled connection; the inversion replaces each component by its negative at a translated link and also preserves that norm. Let σ be one of these maps and let U be the representative of part (1) for b, which is critical on its fiber by part (6) of Theorem 10.6. Then σU has block average σb and the same action, it is critical on the fiber over σb, and its rescaled connection has the same small norm. By Lemma 10.7, $E_d(\sigma b) = \mathscr{S}_\varepsilon(\sigma U) = \mathscr{S}_\varepsilon(U) = E_d(b)$. This proves the spatial identities on a common smaller domain.

A constant $u \in \mathrm{SU}(2)$ acts by the orthogonal color rotation $\operatorname{Ad}(u)$ on every path product, every linear operator, the constraints, and the action. It preserves all the domains above. By uniqueness of the fixed point, $v_d^*(\operatorname{Ad}(u)\theta) = \operatorname{Ad}(u) v_d^*(\theta)$ and $A_d(\operatorname{Ad}(u)\theta) = \operatorname{Ad}(u) A_d(\theta)$, which gives the identity $E_d(b^u) = E_d(b)$ for every such u.

Step 6: complex continuation. For translations, the inversion, and each fixed constant u, both sides of the identity are holomorphic functions of the coarse logarithm. Since they agree on a real open ball, every coefficient of the Taylor series of their difference vanishes. For the gauge identity the same argument applies jointly in $\operatorname{Log} b$ and $\operatorname{Log} k$.

Step 7: the radii and the infinitesimal identities. Let C be a constant larger than the constants for the minimum, for the gauge transformation G_d, and for the extension. First fix r_{lift} and κ_{sym} inside the domains used above, and then fix r_{sym} so small that $2Cr_{\mathrm{sym}} < \min(r_{\mathrm{lift}}, \kappa_{\mathrm{sym}})$ and all the requirements of Lemma 10.7 and of Steps 4 and 5 hold. This order gives the dependence of the constants stated in Section 10.1. Differentiating the gauge identity along $k_x(t) = e^{t\xi_x}$ gives the infinitesimal identity for every coarse vertex field ξ; for t in a small interval about zero, both b and $b^{k(t)}$ stay in the chart. □

10.7 One averaging step and nested minimization

We now consider one averaging step, from a lattice of side Mm to the lattice of side $m \geq 4$. We minimize E_d over the configurations on the lattice of side Mm whose block average is a given coarse field c. We first recall the local coordinates on the fiber $\{b : T_M b = c\}$ and prove the bounds we need for them; then we prove the nested minimization identity.

Coordinates for one averaging step. The coordinates are those of Definition 4.3 and Lemma 6.3; the eliminated edges are denoted $e^*_{c'}$ here. In this paragraph c denotes a coarse field and c' a positive coarse link. The coarse-field lift $U_0(c)$ is the identity on the internal links of the blocks and equals $c_{c'}$ on the interface links of the coarse link c'; thus $T_M U_0(c) = c$. In each block, the paths $\sigma_{r,x}$ from the block center r form a rooted spanning tree, and we let $\mathcal{F}$ be the set of positive fine links whose unoriented edges belong to these trees. For the coarse link $c' = (r, r + Me_i)$, the eliminated edge is $e^*_{c'} = (r + R_M e_i, r + (R_M + 1)e_i)$, where $M = 2R_M + 1$. We write a fine configuration as $e^X U_0(c)$, and we let

$$\mathsf{C}_{c'}(X) = \operatorname{Log}\big((T_M(e^X U_0(c)))_{c'} c_{c'}^{-1}\big)$$

be the block averaging constraint at c'. The free logarithmic coordinates z are the values X_e on the positive fine links $e \notin \mathcal{F}$ that are not eliminated edges, and $X_e = 0$ for $e \in \mathcal{F}$. The local constraint coordinates $X = \Gamma_c(z)$ solve the constraints $\mathsf{C}_{c'}(X) = 0$ for the eliminated-edge variables $X_{e^*_{c'}}$, with $\Gamma_c(z)_e = z_e$ on the free links. We set

$$b(c,z) = e^{\Gamma_c(z)} U_0(c), \qquad B(c,z) = \operatorname{Log} b(c,z), \qquad \mathsf{E}_{\mathrm{f}} = D_z B(I,0).$$

Let f be the number of free coordinates, each a group variable, let $c_{\mathrm{Haar}} = 1/(16\pi^2)$ and $j_H(X) = \operatorname{sinc}^2(|X|/2)$ be as in (4.2), and define the Haar disintegration density

$$\mathcal{J}_c(z) = c_{\mathrm{Haar}}^f \frac{\prod_{e \notin \mathcal{F}} j_H(\Gamma_c(z)_e)}{\prod_{c'} \det D_{X_{e^*_{c'}}} \mathsf{C}_{c'}(\Gamma_c(z))},$$

where e runs over the positive fine links and c' over the positive coarse links. In complex formulas $|X|^2$ denotes the bilinear sum of the squares of the three coordinates of X. This

is the density of Lemma 6.3; the numerator contains the Haar factors of the eliminated edges, which lie outside $\mathcal{F}$. We recall its derivation in the proof below, since the estimates use its explicit form.

Lemma 10.9. *There exist $R'_M, b, K_M > 0$ such that the following hold for every $m \geq 4$.*

1. *On the complex product $\|\theta\|_\infty < R'_M$, $\|z\|_\infty < R'_M$, with $c = e^\theta$, the maps $\Gamma_c(z)$ and $B(c,z)$ are holomorphic, their absolute derivative tensors have factorial bounds and finite stencils, and*

$$\|B(c,z)\|_\infty \leq K_M(\|\theta\|_\infty + \|z\|_\infty), \qquad \|D_z B(c,z) - \mathsf{E}_{\mathrm{f}}\|_{b,\mathrm{row+col}} \leq K_M(\|\theta\|_\infty + \|z\|_\infty).$$

2. *On a smaller real product, the constraint Jacobian determinants $\det D_{X_{e^*_{c'}}} \mathsf{C}_{c'}(\Gamma_c(z))$ are bounded below by a fixed positive constant, and*

$$\|D_z^2 \log \mathcal{J}_c(z)\|_{b,\mathrm{row+col}} \leq K_M.$$

3. *Let $t \mapsto b(t)$ be a differentiable curve in the fiber $\{T_M b = c\}$, and let $k(t)$, equal to the identity at the coarse vertices, be the block axial gauge transformation of $b(t)$, so that $b(t)^{k(t)} = b(c, z(t))$, with $z(t)$ in the domain of (1). Put $k_0 = k(0)$ and $z_0 = z(0)$, and let $\mathcal{G}_h(U) = U^h$. Then*

$$b'(0) = D\mathcal{G}_{k_0^{-1}}\big|_{b(c,z_0)} D_z b(c,z_0) z'(0) + \frac{d}{dt}\Big[b(c,z_0)^{k(t)^{-1}}\Big]\Big|_{t=0}.$$

The second term is the tangent vector at $b(0)$ of a curve of fine gauge transformations along the block trees which are the identity at the coarse vertices. If $b(0) = b(c,z_0)$, then $k_0 = I$, and the first term is $D_z b(c,z_0) z'(0)$.

Proof of Lemma 10.9. We construct the block axial gauge (Step 1), solve the constraint for the eliminated edges (Steps 2 and 3), derive the density and bound its Hessian (Steps 4 and 5), and prove the decomposition of tangent vectors (Step 6). The density formula is the tree-gauge specialization of the disintegration of Haar measure for this averaging constraint.

Step 1: the block axial gauge. We gauge the links of $\mathcal{F}$ to the identity with $k_r = I$ at each block center r. On a tree edge directed from a parent x to a child y we prescribe

$$k_y = k_x U_{xy}, \qquad k_x = U(\sigma_{r,x}). \tag{10.21}$$

If this direction reverses a positive link, U_{xy} is the inverse of the variable of that link, as in the path convention. Then $k_x U_{xy} k_y^{-1} = I$ on every tree edge. By recursion along the tree, we see that this gauge transformation is unique given the values at the roots and that each k_x is an analytic path product. By (10.14), a gauge transformation equal to the identity at the coarse vertices preserves the coarse field. In these coordinates each straight reference path $C_{c'}$ has only one link that is not gauged to the identity, the eliminated edge $e^*_{c'}$.

Step 2: the derivative in the eliminated edge. We note that in these coordinates the constraint at c' contains, among all the eliminated variables, only its own. Indeed, the root paths are identities, and a straight middle segment crosses only the interface from its starting block to the neighboring block in direction i. Exactly M of the M^3 segments cross $e^*_{c'}$: their transverse offset is zero, and the longitudinal start has M choices. At $z = 0$, let only $X = X_{e^*_{c'}}$ vary. Then the M contours through $e^*_{c'}$ have transport $e^X c_{c'}$, all other contours have transport $c_{c'}$, and the reference path has transport $e^X c_{c'}$. The relative logarithms are 0 for the first M contours and $-X$ for the others, so their mean is $-(1 - M^{-2})X$, and the output is exactly

$$\exp\bigl(-(1 - M^{-2})X\bigr) e^X c_{c'} = e^{M^{-2}X} c_{c'}.$$

Thus the derivative of the constraint in the eliminated edge is $M^{-2} I_3$ at $z = 0$, for every sufficiently small c, not only for $c = I$.

Step 3: solving the constraints. Each constraint involves a bounded number of variables, and a fixed free link meets a bounded number of constraints, both depending only on M. The derivatives of these path products on a fixed smaller polydisc are bounded by $s! K_M^s$. We consider the equation

$$X_{e^*_{c'}} = X_{e^*_{c'}} - M^2 \mathsf{C}_{c'}(X, z).$$

By Step 2, the derivative of its right side in $X_{e^*_{c'}}$ vanishes at $(X, z) = (0, 0)$. On a fixed small product this derivative has norm less than $1/4$, and the constant term is $O_M(\|z\|_\infty)$. Hence the right side maps a ball of radius $K_M \|z\|_\infty$ strictly into itself, and iteration gives the unique small holomorphic solution. Majorizing by the scalar quadratic implicit series of Lemma 5.3, we obtain factorial bounds on its derivatives. Since the equations are independent in their eliminated unknowns, the solution on the whole lattice has the same bounds and a fixed stencil, with no factor depending on the dimension. At $z = 0$ the solution vanishes identically. Multiplying by $U_0(c)$ and taking the local logarithm, we obtain the bounds on B and on $D_z B - \mathsf{E}_\mathrm{f}$ from Taylor's formula. Since a stencil has bounded diameter, a fixed spatial weight changes only the constant. A fixed input enters a bounded number of outputs, which gives the column bounds. This proves part (1).

Step 4: the density. To derive the density, we first eliminate the gauge transformations along the trees recursively, by left and right translations of the Haar probability measure; their integral is one. With the remaining links fixed, we change each eliminated link to the output of its constraint; the Jacobian of this change is the displayed 3×3 determinant. The remaining exponential coordinates lie outside $\mathcal{F}$ and contribute their Haar factors to the numerator of $\mathcal{J}_c$, including those of the eliminated edges. Since these changes of variables are triangular, a derivative in an earlier coordinate contributes no further determinant. More explicitly, we fix c as a parameter before the change of variables. A nearby output

is $e^{\varphi}c$, and the Haar probability measure in this coordinate is $c_{\mathrm{Haar}}^{q}\prod_{c'} j_H(\varphi_{c'})\,d\varphi$, where q is the number of positive coarse links. On the fiber $\varphi = 0$ these factors j_H equal one. There are $f + q$ input links outside $\mathcal{F}$, so dividing their Haar constants by those of the output leaves c_{Haar}^{f}. Right translation by the fixed configuration $U_0(c)$ preserves the Haar measure of the inputs. This gives the displayed density at each fixed coarse field. Letting this parameter vary afterwards introduces no further Jacobian and no additional Haar factor for the coarse field.

Step 5: the Hessian of the logarithm of the density. We shrink the product until the Haar factors are bounded away from zero and the derivatives of the constraints in the eliminated edges differ from $M^{-2}I_3$ by less than $M^{-2}/4$. Then the real determinants are positive, and their logarithms and the logarithms of the Haar factors have bounded local analytic derivatives. The function $\log \mathcal{J}_c$ is the sum of these local terms and of the constant $f \log c_{\mathrm{Haar}}$. Each differentiated row meets a bounded number of terms, and each term involves a bounded number of coordinates. This proves the bounds on the rows and columns of the Hessian in part (2); the undifferentiated density depends on the volume.

Step 6: tangent vectors to the fiber. For a curve $b(t)$ in the fiber as in part (3), we apply to each $b(t)$ its unique block axial gauge transformation $k(t)$, which is the identity at the coarse vertices and depends differentiably on t, since each $k_x(t)$ is a path product. The gauged curve has the same block average c, and its free coordinates are some $z(t)$. By uniqueness of the solution of the constraints, all its remaining coordinates are those of $\Gamma_c(z(t))$, that is, $b(t)^{k(t)} = b(c, z(t))$. Hence $b(t) = \mathcal{G}_{k(t)^{-1}}(b(c, z(t)))$. Differentiating at $t = 0$ by the product rule, we obtain the displayed formula: the first term comes from the derivative of $b(c, z(t))$ at the fixed gauge transformation k_0^{-1}, and the second from the derivative of $k(t)^{-1}$ at the fixed configuration $b(c, z_0)$. If $b(0) = b(c, z_0)$, the uniqueness of the block axial gauge transformation gives $k_0 = I$. The argument is local and requires no global choice on the compact fiber. □

In the following theorem, E_{d_0} is the effective classical action of depth d_0 over the lattice of side Mm, in the coarse lattice units of that lattice, and E_{d_0+1} is the effective classical action of depth $d_0 + 1$ over the lattice of side m. The coordinates z are the free logarithmic coordinates of Lemma 10.9; no coupling has been inserted.

Theorem 10.10. *There exist $r_c, r_z, m_0, C_0, a, C, g_* > 0$ such that the following hold for every $d_0 \geq 0$ and every $m \geq 4$. Let*

$$F_{d_0}(c, z) = E_{d_0}(b(c, z)), \qquad K_{d_0}^{0} = \mathsf{E}_{\mathrm{f}}^{T} D^2 E_{d_0}(I) \mathsf{E}_{\mathrm{f}}.$$

Here $D^2 E_{d_0}(I)$ is the effective Maxwell quadratic form of Theorem 8.3; its gauge and constant null directions are kept.

1. *On the real space of free coordinates,*

$$m_0 I \le K^0_{d_0} \le C_0 I, \qquad \|K^0_{d_0}\|_{a,\mathrm{row+col}} + \|(K^0_{d_0})^{-1}\|_{a,\mathrm{row+col}} \le C_0.$$

2. *On the real product $\|\mathrm{Log}\, c\|_\infty < r_c$, $\|z\|_\infty \le r_z$, the configuration $b(c,z)$ lies in the domain of E_{d_0} and in the domain of positivity of the Haar disintegration density with fixed margins. The Hessian*

$$D^2_z F_{d_0} = (D_z B)^T D^2 E_{d_0}(B) D_z B + D E_{d_0}(B) D^2_z B, \qquad B = B(c,z),$$

satisfies

$$\|D^2_z F_{d_0} - K^0_{d_0}\|_{a,\mathrm{row+col}} \le C(\|\mathrm{Log}\, c\|_\infty + \|z\|_\infty), \qquad D^2_z F_{d_0} \ge \tfrac{1}{2} m_0 I.$$

3. *For real c with $\|\mathrm{Log}\, c\|_\infty < r_c$ there is a unique minimizer $z^*_{d_0}(c)$ of $z \mapsto F_{d_0}(c,z)$ on the closed real ball $\|z\|_\infty \le r_z$. It is an interior point, it depends real analytically on c, and it has a holomorphic continuation to the complex ball $\|\mathrm{Log}\, c\|_\infty < r_c$. Further,*

$$D_z F_{d_0}(c, z^*_{d_0}(c)) = 0, \qquad \|z^*_{d_0}(c)\|_\infty \le C\|\mathrm{Log}\, c\|_\infty < r_z/8,$$

$$E_{d_0+1}(c) = M \min_{\|z\|_\infty \le r_z} F_{d_0}(c,z) = M F_{d_0}(c, z^*_{d_0}(c)).$$

We call $z^*_{d_0}(c)$ the conditional constrained minimizer.

4. *There exists $0 < r'_c \le r_c$, independent of d_0 and m, such that for every integer $s \ge 1$ there exist $a_s, C_s > 0$, depending on s but independent of d_0 and m, for which the following bound holds on the complex ball $\|\theta\|_\infty < r'_c$:*

$$\|D^s_\theta z^*_{d_0}(e^\theta)\|_{a_s,\mathrm{out}} + \|D^s_\theta z^*_{d_0}(e^\theta)\|_{a_s,\mathrm{input,count}} \le C_s,$$

where the outputs are the free coordinates, the inputs are the coarse links, and distances are measured in the coarse lattice units of the lattice of side m. The volume-normalized column differs from the counting column by the fixed factor M^{-3}.

5. *The identity $E_{d_0+1}(c) = M F_{d_0}(c, z^*_{d_0}(c))$ holds for complex c in the ball of (3), with the holomorphic continuation of $z^*_{d_0}$. For real c and couplings $g^2_+ = Mg^2$, the identity in (3) reads*

$$\frac{E_{d_0+1}(c)}{g^2_+} = \frac{1}{g^2} \min_{\|z\|_\infty \le r_z} F_{d_0}(c,z).$$

6. *Let c be real with $\|\mathrm{Log}\, c\|_\infty < r_c$, let $p \ge 1$, and let $0 < g \le g_*$ with $gp < r_z/4$. Then the function*

$$y \longmapsto \frac{1}{g^2}\big[F_{d_0}(c, z^*_{d_0} + gy) - F_{d_0}(c, z^*_{d_0})\big] - \log \frac{\mathcal{J}_c(z^*_{d_0} + gy)}{\mathcal{J}_I(0)}$$

of real y has Hessian at least $m_0 I/4$ on the product $\prod_e \{|y_e| \le p\}$.

Since the radii and the lower bounds in the theorem do not decrease with d_0, the theorem can be iterated over arbitrarily many averaging steps. The minimization statements and the lower bounds on Hessians concern real coarse fields and real free coordinates. The identity in (5) for complex c and the bounds in (4) concern the holomorphic continuations of the critical point and the critical value. In (6) the denominator $\mathcal{J}_I(0)$ is a constant, so the value of the numerator at the shifted point is kept.

Proof of Theorem 10.10. We identify the Hessian of E_{d_0} at the identity (Step 1), obtain the bounds on $K^0_{d_0}$ (Step 2), and bound the Hessian away from the identity (Step 3). We then choose the radii (Step 4), construct the minimizer (Step 5), identify the nested minimum with the background field of depth $d_0 + 1$ (Steps 6–8), and prove part (6) (Step 9).

Step 1: the Hessian of the action at the identity. Differentiating the action twice at $\theta = 0$ in Theorem 10.6, using $DA_{d_0}(0) = \mathsf{H}_{d_0}$ and the vanishing of the gradient of $\mathscr{S}_\varepsilon$ at 0, we obtain

$$D^2 E_{d_0}(I) = \mathsf{H}^\sharp_{d_0} d^*_\varepsilon d_\varepsilon \mathsf{H}_{d_0}. \tag{10.22}$$

We show that this is the effective Maxwell quadratic form of Theorem 8.3, which is defined with the linearization of $T^{d_0}_M$ rather than with the gauge-corrected average. Let $\ell(a)$ be the derivative at $a = 0$ of $\operatorname{Log} T^{d_0}_M e^{\varepsilon a}$, and let $\gamma(a)$ be the derivative at $a = 0$ of $\operatorname{Log} G_{d_0}(a)$, a field on the coarse vertices. For a coarse vertex field κ we write $(\nabla^{\mathrm{c}}\kappa)_{(r,s)} = \kappa_s - \kappa_r$. Linearizing (10.11) at $j = d_0$ and (10.14), we obtain, for fine fields a and fine scalar fields λ,

$$\mathsf{Q}_{d_0} a = \ell(a) - \nabla^{\mathrm{c}}\gamma(a), \qquad \ell(\nabla_\varepsilon \lambda) = \nabla^{\mathrm{c}}(\lambda|_{\mathrm{roots}}).$$

Thus the linearized block average and Q_{d_0} differ by a coarse gradient, and a fine gradient changes the linearized block average by a coarse gradient and has zero curl. Let a have $\ell(a) = \eta$. Linearizing the gauge slice of Theorem 9.9 with prescribed coarse datum zero, we obtain a fine scalar field λ such that $a' = a - \nabla_\varepsilon \lambda$ has $\mathsf{P}^{\mathrm{div}}_{d_0} \operatorname{div}_\varepsilon a' = 0$ and $\gamma(a') + \lambda|_{\mathrm{roots}} = 0$. Then $d_\varepsilon a' = d_\varepsilon a$ and $\mathsf{Q}_{d_0} a' = \eta - \nabla^{\mathrm{c}}(\lambda|_{\mathrm{roots}}) - \nabla^{\mathrm{c}}\gamma(a') = \eta$. Conversely, let a' have $\mathsf{Q}_{d_0} a' = \eta$, and let λ' be a fine scalar field with $\lambda'|_{\mathrm{roots}} = \gamma(a')$, for instance the linearization of the cardinal extension of Lemma 10.8. Then $a'' = a' - \nabla_\varepsilon \lambda'$ has $d_\varepsilon a'' = d_\varepsilon a'$ and $\ell(a'') = \eta$. We conclude that the minimum of $\|d_\varepsilon a\|^2_\varepsilon$ over the fields with $\ell(a) = \eta$ equals its minimum over the fields with $\mathsf{Q}_{d_0} a = \eta$ and $\mathsf{P}^{\mathrm{div}}_{d_0} \operatorname{div}_\varepsilon a = 0$. Every field of the latter kind is $\mathsf{H}_{d_0}\eta + v$ with $v \in \mathcal{V}_{d_0}$, and the minimizing property of H_{d_0} shows that the minimum equals the right side of (10.22) evaluated at η. This identifies $D^2 E_{d_0}(I)$ with the effective Maxwell quadratic form of Theorem 8.3, including its gauge and constant null directions. The function $W_{d_0,g}(B) = g^{-2} E_{d_0}(e^{gB})$ has the same Hessian at $B = 0$, since the two factors g from the derivatives cancel g^{-2}.

Step 2: the constrained Hessian at the identity. We apply the statement of Theorem 8.3 about the next constrained fluctuation space, with the lattice of side Mm as the coarse lat-

tice of that theorem, the next lattice of side m, depth d_0, and the embedding $E_0 = D_z\Gamma_I(0)$ of Lemma 6.5, which equals E_f because $U_0(I) = I$. That theorem gives $m_0, C_0, a_0 > 0$, independent of d_0 and m, for the lower bound, the upper bound, and the weighted bounds on $K^0_{d_0}$ and on its inverse. The inverse is asserted only on the next constrained fluctuation space, on which the vanishing of the linearized next average removes the constant fluctuation. If distances are measured in the coarse units of the lattice of side m rather than in those of the lattice of side Mm, they are divided by M, and we decrease the exponent once. This proves part (1).

Step 3: the Hessian away from the identity. We write $t = \operatorname{Log} c$, $H_0 = D^2E_{d_0}(I)$, and $B = B(c, z)$. The Hessian in the coordinates z is

$$D^2_z F_{d_0} = (D_z B)^T D^2 E_{d_0}(B) D_z B + DE_{d_0}(B) D^2_z B. \tag{10.23}$$

By the bounds on the third derivatives and on the gradient in Theorem 10.6, we have

$$\|D^2E_{d_0}(B) - H_0\|_{a,\mathrm{row+col}} \le K\|B\|_\infty, \qquad \|DE_{d_0}(B)\|_\infty \le K\|B\|_\infty.$$

For the second term in (10.23), we fix a free coordinate and use the column of $D^2_z B$ with this input fixed; the remaining input and the output are summed against the bound on the components of $DE_{d_0}(B)$. This term is $O(\|B\|_\infty)$ in both the row and the column norm. For the first term we expand around $\mathsf{E}_\mathrm{f}^T H_0 \mathsf{E}_\mathrm{f}$, using the bound on $D_z B - \mathsf{E}_\mathrm{f}$ in Lemma 10.9 and the displayed bound on $D^2E_{d_0}(B) - H_0$. Using the contraction rule of Lemma 5.3 and $\|B\|_\infty \le K(\|t\|_\infty + \|z\|_\infty)$, we obtain

$$\|D^2_z F_{d_0} - K^0_{d_0}\|_{a,\mathrm{row+col}} \le K(\|t\|_\infty + \|z\|_\infty). \tag{10.24}$$

Every sum here has one index fixed; no sum of $|DE_{d_0}|$ over all links, and no factor of the volume, occurs.

Step 4: the radii. We take a complex radius for the coordinates of Lemma 10.9 that leaves fixed margins for four requirements: the relative logarithms, the solution of the constraints, the positivity of the real density, and the larger domain of E_{d_0}. Let C_inv bound the weighted norm of the inverse of $K^0_{d_0}$. Fix $r_z > 0$ so small that the entire product lies inside these domains and

$$2Kr_z \le m_0/2, \qquad 2C_\mathrm{inv} K r_z \le 1/2.$$

Next we take $r_c \le r_z$ inside the domains for the coarse field. Since the weighted bound (10.24) also bounds the Euclidean operator norm, the real Hessian is at least $m_0 I/2$ on the entire product. This proves part (2). The radii use only the bounds on the fixed larger domains of Theorem 10.6, which do not depend on d_0, and not a recursively reduced domain of E_{d_0}; the same radii work for every d_0.

Step 5: the conditional constrained minimizer. At $t = 0$ and $z = 0$ the gradient in z vanishes. Integrating its mixed derivative in the coarse field, we obtain $\|D_z F_{d_0}(c, 0)\|_\infty \leq K_1 \|t\|_\infty$. The equation for the minimizer is the fixed point equation

$$z = -(K^0_{d_0})^{-1}\big[D_z F_{d_0}(c, z) - K^0_{d_0} z\big].$$

By (10.24), the right side has Lipschitz constant at most $1/2$ on the complex ball of radius r_z. If we reduce r_c so that $2C_{\mathrm{inv}} K_1 r_c < r_z/8$, the right side maps this ball strictly into itself, and its fixed point satisfies

$$\|z^*_{d_0}(c)\|_\infty \leq 2C_{\mathrm{inv}} K_1 \|t\|_\infty < r_z/8.$$

Using iteration and the convergent majorant series of Lemma 5.3, we obtain the holomorphy on the complex ball of coarse fields and the bounds on the derivative tensors of every fixed order. For the rows we use the rows of $(K^0_{d_0})^{-1}$, of the derivatives of E_{d_0} of each fixed order in Theorem 10.6, and of the derivatives of B. For the columns we follow the fixed input through the weighted inverse and the mixed derivatives of $D_z F_{d_0}$. Since the derivative tensors of the action and of B have both row and column bounds, the same implicit-series argument applies. The rates obtained depend on the order through the rates a_s of Theorem 10.6. We take $r'_c = r_c/2$, where r_c denotes its final value after the reductions in this step and in Step 7. The implicit-series clause of Lemma 5.3 includes the translation to backgrounds in such a fixed smaller ball, so the coefficient bounds of each fixed order hold on $\|\theta\|_\infty < r'_c$. This proves part (4). Strict convexity in the real variables shows that this interior critical point is the unique minimum on the closed real ball $\|z\|_\infty \leq r_z$.

Step 6: the nested minimizer is critical on the longer fiber. We now identify the minimum with the effective classical action of depth $d_0 + 1$. Let $b_* = b(c, z^*_{d_0}(c))$, so that $\|\mathrm{Log}\, b_*\|_\infty \leq K\|t\|_\infty$. For coarse fields b near b_*, let $s_{d_0}(b)$ be the representative of part (1) of Lemma 10.8: it lies in the gauge orbit of the background field of depth d_0, it depends analytically on b, its rescaled connection is small in C^1_ε, and $T^{d_0}_M s_{d_0}(b) = b$. Its action is $E_{d_0}(b)$. The fine configuration $U_* = s_{d_0}(b_*)$ satisfies

$$T^{d_0}_M U_* = b_*, \qquad T^{d_0+1}_M U_* = c.$$

Let $\dot U$ be a tangent vector at U_* to the fiber $\{T^{d_0+1}_M U = c\}$, and let $\dot b = D(T^{d_0}_M)\dot U$; then $DT_M\, \dot b = 0$. The vector $\dot U - Ds_{d_0}(b_*)\dot b$ is tangent to the fiber $\{T^{d_0}_M U = b_*\}$. By part (6) of Theorem 10.6, the first variation of the action in this direction vanishes. Indeed, U_* is of the form considered there: it is obtained from the background field with coarse field b_* by the cardinal extension of Step 3 of the proof of Lemma 10.8, whose values at the coarse vertices are $G_{d_0}(A_{d_0}(\mathrm{Log}\, b_*))$. The remaining first variation, in the direction $Ds_{d_0}(b_*)\dot b$, equals $DE_{d_0}(b_*)\dot b$, in the coarse units of the lattice of side Mm, since the action

on the analytic family s_{d_0} equals E_{d_0}. Since $b_* = b(c, z^*_{d_0})$ is already in block axial gauge, the fixed transport in part (3) of Lemma 10.9 is the identity. That part then shows that $\dot b$ is the sum of a tangent vector $D_z b(c, z^*_{d_0})\dot z$ of the free coordinates and of a tangent vector of gauge transformations along the block trees that are the identity at the coarse vertices. The first is annihilated by $D_z F_{d_0}(c, z^*_{d_0}) = 0$, and the second by the infinitesimal gauge-invariance identities of Lemma 10.8. This shows that U_* is critical on the fiber $\{T_M^{d_0+1} U = c\}$.

Step 7: identification with the background field of depth $d_0 + 1$. In the coarse units of the lattice of side m, the same fine lattice has mesh ε/M, where $\varepsilon = M^{-d_0}$. By item (4) of the normalizations in Section 10.1, the rescaled connection of U_* is multiplied by M and its first differences by M^2, so its $C^1_{\varepsilon/M}$ norm is at most $K_M \|t\|_\infty$. We decrease r_c once more so that $K_M r_c < r_{\mathrm{tr}}$ and $r_c < r_{\mathrm{tr}}$, the radius of Lemma 10.7. That lemma, at depth $d_0 + 1$, shows that U_* lies in the gauge orbit of the background field of depth $d_0 + 1$ with coarse field c, and that $\mathscr{S}_{\varepsilon/M}(U_*) = E_{d_0+1}(c)$.

Step 8: the change of units. By item (4) of the normalizations, we have $\mathscr{S}_{\varepsilon/M} = M \mathscr{S}_\varepsilon$ for the same fine configuration, and therefore

$$E_{d_0+1}(c) = \mathscr{S}_{\varepsilon/M}(U_*) = M \mathscr{S}_\varepsilon(U_*) = M E_{d_0}(b_*) = M \min_{\|z\|_\infty \le r_z} F_{d_0}(c, z).$$

This proves part (3) on the real ball of coarse fields. The value $M F_{d_0}(c, z^*_{d_0}(c))$ at the holomorphic minimizer and the effective classical action $E_{d_0+1}(c)$ are both holomorphic, and their difference has vanishing real Taylor coefficients on a real open ball. Its convergent complex Taylor series therefore vanishes as well, which proves the first statement of part (5). The second statement follows by dividing by $g_+^2 = M g^2$.

Step 9: the Hessian with the density. Let c and y be real. Under $gp < r_z/4$ we have $\|z^*_{d_0} + gy\|_\infty < 3r_z/8$. Two derivatives in y cancel the prefactor g^{-2} of the classical part, while two derivatives of the logarithm of the density give $g^2 D_z^2 \log \mathcal{J}_c$. By part (2) and Lemma 10.9, the Hessian of the function in part (6) is

$$D_z^2 F_{d_0}(c, z^*_{d_0} + gy) - g^2 D_z^2 \log \mathcal{J}_c(z^*_{d_0} + gy) \ge \tfrac{1}{2} m_0 I - K_M g^2 I.$$

Taking $g_* \le 1$ with $K_M g_*^2 \le m_0/4$, we obtain part (6) on the entire convex product. All the choices above have the dependence stated in Section 10.1. □

10.8 Analytic estimates at intermediate scales

The last theorem collects the factorial bounds proved so far and extends them to the block averages of the background field at every intermediate scale and to their curvature. At

the intermediate scales we use the gauge-corrected averages of (10.9) as representatives; they differ from the iterates of T_M by the explicit gauge transformations G_j of (10.11). As in Section 10.3, $\epsilon_j = \varepsilon_{d,j} = M^{j-d}$.

Theorem 10.11. *There exist $r_*, a_*, C_* > 0$ such that the following hold for every $d \geq 0$, $n \geq 4$, $0 \leq j \leq d$, and every real or complex coarse field θ with $\|\theta\|_\infty < r_*$. All connecting lengths are measured in coarse lattice units.*

1. *For $s \geq 2$,*
$$\|D_\theta^s E_d(e^\theta)\|_{a_*,\mathrm{root}} \leq C_*^{s+1} s!, \qquad \|DE_d(e^\theta)\|_\infty \leq C_* \|\theta\|_\infty.$$
2. *Put $\varepsilon_{d,j} = M^{j-d}$, and let $A_{d,j}(\theta)$ be the j-th iterate of* (10.9) *started at $A_{d,0}(\theta) = A_d(\theta)$. Then $e^{\varepsilon_{d,j} A_{d,j}(\theta)}$ is a representative of the gauge orbit of $T_M^j(e^{\varepsilon_d A_d(\theta)})$, related to it by the gauge transformation G_j of* (10.11)*, and for every $s \geq 1$,*
$$\|D_\theta^s(A_{d,j}, \nabla_{\varepsilon_{d,j}} A_{d,j})\|_{a_*,\mathrm{out}} + \|D_\theta^s(A_{d,j}, \nabla_{\varepsilon_{d,j}} A_{d,j})\|_{a_*,\mathrm{input};\varepsilon_{d,j}^3} \leq C_*^{s+1} s!.$$
In the second norm one coarse input is fixed, and the intermediate outputs and the remaining inputs are summed, with the output measure $\varepsilon_{d,j}^3$.
3. *For the coarse correction D_d we use the counting input columns $\|\cdot\|_{a_*,\mathrm{input,count}}$ of Lemma 10.4; multiplying them by ε_d^{-3} gives the volume-normalized columns. Then*
$$\|D_w^s \mathsf{D}_d\|_{a_*,\mathrm{out}} \leq C_*^s s!, \qquad \|D_w^s \mathsf{D}_d\|_{a_*,\mathrm{input,count}} \leq \varepsilon_d^3 C_*^s s! \quad (s \geq 2),$$
and, on a fixed smaller ball of fine fields w, the first derivative satisfies the corresponding bounds $C_*\|w\|_\infty$ and $\varepsilon_d^3 C_* \|w\|_\infty$.
4. *For a plaquette f of the lattice of mesh $\varepsilon_{d,j}$ put*
$$\mathcal{F}_{d,j,f}(\theta) = \varepsilon_{d,j}^{-2} \operatorname{Log}\big[(e^{\varepsilon_{d,j} A_{d,j}(\theta)})_f\big].$$
It vanishes at $\theta = 0$, and it satisfies the bound of (2) for every $s \geq 1$: the sum of its output row and its volume-normalized input column with output measure $\varepsilon_{d,j}^3$ is at most $C_*^{s+1} s!$. The underlying local fact is that the function
$$\varepsilon^{-2} \operatorname{Log}\big(e^{\varepsilon a} e^{\varepsilon b + \varepsilon^2 v} e^{-\varepsilon a - \varepsilon^2 u} e^{-\varepsilon b}\big)$$
of independent variables (a, b, u, v) in a small ball extends holomorphically to $\varepsilon = 0$, with value $v - u + [a, b]$ there, uniformly for $0 \leq \varepsilon \leq 1$.
5. *In the coupling-rescaled variables $\theta = g_+ B$, with $g_j = \sqrt{\varepsilon_{d,j}}\, g_+$, let*
$$X_1(B) = \varepsilon_{d,j} A_{d,j}(g_+ B)/g_j, \qquad X_2(B) = \operatorname{Log}\big[(e^{\varepsilon_{d,j} A_{d,j}(g_+ B)})_f\big]/g_j$$

be the normalized connection and curvature. Then, for every $s \geq 1$,

$$\|D_B^s X_1\|_{a_*,\mathrm{out}} + \|D_B^s X_1\|_{a_*,\mathrm{input};\varepsilon_{d,j}^3} \leq C_*^{s+1} s!\, \sqrt{\varepsilon_{d,j}}\, g_+^{s-1},$$
$$\|D_B^s X_2\|_{a_*,\mathrm{out}} + \|D_B^s X_2\|_{a_*,\mathrm{input};\varepsilon_{d,j}^3} \leq C_*^{s+1} s!\, \varepsilon_{d,j}^{3/2} g_+^{s-1}.$$

The columns use the output measure $\varepsilon_{d,j}^3$, as in (2).

If the connecting lengths are replaced by the lengths of spanning trees on the external indices, the bounds hold with a_* replaced by $a_*/2$. No reduction of the rate or of the radius depends on the order s.

The bounds in (2)–(5) concern the representatives $e^{\varepsilon_{d,j} A_{d,j}}$ on the stated domain of fields and first differences; in other gauges the iterates $T_M^j(e^{\varepsilon_d A_d(\theta)})$ need not satisfy them.

Proof of Theorem 10.11. Parts (1) and (3), and part (2) at $j = 0$, follow from the earlier coefficient bounds (10.20), (10.17), (10.18), and (10.10). It remains to prove the estimates at intermediate scales and for the curvature. We first construct a map on independent field and difference variables that describes one averaging step (Step 1). We check its mesh powers (Step 2) and its domain (Step 3), apply Lemma 10.3 (Step 4), compose with the background field (Step 5), treat the curvature (Steps 6 and 7), and collect the constants (Step 8). For $d = 0$ only $j = 0$ occurs, so let $d \geq 1$.

Step 1: one step on field and difference variables. We consider one step at mesh $\epsilon \leq 1/M$. A shift of the coarser lattice by one coarse spacing $M\epsilon$ is a shift of the fine lattice by M sites, and it preserves the centered partition and every ordered path in (10.9). Let $S_{M,\mu}$ be this shift of the fine lattice and S'_μ the shift by one spacing of the coarser lattice, in direction μ. Then

$$S'_\mu \Psi_\epsilon(A) = \Psi_\epsilon(S_{M,\mu} A),$$

also at periodic seams. For a triple $G = (G_\mu)$ of fine fields, we define

$$(T_\mu G_\mu)_i(x) = M^{-1} \sum_{l=0}^{M-1} G_{i,\mu}(x + l\epsilon e_\mu).$$

This average of shifts on the fine lattice has counting row and column mass one. If $G = \nabla_\epsilon A$, telescoping gives $S_{M,\mu} A - A = M\epsilon\, T_\mu G_\mu$, and by the fundamental theorem of calculus in finitely many variables we have

$$\nabla_{M\epsilon,\mu} \Psi_\epsilon(A) = \int_0^1 D\Psi_\epsilon\big(A + tM\epsilon\, T_\mu G_\mu\big)\,[T_\mu G_\mu]\, dt. \tag{10.25}$$

We define the right side for independent (A, G) and let $\mathcal{P}_\epsilon$ be the map whose outputs are $\Psi_\epsilon(A)$ and these three expressions. It is holomorphic on a common small ball of

(A, G): since $M\epsilon \leq 1$, the auxiliary arguments $A + tM\epsilon T_\mu G_\mu$ stay in the domain of the local expressions. By (10.25), on the fields with $G = \nabla_\epsilon A$ its outputs are the next pair $(\Psi_\epsilon(A), \nabla_{M\epsilon}\Psi_\epsilon(A))$.

The linear part of $\mathcal{P}_\epsilon$ at zero is

$$\operatorname{diag}(Q, QT_1, QT_2, QT_3),$$

with Q from (10.12). For each of the four component types, its row mass is 1 and its counting column mass is M^{-3}; for the latter, we sum first over the outputs of Q, whose column mass is M^{-3}, and then use the column mass one of T_μ. We keep the four component types as separate labels, so that no factor comparing norms of different components enters at any scale.

Step 2: the mesh powers. We record the powers of the mesh in the nonlinear part, rather than differentiating a bound on values. With the fixed local expression P of the proof of Lemma 10.4, the integrand in (10.25) is

$$M^{-1}DP\big(\epsilon A + tM\epsilon^2 T_\mu G_\mu\big)[T_\mu G_\mu]. \tag{10.26}$$

The constant coefficient $DP(0)$ contributes the linear term $QT_\mu G_\mu$, and every other term contains ϵA or $M\epsilon^2 T_\mu G_\mu$. On a ball $\|A\|_\infty \leq a$, $\|G\|_\infty \leq b$, the nonlinear part is bounded by $K_M(\epsilon ab + \epsilon^2 b^2)$, with first derivatives $O_M(\epsilon b)$ in A and $O_M(\epsilon a + \epsilon^2 b)$ in G. We consider a derivative of order s of the integrand, with p derivatives in A and q in G. If $q \geq 1$ and one of the derivatives in G falls on the external factor $T_\mu G_\mu$, the explicit factor is $\epsilon^p (M\epsilon^2)^{q-1}$. If none falls on it, the factor is $\epsilon^p (M\epsilon^2)^q$ times an undifferentiated G. When $p = 0$ and $q = 1$, the contribution from $DP(0)$ is the linear operator separated above; the remaining terms contain ϵA or $M\epsilon^2 T_\mu G_\mu$. When $q = 0$ and $p \geq 2$, the factor is ϵ^p times G. For the field output the factor at order s is ϵ^{s-1}/M. Using Cauchy estimates in finitely many variables on the fixed polydisc, we obtain, for $s \geq 2$,

$$\begin{aligned} &\|D\mathcal{P}_\epsilon\|_{\text{out}} \leq 1 + K_M\epsilon(a+b), \quad &&\|D\mathcal{P}_\epsilon\|_{\text{input,count}} \leq M^{-3}[1 + K_M\epsilon(a+b)], \\ &\|D^s\mathcal{P}_\epsilon\|_{\text{out}} \leq s!K_M^s\epsilon, &&\|D^s\mathcal{P}_\epsilon\|_{\text{input,count}} \leq M^{-3}s!K_M^s\epsilon. \end{aligned} \tag{10.27}$$

For the columns, the nonlinear terms have a fixed enlarged stencil of inputs, which includes the M shifts in T_μ. A fixed input lies in at most q''_M such stencils; this count enters as a factor only in the nonlinear part, while the linear masses are those computed in Step 1. Integration in t preserves all the bounds.

Step 3: a common domain under iteration. Let u_j be the maximum of the norms of the field and difference variables after j steps. By the bound on the field in Step 3 of the proof of Lemma 10.4 and the bound on the nonlinear part of the difference outputs in Step 2, we have $u_{j+1} \leq u_j + K_M\epsilon_j u_j^2$, after enlarging K_M. As in Lemma 10.3, with

$\sum_j \epsilon_j < 1/(M-1)$, the radius stays below twice its initial value if that value is small enough. On the fields with $G = \nabla_\epsilon A$, the argument $A + tM\epsilon T_\mu G_\mu$ in (10.25) is a convex combination of A and its shift. This shows directly that the difference variables after step $j+1$ have norm at most $(1 + K_M\epsilon_j \|A_j\|_\infty)$ times their norm after step j. This common domain justifies treating A and G as independent variables in (10.27).

Step 4: composition of the steps. By Steps 2 and 3, the maps $\mathcal{P}_{\epsilon_j}$ satisfy the hypotheses of Lemma 10.3, with the nonlinear coefficient ϵ_j and the linear column factor M^{-3} as before. The labels consist of a link and one of the four component types, and the joint radius takes the place of R. Each output depends only on inputs within distance $K_M\epsilon_j$. Applying the lemma, we obtain, for the composition of j steps,

$$R_s(j) \le K^{s+1}s!, \qquad C_s(j) \le (\epsilon_0/\epsilon_j)^3 K^{s+1}s!, \tag{10.28}$$

where $R_s(j)$ and $C_s(j)$ are the output row and the counting input column of the derivative of order s. This holds for all orders and all $0 \le j \le d$. Since the enlarged stencils have total radius at most $K_M\epsilon_j$, a nonzero tensor has connecting length at most $K_M s\epsilon_j$, and a fixed spatial weight only changes K^s.

Step 5: composition with the background field. We start the recursion from the pair $(A_d(\theta), \nabla_{\epsilon_0} A_d(\theta))$. Its value is $O(\|\theta\|_\infty)$, and it has the majorant (10.17). We take the radius of θ so small that this pair lies strictly inside the common domain of Step 3. Composing the two majorant series, we obtain factorial output rows at one fixed smaller radius and one rate. For a column with a coarse input fixed, we follow the branch of the composition containing that input. The initial tensor has counting column $O(\epsilon_0^{-3})$, by (10.18), and the composed map has counting column $O((\epsilon_0/\epsilon_j)^3)$ by (10.28); their product is $O(\epsilon_j^{-3})$, and all other branches use output rows. The output measure ϵ_j^3 cancels the factor ϵ_j^{-3}. By the contraction rule of Lemma 5.3, the same bound holds for every fixed coarse input. The field outputs of the composition are the fields $A_{d,j}(\theta)$ of part (2), and their gauge transformation is the G_j of (10.11), evaluated at the initial field $A_d(\theta)$. These fields represent the gauge orbits of $T_M^j(e^{\epsilon_d A_d(\theta)})$, including for $j = 0$ and $j = d$. For complex θ the gauge transformations are the analytic continuations of these path products, with values in $\mathrm{SL}(2,\mathbb{C})$; for real θ they are unitary. This proves part (2).

Step 6: the local curvature formula. It remains to treat the curvature and its factor ϵ^{-2}. At a plaquette in the directions μ, ν based at x, let

$$a = A_\mu(x), \qquad b = A_\nu(x), \qquad u = \nabla_{\epsilon,\nu} A_\mu(x), \qquad v = \nabla_{\epsilon,\mu} A_\nu(x).$$

The plaquette variable is

$$P_\epsilon = e^{\epsilon a} e^{\epsilon b + \epsilon^2 v} e^{-\epsilon a - \epsilon^2 u} e^{-\epsilon b}.$$

We treat a, b, u, v as independent and fix a small complex ball of these variables on which this product has a logarithm for all complex $|\epsilon| \le 2$. The constant and the linear terms in ϵ of $P_\epsilon - I$ vanish identically. Expanding the four factors to second order, we obtain

$$\operatorname{Log} P_\epsilon = \epsilon^2 (v - u + [a, b]) + O(\epsilon^3).$$

The quotient $\epsilon^{-2} \operatorname{Log} P_\epsilon$ therefore has a removable singularity at $\epsilon = 0$, with the value stated in part (4). Cauchy's formula on the disc $|\epsilon| \le 2$, or the Taylor series beginning at degree two, bounds the quotient uniformly for $|\epsilon| \le 1$. Cauchy's formula in the finitely many variables (a, b, u, v) on a strictly smaller ball then bounds its coefficients by $K^{s+1} s!$, uniformly for $0 \le \epsilon \le 1$. This division by ϵ^2 uses no second difference of the field.

Step 7: composition with the intermediate pair. We compose this local quotient with the majorant of Step 5 for the intermediate pair. Each plaquette involves a fixed number of field and difference entries, at distance $O(\epsilon_j)$, and each entry occurs in a fixed number of plaquettes. The composition rule gives the factorial row for the curvature. With a coarse input fixed, the branch containing it uses the volume-normalized column of the pair, with the factor ϵ_j^3, and the other branches use rows. Hence the plaquette output has the same volume-normalized column, with no inverse power of the mesh. Its value at $\theta = 0$ is zero, because all fields and differences vanish there. This proves part (4).

Step 8: constants and coupling-rescaled variables. We take a_* smaller than the finitely many rates used for the extension H_d, the Green operator, the correction, the background field, the envelope formula for the action, and the passage from rows to columns. We take r_* inside all the finitely many common balls, and we increase C_* to dominate their constants and the fixed counts of incidences and comparisons of norms. These choices are independent of d, n, and j. With them, parts (1) and (3) are (10.20), the bound $\|\nabla_\theta E_d\|_\infty \le K \|\theta\|_\infty$ of the proof of Theorem 10.6, and (10.10). Since $\epsilon_j = \varepsilon_{d,j}$ and $g_j = \sqrt{\epsilon_j}\, g_+$,

$$\frac{\epsilon_j A_{d,j}(g_+ B)}{g_j} = \sqrt{\epsilon_j}\, g_+^{-1} A_{d,j}(g_+ B), \qquad \frac{\operatorname{Log}[(e^{\epsilon_j A_{d,j}(g_+ B)})_f]}{g_j} = \epsilon_j^{3/2} g_+^{-1} \mathcal{F}_{d,j,f}(g_+ B).$$

Each of the s derivatives in B produces a factor g_+, which gives the powers g_+^{s-1} in part (5), with the same row and column conventions. Finally, by Lemma 5.3, the length of a spanning tree on the external indices is at most twice the connecting length, and replacing a_* by $a_*/2$ proves the last assertion. □

SECTION 11

Classical continuum limits and contraction estimates

This section proves four deterministic properties of the effective classical actions E_d and of the classical background fields constructed in Section 10. They are the classical inputs to the fluctuation integration in Part IV and to the large-field analysis in Part VI.

1. Section 11.2 fixes the coarse lattice and the coarse field and lets the number d of averaging steps tend to infinity, so that the fine lattice spacing M^{-d} tends to zero. We prove that a summably corrected version of E_d is nondecreasing in d, that E_d converges, that E_d is bounded below by a fixed multiple of the Wilson action, and that, at a fixed coarse lattice, E_d converges in the weighted analytic coefficient norm. We also prove that the reconstruction maps through finitely many averaging steps converge, together with all the matrices and densities entering them. This is Theorem 11.2; it is used in Sections 14, 15, and 22.
2. Section 11.3 proves that two small representatives of the same periodic gauge orbit have the same effective classical action, even when the gauge transformation relating them has no small logarithm. This implies that E_d extends to a real analytic function on the gauge-invariant small-field domain D_ρ (Theorem 11.6). This is used in Sections 13, 14, and 19.
3. Section 11.4 constructs, for one renormalization group step of J averaging steps, a representative of the gauge orbit of the classical background field that satisfies the block averaging constraint exactly and whose potential and first differences have coefficient bounds uniform in J. For each fixed J it identifies this representative, after an explicit gauge transformation, with the zero-fluctuation reconstruction (Lemma 11.9). This is used in Sections 13, 15, 23, and 31.
4. Section 11.5 proves that evaluating an effective interaction R at the classical background field of one renormalization group step contracts its weighted analytic norm by a factor $O(M^{-J})$, at the same analytic radius and the same spatial decay rate, provided that R is invariant under lattice translations, constant gauge transformations, spatial inversion, and infinitesimal gauge transformations (Theorem 11.10). This contraction allows us to choose J in Theorem 13.5.

The inputs are the results of Section 10 on the classical background field, its symmetries, the nested minimization identity for E_d, and its derivative estimates (Theorems 10.6, 10.10, and 10.11 and Lemma 10.8); the gauge slice with prescribed coarse gauge of Theorem 9.9;

the finite-torus estimate for gauge-invariant quadratic forms of Lemma 8.6; and the one-step energy estimate of Theorem 7.3 and Lemma 7.2.

The classical background fields are constrained minimizers in the sense of Bałaban's variational construction [16, Theorem 1, p. 279], which rests on his averaging operations and gauge-fixing conditions [12, 14]. The constraints, coordinate domains, and coefficient norms used here are those of Sections 9 and 10, and the results of this section are proved here.

11.1 Setting and conventions

Units and norms. Fix an odd integer $M \geq 3$. Throughout this section we measure lengths in units of the coarse lattice, which has integer side $n \geq 4$ (or $m \geq 4$ when we consider one renormalization group step) and spacing one. For $d \geq 0$ the fine lattice has side nM^d and spacing

$$\varepsilon_d = M^{-d}$$

in these units; its physical spacing on the torus $\mathbb{T}_L^3$ is $a_n \varepsilon_d$. For a configuration $U = e^{\varepsilon A}$ on a lattice of spacing ε we write

$$\mathscr{S}_\varepsilon(U) = 4\varepsilon^{-1} \sum_p q(U_p), \qquad \|A\|_{C^1_\varepsilon} = \|A\|_\infty + \|\nabla_\varepsilon A\|_\infty,$$

where ∇_ε is the collection of all componentwise forward differences divided by ε, as in Definition 10.1. We also write $\mathscr{S}_\varepsilon(A)$ for $\mathscr{S}_\varepsilon(e^{\varepsilon A})$. All spatial statements in this section concern complete periodic tori. In analytic coefficient norms, a and b denote spatial decay rates. We use ε_d, t, δ, and δ_l for dimensionless lattice spacings and a_n for the physical coarse spacing.

Tensor norms, their Taylor factorials, and their volume normalizations are those of Definition 4.6. For a derivative tensor of a scalar function, $\|\cdot\|_{a,\mathrm{root}}$ denotes the coefficient bound with each external index fixed in turn: it fixes any one index and sums the absolute values of the coefficients over the other indices, with weight $e^{a\mathrm{t}}$, where t is the length of a shortest network connecting the locations of all indices (internal vertices allowed). Let F be an analytic field of a coarse variable θ, with values in the link variables of a lattice of spacing ε, and let $v = \varepsilon^3$. The output-row norm $\|D_\theta^s F\|_{b,\mathrm{out}}$ fixes one output index and sums the absolute values of the coefficients over all coarse input indices, with weight $e^{b\mathrm{t}}$. The volume-normalized column norm $\|D_\theta^s F\|_{b,\mathrm{input};v}$ fixes one coarse input index, sums over the output index and the remaining inputs with the same weight, and multiplies the result by the output volume v.

Constants. Unless stated otherwise, a constant in this section depends only on M and on the fixed larger domains, spatial decay rates, and coefficient bounds of Sections 9 and 10, with the dependence described in item (2) of Definition 4.14. Such a constant does not

depend on the coarse side, on the depth d, on the coarse field, on L, on γ, or on J. We identify explicitly the constants that may depend on J, on a finite lattice, or on a fixed number of averaging steps.

Real and complex arguments. Variational comparisons and lower bounds on Hessians are applied only at real coarse fields and real free coordinates. At complex arguments the effective classical action and the conditional constrained minimizers denote the holomorphic continuations of the critical values and critical points from real data, as in Theorems 10.6 and 10.10.

The effective classical action and the gauge orbit of the classical background field. We recall the objects of Section 10. For a small real coarse logarithm θ, Theorem 10.6 constructs the classical background field $A_d(\theta)$ on the lattice of spacing ε_d. It is the unique minimizer of $\mathscr{S}_{\varepsilon_d}$ among the fields whose gauge-corrected block average (see below) equals e^θ, in a convex coordinate domain inside the gauge slice $\mathsf{P}_d \operatorname{div}_{\varepsilon_d} A = 0$, where P_d is the projection of Theorem 9.9. The effective classical action is its value,

$$E_d(e^\theta) = \mathscr{S}_{\varepsilon_d}(A_d(\theta)), \qquad E_0 = S_W.$$

We distinguish three objects.

1. The value $E_d(c)$, a function of the coarse field c. It is the minimum on the locally unique branch constructed in Sections 9 and 10; it is not asserted to be the infimum of $\mathscr{S}_{\varepsilon_d}$ over the whole fiber $\{U : T_M^d U = c\}$.
2. The gauge orbit of the classical background field, that is, the orbit of $e^{\varepsilon_d A_d(\theta)}$ under periodic gauge transformations of the fine lattice. By gauge invariance of the Wilson action, every point of this orbit has action $E_d(e^\theta)$.
3. Representatives at the fine and intermediate resolutions. On the fine lattice, the slice representative $e^{\varepsilon_d A_d(\theta)}$ and the representative with $T_M^d U = e^\theta$ from Lemma 10.8 belong to the orbit in item (2). For each j, the field $e^{\varepsilon_{d,j} A_{d,j}(\theta)}$, with $\varepsilon_{d,j} = M^{j-d}$, represents the gauge orbit of $T_M^j(e^{\varepsilon_d A_d(\theta)})$ on its intermediate lattice, as in Theorem 10.11. The representative $C_{d_0,J}(\theta)$ and its orbit on the fine lattice of one renormalization group step are defined in Section 11.4.

We prove convergence of the values and of specified finite reconstruction maps. We do not prove convergence of the representatives in a fixed gauge as $d \to \infty$, and we do not identify a continuum variational problem.

Block averages and gauge-corrected block averages. Two maps from fine to coarse configurations appear below. The first is the iterated block averaging map T_M^d. The second is the gauge-corrected block average of Lemma 8.10, which at each averaging step multiplies the output of T_M by explicit vertex gauge factors at the coarse vertices. Let

$V_d(U)$ denote the gauge-corrected block average of a configuration U after d steps, and let $\mathsf{G}_d(U)$ denote the accumulated gauge transformation at the coarse vertices. Then

$$V_d(U) = \big(T_M^d U\big)^{\mathsf{G}_d(U)}, \tag{11.1}$$

for configurations in the domain of Lemma 8.10. This follows from the gauge covariance of T_M (Section 6), induction over the d steps, and the composition rule $(U^k)^l = U^{lk}$ of (4.1); for the representatives of Theorem 10.11 we verify it explicitly in (11.12) below. The classical background field is defined through V_d, but the block averaging constraint in the renormalization group is $T_M^d U = c$.

The gauge slice of Theorem 9.9 connects the two. Given a small field A on the lattice of spacing ε_d and a small prescribed coarse gauge logarithm ζ, it produces a gauge transformation e^λ such that A^{e^λ} satisfies $\mathsf{P}_d \operatorname{div}_{\varepsilon_d} A^{e^\lambda} = 0$ and

$$V_d\big(e^{\varepsilon_d A^{e^\lambda}}\big) = b^{e^\zeta}, \qquad b = T_M^d\big(e^{\varepsilon_d A}\big).$$

With prescribed coarse gauge logarithm $\zeta = 0$, the gauge-corrected block average of the transformed field is exactly the block average b of the original field. Since gauge transformations preserve the Wilson action, this converts a configuration U with $T_M^d U = b$ into a field in the gauge slice with gauge-corrected block average b and the same action. We use this in the comparison of Section 11.2, the transfer of criticality in Section 11.3, and the identification in Section 11.4. We also use that the transformed field has small potential and curl (Theorem 9.9). It therefore lies in the larger domain of Theorem 9.7, on which the background field is still the unique minimum (Theorem 10.6). We do not need an estimate on all first differences of the output.

Majorant series. For power series with nonnegative coefficients we write $P \preccurlyeq Q$ if every coefficient of P is at most the corresponding coefficient of Q. For an analytic field F of the coarse variable θ, a decay rate b, and an output volume v, we define

$$\begin{aligned} \mathscr{R}_b(F;u) &= \sum_{s\ge 1} \frac{u^s}{s!} \|D_\theta^s F(0)\|_{b,\mathrm{out}}, \\ \mathscr{C}_{b,v}(F;u) &= \sum_{s\ge 1} \frac{u^{s-1}}{(s-1)!} \|D_\theta^s F(0)\|_{b,\mathrm{input};v}. \end{aligned} \tag{11.2}$$

For a group-valued F, only $F - F(0)$ enters these series, so the identity matrix does not contribute to a series vanishing at $u = 0$. All comparisons of series below are coefficientwise comparisons of absolute tensor sums, not comparisons of values. The following lemma gives the counting rule for compositions of such series.

Lemma 11.1. *Let $k \geq 1$, let T be a symmetric k-linear map between finite-dimensional spaces, let F be holomorphic near $0 \in \mathbb{C}^D$ with $F(0) = 0$, and put $G(\theta) = T[F(\theta), \dots, F(\theta)]/k!$. For $s \geq 1$ and $h_1, \dots, h_s \in \mathbb{C}^D$,*

$$\frac{1}{s!} D^s G(0)[h_1, \dots, h_s] = \frac{1}{k!} \cdot \frac{1}{s!} \sum_{(S_1, \dots, S_k)} T\big[D^{|S_1|} F(0)[h_{S_1}], \dots, D^{|S_k|} F(0)[h_{S_k}]\big], \tag{11.3}$$

where the sum runs over the ordered partitions of $\{1, \dots, s\}$ into k nonempty sets and h_S is the list of the h_i with $i \in S$. For given sizes $s_1 + \cdots + s_k = s$ there are $s!/\prod_i s_i!$ such partitions.

Proof. Since $F(0) = 0$, inserting the Taylor series of F in each argument of T, we find that the homogeneous part of degree s of G at h is

$$\frac{1}{k!} \sum_{\substack{s_1 + \cdots + s_k = s \\ s_i \geq 1}} T\Big[\frac{D^{s_1} F(0)[h^{\otimes s_1}]}{s_1!}, \dots, \frac{D^{s_k} F(0)[h^{\otimes s_k}]}{s_k!}\Big].$$

The right side of (11.3) is symmetric in $h_1, \dots, h_s$, and at $h_1 = \cdots = h_s = h$ it equals this expression, because the partitions with sizes $(s_1, \dots, s_k)$ number $s!/\prod_i s_i!$. A symmetric multilinear form is determined by its values on the diagonal, which proves (11.3). □

We use Lemma 11.1 as follows. In (11.3), the factor $1/k!$ cancels the reorderings of the k slots of T. After division by $s!$, the partitions with sizes $(s_1, \dots, s_k)$ carry exactly the weights $\prod_i 1/s_i!$ of the Taylor coefficients of the arguments. Taking absolute values before summing over labels, we bound the absolute order-s coefficients of G, divided by $s!$, by the products of the absolute order-s_i coefficients of F, divided by $s_i!$, summed over $s_1 + \cdots + s_k = s$, with the weight $1/k!$ and no further factorial. This also holds when some labels coincide. Consider an absolute weighted sum over labels in which the vertex T contributes a factor τ and each argument contributes the coefficients of a series $f(u)$ with nonnegative coefficients. Then the series of G is dominated by $\tau f(u)^k/k!$. If one label is fixed, it lies in exactly one of the k groups, and a coefficient of order j containing the fixed label has denominator $(j-1)!$ rather than $j!$. Summing over the k choices replaces one factor f by its termwise derivative f', which gives $\tau f(u)^{k-1} f'(u)/(k-1)!$. Any external index may serve as the fixed one. The spatial weights are handled separately in each application: the network connecting the external indices of a composition is contained in the union of the networks of T and of the arguments, so the weight $e^{b\mathrm{t}}$ of the composition is at most the product of the weights of the factors.

11.2 Classical actions at a fixed coarse lattice

Theorem 11.2. *Fix an odd integer $M \geq 3$. There exist $r_{\mathrm{CK}}, a_0, C > 0$, depending only on M and the fixed domains, and in particular independent of the coarse side $n \geq 4$ and of $d \geq 0$, with the following properties.*

1. *Let $0 < r \le r_{\mathrm{CK}}$ and let $c = e^{\theta}$ be a real coarse field with $\|\theta\|_\infty < r$. Then, with both actions evaluated at the same coarse field on the same coarse lattice,*

$$E_d(c) \le (1 + CrM^{-2(d+1)})E_{d+1}(c) \qquad (d \ge 0).$$

Set $P_0 = 1$, $P_d = \prod_{\ell=0}^{d-1}(1 + CrM^{-2(\ell+1)})$, and $\kappa_* = P_\infty^{-1} > 0$. Then $P_d E_d(c)$ is nondecreasing in d, $0 \le E_d(c) \le Cn^3\|\theta\|_\infty^2$, the limit $E_\infty(c) = \lim_{d\to\infty} E_d(c)$ exists, and

$$E_d(c) \ge P_d^{-1}E_0(c) \ge \kappa_* E_0(c), \qquad E_\infty(c) \ge (P_d/P_\infty)E_d(c),$$
$$E_d(c) - E_\infty(c) \le C_M r M^{-2d} E_d(c).$$

In particular these inequalities apply to $c = U^k$ whenever U is a coarse configuration and k is a fixed periodic gauge transformation with U^k in the stated domain; the identification of the values for different choices of k is Theorem 11.6.

2. *For each fixed n, the whole sequence E_d converges locally uniformly and holomorphically on a common complex polydisc of coarse logarithms to a holomorphic function E_∞. For $0 < a \le a_0$ and every sufficiently small fixed $\rho > 0$ inside that polydisc,*

$$\mathcal{B}_{\rho,a}(E_d - E_\infty) \longrightarrow 0 \qquad (d \to \infty).$$

Every derivative of fixed order converges on strictly smaller neighborhoods. The radii, the coefficient bounds, and κ_* are chosen uniformly in n; the convergence modulus is asserted only at fixed n.

3. *Fix two lattices of sides $M^s m$ and m, with $1 \le s < \infty$, and fix the couplings. Consider the reconstruction maps through s averaging steps in the free logarithmic coordinates, built from E_{d+i}, $0 \le i < s$, as in Theorem 10.10. As $d \to \infty$ they converge, and so do the conditional constrained minimizers, the constrained Hessians, their positive square roots and inverse square roots, every Haar disintegration density, and the whole triangular reconstruction map. The convergence holds with every derivative of fixed order in the coarse and free variables, uniformly on every compact set of real coarse fields and real free coordinates that lies in the domains of Theorem 10.10 with a fixed strict margin, and on a complex neighborhood of each such set. On these fixed finite lattices it also holds in an absolute coefficient norm with a smaller radius. The constants and convergence moduli in this item may depend on the two lattices, on s, on the couplings, and on the margins.*

The proof uses two lemmas. The first controls one application of T_M; the second is a form of Montel's theorem with a statement about coefficient norms.

Lemma 11.3. *There exist $b_M > 0$ and $C_M < \infty$, depending only on M and on fixed margins of the identity chart of the logarithm, with the following properties. Let U be a configuration on a periodic lattice of side Mn, with $n \ge 4$, such that $\eta = \max_p \rho_G(U_p) \le b_M$. Then every based*

loop holonomy entering the definition of the plaquettes of $T_M U$ lies in a fixed strict identity chart of the logarithm, and

$$\sum_P q((T_M U)_P) \le M(1 + C_M \eta) \sum_p q(U_p). \tag{11.4}$$

If, in addition, the spacing of this lattice is $t \le M^{-1}$ in coarse units, $U = e^{tA}$, and $\|A\|_{C^1_t} \le R \le b_M$, then

$$T_M U = e^{MtB}, \qquad \|B\|_{C^1_{Mt}} \le C_M R, \qquad \max_p \rho_G(U_p) \le C_M t^2 (R + R^2). \tag{11.5}$$

All constants are independent of the spacing and of the side.

Proof. Let $b_M \le \min(\delta_*(M), \delta_M)$, where $\delta_*(M)$ and δ_M are the thresholds of Theorem 7.3 and Lemma 7.2, reduced further for the fixed margins of the logarithm if needed. Theorem 7.3, applied to the averaging step from side Mn to side n with maximal plaquette distance η, implies (11.4). The part of Lemma 7.2 that assumes only a bound on plaquette distances places every based loop holonomy in a fixed strict identity chart, without a bound on the link variables themselves. Its constants depend only on M and the fixed margins, and not on t, n, or any coupling.

For the bound on the potential, consider the averaging word (4.3) with every fine link variable written as e^{ta_e}. Its identity logarithm vanishes at $t = 0$ for all small a. Division by Mt is removable, since after expanding the absolutely convergent product and logarithm series, every nonconstant monomial contains at least one factor t. We obtain a local analytic function of the finitely many a_e, with first derivative bounded uniformly for $0 \le t \le M^{-1}$ and value zero at $a = 0$. Its value is bounded by $C_M R$. To compare the words at two neighboring coarse vertices, we translate every input edge by Mt. By telescoping M fine differences, each input changes by at most $Mt\|\nabla_t A\|_\infty$. Integrating the derivative of the local function along the segment between the two lists of inputs gives the bound on $\nabla_{Mt} B$ in (11.5). Finally, in a fine plaquette the linear sum of the four exponents tA is bounded by $Ct^2\|\nabla_t A\|_\infty$, and the remainder of the product series is at most $Ct^2\|A\|_\infty^2$. The logarithm series preserves this bound, which gives the last assertion of (11.5). □

Lemma 11.4. *Fix $D \ge 1$, and let (f_j) be holomorphic functions on a fixed open polydisc in $\mathbb{C}^D$, uniformly bounded on every strictly smaller closed polydisc.*

1. *Every sequence of the f_j has a subsequence converging locally uniformly to a holomorphic function, together with all derivatives of fixed order.*
2. *If (f_j) converges pointwise on a real open subpolydisc, then the whole sequence converges locally uniformly on the polydisc.*
3. *Under the convergence hypothesis of item (2), let f be the locally uniform limit. If also $\|D^k f_j(0)\|_{a,\mathrm{root}} \le C^{k+1} k!$ for all $k \ge 2$ and all j, then for $C\rho < 1$ we have $\mathcal{B}_{\rho,a}(f_j - f) \to 0$.*

Here D and the finite spatial weights are fixed; only the coefficient bound C may be uniform over a family of dimensions.

Proof. Consider a polydisc of radius R on which $|f_j| \le B_R$. By the iterated one-variable Cauchy integral for the Taylor coefficient c_α, we have $|c_\alpha| \le B_R R^{-|\alpha|}$. (The Cauchy formula follows by integrating the power series on a smaller circle, where it converges uniformly, and then enlarging the circle inside the domain of holomorphy.) Fix an increasing sequence of radii approaching the outer radius. By successive selection over the countably many multi-indices, the bounded complex coefficients have a common convergent subsequence. On a smaller radius $r < R$, the tails of the series are bounded uniformly by $B_R \sum_{k>K} \binom{D+k-1}{k} (r/R)^k$, which tends to zero as $K \to \infty$. This implies that the subsequence converges locally uniformly to the corresponding power series. Multiplying the coefficients by a fixed power of k keeps these tails summable, which gives the convergence of all derivatives of fixed order. This proves (1).

For (2), two subsequential limits agree on the real open subpolydisc. Fix all but one coordinate at real values there. A holomorphic function of one variable that vanishes on a real interval vanishes on its disc: if it had a first nonzero Taylor coefficient, factoring out the corresponding power would make its zeros isolated. Repeating this for each coordinate, we find that the two limits agree on a complex subpolydisc. By continuation along line segments through overlapping Taylor discs, they agree on the whole polydisc. Suppose that the whole sequence fails to converge uniformly on some compact subset. Then a subsequence stays at a fixed positive distance from any limit there. By (1), it has a further locally convergent subsequence, whose limit is the common limit just identified. This contradiction proves (2).

For (3), at fixed D, convergence of the finitely many entries of order k implies convergence of every absolute sum at that order with a fixed index, and the limit inherits the assumed bound. The term of order k in $\mathcal{B}_{\rho,a}(f_j - f)$ is therefore at most $2C^{k+1}k!\rho^{k-2}/k! \le 2C^3(C\rho)^{k-2}$. Its tail is a geometric series, uniformly in j, while every finite initial sum converges. This proves (3). For derivatives at other centers on a strictly smaller neighborhood, we use the Cauchy integrals about those centers on a larger compact neighborhood; by the uniform convergence just proved, these integrals converge uniformly. □

Proof of Theorem 11.2. The proof has four steps: the comparison of consecutive depths, the monotone limit and its consequences, the analytic convergence at fixed n, and the convergence of the finite reconstruction maps.

Step 1: comparison of consecutive depths. Let θ be real and lie in a ball of coarse logarithms inside the common domains of Theorems 10.6, 10.10, and 10.11 and Lemma 10.8

and of the gauge slice of Theorem 9.9. By Lemma 10.8, the gauge orbit of the classical background field of depth $d+1$ has a real representative

$$U = e^{tA^{\mathrm{ord}}}, \qquad t = M^{-(d+1)}, \qquad T_M^{d+1}U = c, \qquad \|A^{\mathrm{ord}}\|_{C^1_t} \le C\|\theta\|_\infty,$$

with action $\mathscr{S}_t(U) = E_{d+1}(c)$. Let $b = T_M U$, a configuration on the lattice of spacing $Mt = \varepsilon_d$. Since the fine side is $nM^{d+1} = M(nM^d)$, the map $U \mapsto b$ is one averaging step with integer coarse side $nM^d \ge 4$, and $T_M^d b = T_M^{d+1}U = c$. If $C\|\theta\|_\infty \le b_M$, which holds after reducing r_{CK}, then Lemma 11.3 implies that $b = e^{\varepsilon_d B}$ with $\|B\|_{C^1_{\varepsilon_d}} \le C_M\|\theta\|_\infty$. The divergence and the curl of B are also bounded by this number. Let $r_{\mathrm{CK}} > 0$ be so small that these three bounds meet the hypotheses of Theorem 9.9 with prescribed coarse gauge logarithm zero, and that the output of the slice lies strictly inside the larger domain of Theorem 9.7 on which Theorem 10.6 applies. Each of these requirements divides a fixed positive radius by a fixed constant, so r_{CK} is independent of d and n. By the discussion in Section 11.1, the slice output has gauge-corrected block average exactly c and the same action as b. By the minimizing property of the background field in that larger domain, we have

$$E_d(c) \le \mathscr{S}_{\varepsilon_d}(b).$$

For $d = 0$ this is an equality, since $b = c$ and $E_0 = S_W$. No stationarity of b is needed.

Let $\|\theta\|_\infty < r \le r_{\mathrm{CK}}$. By the last bound of (11.5), we have $\eta = \max_p \rho_G(U_p) \le Crt^2$. Inserting this into (11.4), with the normalization of $\mathscr{S}$, we obtain

$$\mathscr{S}_{Mt}(T_M U) \le \frac{4}{Mt} M(1 + C\eta) \sum_p q(U_p) \le (1 + CrM^{-2(d+1)}) E_{d+1}(c).$$

Combining the last two displays, we obtain the comparison in item (1).

Step 2: the monotone limit. We integrate the bound $\|DE_d(e^\theta)\|_\infty \le C_*\|\theta\|_\infty$ of Theorem 10.11 along the segment $u\theta$, $0 \le u \le 1$, and use $E_d(I) = 0$ (Theorem 10.6). Since there are $3n^3$ link variables, each with a fixed number of color components, on both the real and the complex balls of coarse logarithms we have

$$|E_d(e^\theta)| \le Cn^3\|\theta\|_\infty^2. \tag{11.6}$$

Nonnegativity on real data is part of Theorem 10.6. Since $P_{d+1} = P_d(1 + CrM^{-2(d+1)})$, the comparison of Step 1 is equivalent to $P_d E_d \le P_{d+1}E_{d+1}$. Further, using $\log(1+x) \le x$ and $\sum_{\ell \ge d} M^{-2(\ell+1)} = M^{-2d}/(M^2-1)$, we have

$$1 \le P_d \le P_\infty \le \exp\Big(\frac{Cr}{M^2-1}\Big), \qquad 0 \le \log(P_\infty/P_d) \le \frac{CrM^{-2d}}{M^2-1}.$$

The sequence $P_d E_d(c)$ is nondecreasing and, by (11.6) and $P_d \le P_\infty$, bounded. It therefore has a limit, and dividing by $P_d \to P_\infty$ shows that $E_\infty(c) = \lim_d E_d(c)$ exists. The inequality

$P_d E_d \geq P_0 E_0$ implies $E_d \geq P_d^{-1} E_0 \geq P_\infty^{-1} E_0$, and $P_\infty E_\infty = \lim_j P_j E_j \geq P_d E_d$ implies $E_\infty \geq (P_d/P_\infty) E_d$. We conclude that

$$E_d - E_\infty \leq \big(1 - P_d/P_\infty\big) E_d \leq \log(P_\infty/P_d)\, E_d \leq \frac{Cr}{M^2-1} M^{-2d} E_d,$$

where we used $1 - e^{-u} \leq u$ for $u \geq 0$. This is the one-sided error bound in item (1). We obtain no bound of the same order for $E_\infty - E_d$.

Step 3: analytic convergence at fixed n. Fix n. The coarse field has finitely many coordinates, and (11.6) bounds the holomorphic functions E_d uniformly on the common complex polydisc of Theorem 10.11. By Step 2, they converge on real points. By part (2) of Lemma 11.4, the whole sequence converges locally uniformly and holomorphically. Let $a_0 \leq a_*$, and let the norm radius ρ satisfy $C_* \rho < 1/2$ and lie strictly inside that polydisc, where a_*, C_* are the constants of Theorem 10.11. Since $\|D^k E_d\|_{a_*,\mathrm{root}} \leq C_*^{k+1} k!$ for $k \geq 2$, part (3) of the same lemma implies that $\mathcal{B}_{\rho,a}(E_d - E_\infty) \to 0$ for $0 < a \leq a_0$. Cauchy integrals on larger compact neighborhoods give the convergence of derivatives of fixed order on strictly smaller neighborhoods. The radii, the coefficient bound, and κ_* were chosen before n was fixed; only the subsequence argument and the finite list of coefficients use the fixed value of n.

Step 4: finite reconstruction maps. Fix the two lattices, the number s of averaging steps, and the couplings. For the i-th averaging step write

$$F_{d+i}(c,z) = E_{d+i}(b(c,z)), \qquad D_z F_{d+i}(c, z^*_{d+i}(c)) = 0,$$
$$K_{d+i}(c) = D_z^2 F_{d+i}(c, z^*_{d+i}(c)),$$

where $b(c,z)$ is the configuration of Theorem 10.10 with coarse field c and free logarithmic coordinates z. At real c, the conditional constrained minimizers $z^*_{d+i}(c)$ are real minima; at complex c, they are the holomorphic continuations solving the displayed critical equation. The map $b(c,z)$ does not depend on d, and Theorem 10.10 provides its coordinate neighborhoods and the uniform lower bound on the real Hessian. Since E_{d+i} converges on each fixed lattice by Step 3, F_{d+i} and all its derivatives of fixed order converge on every compact complex product with a strict margin. On real products the Hessian is at least $m_0 I/2$. We subtract the critical equations at depths $d+i$ and $d'+i$, and integrate the Hessian of $F_{d'+i}$ along the segment joining the two minimizers, which lies in the convex ball of free coordinates. We obtain

$$|z^*_{d+i}(c) - z^*_{d'+i}(c)|_2 \leq \frac{2}{m_0} \sup_z |D_z F_{d+i}(c,z) - D_z F_{d'+i}(c,z)|_2.$$

This shows that the conditional constrained minimizers are uniformly Cauchy on compact sets of real coarse fields.

For complex coarse fields, we freeze the Hessian K at a real minimizer, so that $\|K^{-1}\|_2 \le 2/m_0$. On a sufficiently small complex neighborhood in the coarse and free variables, the uniform analytic bounds on third and mixed derivatives give $\|I - K^{-1}D_z^2 F_{d+i}\|_2 \le 1/2$. These bounds are uniform in d; their conversion between finite-dimensional norms may depend on the fixed lattice. The map $z \mapsto z - K^{-1}D_z F_{d+i}(c, z)$ is therefore a contraction there and maps a smaller closed ball into itself. Its iterates are holomorphic and converge geometrically, and they define a holomorphic critical point on a common neighborhood. For two late depths, we may use the matrix K of the first depth for both equations, since their Hessians converge. If Φ_d and $\Phi_{d'}$ denote the two contraction maps, then

$$|z_d - z_{d'}| \le |\Phi_d(z_d) - \Phi_d(z_{d'})| + |\Phi_d(z_{d'}) - \Phi_{d'}(z_{d'})| \le \frac{1}{2}|z_d - z_{d'}| + \sup|\Phi_d - \Phi_{d'}|,$$

which implies that the difference of the fixed points is at most twice the uniform difference of the maps. A finite cover of the compact set of real coarse fields gives common complex neighborhoods, and on overlaps the branches agree by uniqueness of the fixed point. This proves locally uniform convergence of the complex minimizers, and Cauchy integrals give the convergence of each derivative of fixed order. The constrained Hessians K_{d+i} then converge with their derivatives. Here the chain rule reads

$$D_z^2 F = (D_z B)^{\mathsf{T}} D^2 E(B) D_z B + DE(B) D_z^2 B, \qquad B = \operatorname{Log} b,$$

and the second term is kept throughout.

The positive square root and its inverse are holomorphic operations on the common matrix neighborhood in use. For a real symmetric $K \ge m_0 I/2$,

$$K^{-1/2} = \frac{2}{\pi}\int_0^\infty (K + t^2 I)^{-1}\, dt, \qquad K^{1/2} = K K^{-1/2}, \tag{11.7}$$

as one checks by diagonalizing K and using $\int_0^\infty (\lambda + t^2)^{-1} dt = \pi/(2\sqrt{\lambda})$. On a complex neighborhood on which the Hermitian part of K is at least $m_0 I/4$, the resolvent norm is at most $(m_0/4 + t^2)^{-1}$. Its Neumann series and the differentiated series converge on smaller neighborhoods, and every derivative is bounded by a finite product of these integrable resolvent bounds. Integrating over $[0, T]$ and using the uniform integrable tails, we obtain the convergence in (11.7) with every derivative of fixed order.

The reconstruction through the s averaging steps has the explicit triangular form

$$z_i = z_{d+i}^*(c_i) + g_i K_{d+i}(c_i)^{-1/2} w_i, \qquad c_{i-1} = b(c_i, z_i),$$

with the indexing adjusted to the input and output sides of each step. Starting at the coarsest field, we prove by finite induction over the s steps the convergence of each z_i and c_{i-1} and of every joint derivative of fixed order in the coarse and free variables. At

each step, the strict margin keeps the argument in a compact subset of the domain of the next map. The Haar disintegration density of one step is the product of the Haar factors $\operatorname{sinc}^2(|\Gamma_e|/2)$ over the non-tree edges, divided by the constraint determinant at the eliminated edges, times the constant Haar normalization ((4.2) and the formula following Definition 4.3). For complex arguments, the Haar factor is defined by its even power series in the bilinear expression $\Gamma_e \cdot \Gamma_e$, whose restriction to real arguments is the real formula; no Hermitian modulus is continued. All the arguments just shown to converge enter these fixed functions, and the fixed margin keeps the denominators uniformly away from zero. These factors and their derivatives therefore converge. The triangular factors $g_i^{3f_i} \det K_{d+i}^{-1/2}$ converge as well.

Finally, on these fixed finite lattices the finitely composed maps have a common holomorphic bound on a strictly larger product. The Cauchy estimate in the proof of Lemma 11.4 then gives a common absolute majorant on a smaller product. The spatial weight and the volume factor are finite here: the weight of a coefficient of degree k is at most $e^{aD_0 k}$, where D_0 is the diameter of the fixed finite set of indices. Let the radius of the coefficient norm be smaller than the larger radius times e^{-aD_0}. Then the tail of degree k is a polynomial in k times a fixed geometric sequence, and the tails are uniformly small, while every finite list of coefficients converges. This proves convergence in an absolute coefficient norm with a smaller radius. All constants in this last step may depend on the fixed lattices, on s, on the couplings, and on the margins, as asserted. □

Remark 11.5. Item (3) of Theorem 11.2 asserts complex convergence on a neighborhood of each compact set of real data; this is what the proof constructs, and it is what is used in Section 15. If, on a polydisc centered at a real point of such a set, all the maps in item (3) are holomorphic and bounded uniformly in d, then part (2) of Lemma 11.4 extends the locally uniform convergence to that polydisc.

11.3 Gauge invariance on overlapping charts

The classical background field exists only in a chart around the identity, but the renormalization group needs a well-defined value of E_d on the gauge-invariant small-field domain $D_\rho = \mathcal{G}B_\rho$. The representatives in B_ρ of a configuration in D_ρ are related by periodic gauge transformations that need not have a small global logarithm.

Theorem 11.6. *There exists $\rho_{\mathrm{ov}} > 0$, depending only on M and the fixed domains, with the following properties. Let $n \geq 4$, $d \geq 0$, and $0 < \rho \leq \rho_{\mathrm{ov}}$, and let k be a real periodic gauge transformation of the coarse lattice such that c and c^k both lie in B_ρ. Then*

$$E_d(c^k) = E_d(c).$$

No smallness of a global logarithm of k is assumed. Moreover the following statements hold.

1. *At adjacent coarse vertices x, y, $\rho_G(k_x k_y^{-1}) < 2\rho$.*
2. *There is a smooth periodic map $\mathscr{K}$ from the torus (in coarse units) to* $\mathrm{SU}(2)$*, obtained in each unit cell by normalizing a nonnegative cardinal average of the values of k at the corners of the cell, regarded as unit quaternions, such that*

$$\mathscr{K} = k \text{ at the coarse vertices}, \qquad \|D\mathscr{K}\|_\infty + \|D^2\mathscr{K}\|_\infty \le C\rho.$$

   The map $k \mapsto \mathscr{K}$ commutes with left and right multiplication by constant elements of $\mathrm{SU}(2)$*, with translations of the coarse lattice, and with spatial inversion. Near every real k satisfying the hypotheses with a fixed strict margin, $\mathscr{K}$ has a holomorphic continuation in the values of k whose absolute Taylor coefficients of order s are bounded by $C^{s+1}s!$, together with the corresponding volume-normalized column sums; these constants depend on the margin but not on d or n. On the fine lattice of spacing ε, the gauge transformation by $\mathscr{K}$ sends a small potential A to a potential whose C^1_ε norm is at most $C(\|A\|_{C^1_\varepsilon} + \rho)$, uniformly in ε.*
3. *Consequently the function $E_{d,\mathrm{sat}}(U) = E_d(U^k)$, where k is any periodic gauge transformation with $U^k \in B_\rho$, is well defined and real analytic on D_ρ, and its local holomorphic expressions agree on every strict real overlap. If, in addition, $\rho \le r_{\mathrm{CK}}$, then $E_{d,\mathrm{sat}} \ge \kappa_* E_0$ on D_ρ, with κ_* as in Theorem 11.2. The same identities and the same extension hold for E_∞ at each fixed coarse side n.*

Remark 11.7. The following picture describes the interpolation in item (2). In a unit cell of the coarse lattice, the values of k at the eight corners are unit quaternions that lie pairwise within angle 3ρ of each other, although they may be far from 1. Their weighted average $m(x)$ lies in the convex hull of these eight points, hence at distance more than $1/2$ from the origin, and $\mathscr{K}(x)$ is its radial projection back to the unit sphere $\mathrm{SU}(2) \cong S^3$. The holomorphic continuation in item (2) concerns the dependence on the corner values; the weights are smooth, but not analytic, functions of the position.

Proof of Theorem 11.6. The proof has seven steps. Steps 1–5 construct the interpolation $\mathscr{K}$ and prove the estimates in items (1) and (2). Step 6 proves $E_d(c^k) = E_d(c)$, and Step 7 proves item (3).

Step 1: neighboring values of k. Let $c' = c^k$. On a coarse edge (x, y) we have $c'_{xy} = k_x c_{xy} k_y^{-1}$, so

$$k_x k_y^{-1} = c'_{xy}\big(k_y c_{xy}^{-1} k_y^{-1}\big), \qquad \rho_G(k_x k_y^{-1}) \le \rho_G(c'_{xy}) + \rho_G(c_{xy}) < 2\rho,$$

where we used that ρ_G is invariant under conjugation and satisfies the triangle inequality. The eight values of k at the corners of any unit cell of the coarse lattice are therefore pairwise within 6ρ. This estimate concerns only differences and does not restrict a logarithm of k.

Step 2: the interpolation. Let

$$b(t) = \begin{cases} e^{-1/t}, & t > 0, \\ 0, & t \le 0, \end{cases} \qquad f(t) = \frac{b(t)}{b(t) + b(1-t)} \quad (0 \le t \le 1).$$

The function f is smooth, flat at both endpoints, takes values in $[0,1]$, and satisfies $f(1-t) = 1 - f(t)$. In a cell $x_0 + [0,1]^3$, we write $x = x_0 + t$ and, for $v \in \{0,1\}^3$, define

$$W_v(t) = \prod_{i=1}^{3} \big[v_i f(t_i) + (1 - v_i)(1 - f(t_i)) \big], \quad m(x) = \sum_v W_v(t) k_{x_0+v}, \quad \mathscr{K}(x) = \frac{m(x)}{|m(x)|}. \tag{11.8}$$

Here elements of $\mathrm{SU}(2)$ are represented by unit quaternions in $\mathbb{R}^4$. The weights W_v are nonnegative, sum to one, and are cardinal at the corners. With our normalization of $\mathfrak{su}(2)$, the angle between two unit quaternions is half the group distance between the corresponding elements. Fix one corner value k_0. By Step 1, every corner value lies within angle 3ρ of k_0, so

$$\langle m(x), k_0 \rangle \ge \cos(3\rho) > 1/2$$

after one fixed reduction of ρ. In particular, $|m(x)| > 1/2$. On a face of the cell, the weights of the corners off that face vanish, and the formulas of the two adjacent cells reduce to the same four-corner formula. Since f is flat at the endpoints, all normal derivatives of every order match across the face. We conclude that (11.8) defines a smooth periodic map, also across the periodic seams.

Step 3: derivative bounds and symmetries. For every spatial derivative of positive order j we have $\sum_v D^j W_v = 0$, so

$$D^j m = \sum_v D^j W_v \, (k_{x_0+v} - k_0).$$

The derivatives of the weights of each fixed order are bounded independently of the cell and of the side, and $|k_{x_0+v} - k_0| \le C\rho$ by Step 1. For $j = 1, 2$, the last display is therefore bounded by $C\rho$. The normalization $m \mapsto m/|m|$ has bounded derivatives on $|m| > 1/2$, and the second derivative of $\mathscr{K}$ contains, besides $D^2 m$, only products of two first derivatives of m. This proves

$$\|D\mathscr{K}\|_\infty + \|D^2\mathscr{K}\|_\infty \le C\rho. \tag{11.9}$$

Since left and right quaternion multiplications by fixed elements of $\mathrm{SU}(2)$ are orthogonal linear maps of $\mathbb{R}^4$, they commute with the average and its normalization. Integer translations commute with the cell formula. Spatial inversion reverses each coordinate of the cell and exchanges v with $1 - v$; the identity $f(1-t) = 1 - f(t)$ then gives the asserted equivariance. We do not assert a multiplication law for the interpolation of two variable gauge transformations.

Step 4: holomorphic continuation. We regard a quaternion as a 2×2 matrix. On real inputs,

$$\mathscr{K} = m(\det m)^{-1/2}, \qquad \det m = |m|^2 > 1/4.$$

We use exponential coordinates for the eight corner values about their fixed real values. By the equivariance under left multiplication, multiplying all eight on the left by the inverse of one real corner value puts them in a common fixed neighborhood of the identity. For sufficiently small complex increments of the coordinates, $\det m$ stays in a disc around its positive real value that avoids zero. The absolutely convergent binomial series then continues the branch of the square root that is positive on real data. On a smaller ball of increments, the exponential and binomial series give an absolute majorant $C/(1-Ct)$ for this function and for each of its first two spatial derivatives. Since there are only eight inputs, the absolute tensors of order s are bounded by $C^{s+1}s!$. The constants depend only on the fixed margins of the determinant and of the coordinates. Since an input vertex belongs to at most eight cells, each of bounded diameter, the tensors have finite range and satisfy the weighted bounds at every fixed decay rate. For a fine output lattice of spacing ε, the column sums with a fixed input index are bounded, because ε^3 times the number of fine vertices in these cells is at most a fixed constant. The same conclusions hold for fixed spatial differences, by integrating the corresponding spatial derivatives of the cell formula. Strict margins allow a common choice of all these neighborhoods. This proves the holomorphic and coefficient assertions of item (2), uniformly in d and n.

Step 5: the effect on a fine potential. For a fine edge in direction i, with $y = x + \varepsilon e_i$, we set

$$V_i(x) = \varepsilon^{-1} \operatorname{Log}\big(\mathscr{K}(x)^{-1}\mathscr{K}(y)\big).$$

By (11.9), the ratio $\mathscr{K}(x)^{-1}\mathscr{K}(y)$ has group distance at most $C\varepsilon\rho$ from the identity, so this logarithm is taken on the identity branch. To see that the factor ε^{-1} is harmless, let $R(x,s) = \mathscr{K}(x)^{-1}\mathscr{K}(x + s\varepsilon e_i)$; then

$$V_i(x) = \int_0^1 D\operatorname{Log}_{R(x,s)}\big[\mathscr{K}(x)^{-1}\partial_i\mathscr{K}(x + s\varepsilon e_i)\big]\, ds.$$

All derivatives of this local logarithm are bounded. Differentiating in x uses only the first and second derivatives in (11.9): differentiating R contributes a factor at most $C\rho$, and differentiating the other factor contributes at most $C(\rho + \rho^2)$. Using the mean value integral in x for the lattice differences, we have $\|V\|_\infty + \|\nabla_\varepsilon V\|_\infty \le C\rho$, uniformly in ε.

Since $\mathscr{K}(y) = \mathscr{K}(x)e^{\varepsilon V_i(x)}$, the transformed link variable $\mathscr{K}(x)e^{\varepsilon A_i(x)}\mathscr{K}(y)^{-1}$ has logarithmic potential

$$\varepsilon^{-1}\operatorname{Log}[(e^{\varepsilon A})^{\mathscr{K}}_{xy}] = \operatorname{Ad}(\mathscr{K}(x))\big(A_i(x) - V_i(x) + \varepsilon\mathcal{R}_\varepsilon(A_i(x), V_i(x))\big). \tag{11.10}$$

Here the remainder is defined by the product and logarithm series for $\varepsilon^{-1}\operatorname{Log}(e^{\varepsilon A}e^{-\varepsilon V})$ after subtracting $A - V$. Since all remaining monomials contain at least one factor ε, the

series and its first derivatives are bounded on a fixed small ball of (A, V), for $0 \le \varepsilon \le 1$. The real factor $\mathrm{Ad}(\mathscr{K}(x))$ is an isometry, and its first difference is bounded by $C\rho$. Taking a first difference in (11.10), by integrating the derivative of the local function between the neighboring arguments, we obtain

$$\big\|\varepsilon^{-1}\,\mathrm{Log}[(e^{\varepsilon A})^{\mathscr{K}}]\big\|_{C^1_\varepsilon} \le C(\|A\|_{C^1_\varepsilon} + \rho) \tag{11.11}$$

on a fixed small ball of potentials. The constants do not depend on the distance of $\mathscr{K}$ from the identity.

Step 6: identification of the minima. Let $U^{\mathrm{ord}}(c)$ be the real representative of the gauge orbit of the classical background field with $T^d_M U^{\mathrm{ord}}(c) = c$ from Lemma 10.8. Its potential has $C^1_{\varepsilon_d}$ norm at most $C\rho$, its action is $E_d(c)$, and by Theorem 10.6 every tangent vector to the fiber $\{U : T^d_M U = c\}$ at $U^{\mathrm{ord}}(c)$ has zero first variation. The restriction of $\mathscr{K}$ to the fine vertices takes the values k at the coarse vertices. The block averaging map is gauge covariant: the vertex factors cancel between adjacent edges of each defining path, and the logarithm of each based loop holonomy is conjugated at its basepoint. Hence

$$T^d_M\big[(U^{\mathrm{ord}}(c))^{\mathscr{K}}\big] = c^k = c'.$$

A fixed real gauge transformation preserves the Wilson action and maps the fiber over c diffeomorphically onto the fiber over c'. It therefore preserves constrained criticality. By (11.11), the potential, the divergence, and the curl of $(U^{\mathrm{ord}}(c))^{\mathscr{K}}$ are bounded by $C'\rho$. Let ρ_{ov} be smaller than the fixed radii of Theorems 9.7 and 9.9 divided by C', and smaller than the thresholds used in Steps 2–5. Then the gauge slice of Theorem 9.9, with prescribed coarse gauge logarithm zero, sends $(U^{\mathrm{ord}}(c))^{\mathscr{K}}$ into the larger domain of Theorem 9.7, with gauge-corrected block average exactly c' (Section 11.1).

We verify that the resulting field is critical in that domain, rather than identifying the two constraint maps. Consider a curve $\gamma(t)$ through it in the gauge slice, with fixed gauge-corrected block average c'. By (11.1), its block average is $T^d_M\gamma(t) = (c')^{\mathsf{G}(t)^{-1}}$, where $\mathsf{G}(t)$ is the accumulated gauge transformation of the gauge-corrected average along the curve. Since all defining words have strict margins in the identity chart of the logarithm, $\mathsf{G}(t)$ is differentiable. We interpolate $\mathsf{G}(t)$ smoothly to the fine vertices with the cardinal interpolation of Lemma 10.8, and apply the resulting gauge transformation to $\gamma(t)$. The new curve has block average fixed at c' and the same action as $\gamma(t)$, and its value at $t = 0$ lies on the critical gauge orbit of $(U^{\mathrm{ord}}(c))^{\mathscr{K}}$. The constrained criticality on the fiber over c' therefore kills its derivative at $t = 0$. The additional term coming from the field-dependent gauge transformation is a gauge tangent and has zero first variation as well. Hence the curve γ has zero first variation of the action. By Theorem 10.6, the unique critical point in the convex domain is the classical background field for c'. Since all transformations used preserve the action, we conclude that $E_d(c') = E_d(c)$. For $d = 0$, this identity follows directly by conjugating the plaquette variables.

Step 7: extension to D_ρ. If $U^k, U^l \in B_\rho$, then $U^l = (U^k)^{lk^{-1}}$, and Step 6 gives the same value in both charts. This proves that $E_{d,\mathrm{sat}}$ is well defined on D_ρ. Each fixed k defines an open set on which $U \mapsto E_d(U^k)$ is real analytic. On a strict real overlap, two such local holomorphic expressions agree on a real open set, and the coordinatewise uniqueness argument in the proof of part (2) of Lemma 11.4 identifies their germs. They therefore patch to a real analytic function. The lower bound follows from Theorem 11.2:

$$E_{d,\mathrm{sat}}(U) = E_d(U^k) \geq \kappa_* E_0(U^k) = \kappa_* E_0(U),$$

since the Wilson action E_0 is gauge invariant. For a fixed coarse side, passing to the limit $d \to \infty$ in the two chart values by Theorem 11.2, we find the same identities and the same extension for E_∞. □

11.4 Gauge alignment of the successive constrained minimizers

In this section, we consider one renormalization group step. Let $J \geq 1$, $d_0 \geq 0$, and $m \geq 4$, and let $\delta = M^{-J}$. The step goes from the fine lattice of side $m/\delta = mM^J$, of spacing δ in coarse units, to the coarse lattice of side m, through the intermediate lattices of spacings $\delta_l = M^{l-J}$, $0 \leq l \leq J$. The effective classical action on the fine lattice of the step is E_{d_0}.

At each step, the renormalization group needs a representative of the gauge orbit of the classical background field that satisfies the block averaging constraint $T_M^J(\cdot) = e^\theta$ exactly. Indeed, the small-field event and the reconstruction maps are defined through T_M, not through the gauge-corrected average. Its coefficient bounds must be uniform in J, since J is chosen only after these bounds are known. The identification with the reconstruction maps of Sections 12 and 13 is needed only for fixed J.

The classical background field of the step. Let θ be a small coarse logarithm. We apply Theorem 10.11 with coarse side $n = m$, depth $d = d_0 + J$, and intermediate index $j = d_0 + l$, $0 \leq l \leq J$. The intermediate spacing is then exactly $M^{j-d} = \delta_l$, and the fine side is $mM^J = m/\delta$. Since these are complete periodic tori of side at least four, Theorem 10.11 applies in its form for arbitrary sides. We denote the resulting representatives by

$$D_l(\theta) = e^{\delta_l A_l(\theta)}, \qquad 0 \leq l \leq J,$$

so that $D_J = e^\theta$ and $D_0 = e^{\delta A_0(\theta)}$ is a configuration on the fine lattice of the step. For real θ, these are gauge-corrected block averages of the classical background field of depth $d_0 + J$; on the common complex ball, they are holomorphic continuations. We refer to the gauge orbit of $D_0(\theta)$ as the gauge orbit of the classical background field of the step. By Theorem 10.11, the pairs $(A_l, \nabla_{\delta_l} A_l)$ have one common factorial majorant, for output-row norms and for column norms with output volume δ_l^3, independent of d_0, J, l, and m.

The next lemma identifies this orbit, for each fixed J, with the configuration obtained by successive conditional constrained minimization. For a configuration V on the fine

lattice of the step in the domain of Lemma 10.8 (applied with depth d_0 and coarse side m/δ), let $U^{\mathrm{ord}}_{d_0}(V)$ denote the representative of the gauge orbit of the classical background field of depth d_0 with $T_M^{d_0} U^{\mathrm{ord}}_{d_0}(V) = V$.

Lemma 11.8. *Let $J \geq 1$, $d_0 \geq 0$, $m \geq 4$, and $\delta = M^{-J}$.*

1. *For $0 \leq j \leq J$ define functions Φ_j of configurations c_j on the lattice of spacing δ_j by $\Phi_0 = E_{d_0}$ and $\Phi_{j+1}(c_{j+1}) = \Phi_j\big(b(c_{j+1}, z^*)\big)$, where $b(c,z)$ is the configuration of Theorem 10.10 for the averaging step from spacing δ_j to δ_{j+1} and z^* is the conditional constrained minimizer of $z \mapsto \Phi_j(b(c_{j+1}, z))$. Then $\Phi_j = M^{-j} E_{d_0+j}$, wherever the successive minimizers lie in the domains of Theorem 10.10. For real data this is an identity between minima on the branch of Theorem 10.10; it extends holomorphically.*
2. *Let $\widehat{c}_0(\theta)$ be the configuration on the fine lattice of the step obtained by successive conditional constrained minimization, starting from e^θ, that is, the zero-fluctuation reconstruction before gauge transformation, and let $\widehat{U}(\theta) = U^{\mathrm{ord}}_{d_0}(\widehat{c}_0(\theta))$. For each fixed J there is $r'_J > 0$, depending on J and the fixed domains but not on d_0, m, L, or γ, such that the following holds for real $\|\theta\|_\infty < r'_J$. The configuration $\widehat{c}_0(\theta)$ is a critical point of E_{d_0} on the fiber $\{V : T_M^J V = e^\theta\}$. The configuration $\widehat{U}(\theta)$ satisfies $T_M^{d_0+J}\widehat{U} = e^\theta$, every tangent vector to the fiber $\{U : T_M^{d_0+J} U = e^\theta\}$ at $\widehat{U}(\theta)$ has zero first variation of the Wilson action, its action in coarse units equals $E_{d_0+J}(e^\theta)$, and it lies in the gauge orbit of the classical background field of depth $d_0 + J$ at e^θ. Finally, $\widehat{c}_0(\theta)$ and $D_0(\theta)$ are gauge equivalent, and $E_{d_0}(\widehat{c}_0(\theta)) = E_{d_0}(D_0(\theta))$.*

Proof. For (1), by Theorem 10.10 we have $E_{d+1}(c) = M \min_z E_d(b(c,z))$ on the branch constructed there, for every depth d. If $\Phi_j = M^{-j} E_{d_0+j}$, then

$$\Phi_{j+1}(c_{j+1}) = M^{-j} \min_z E_{d_0+j}(b(c_{j+1}, z)) = M^{-j-1} E_{d_0+j+1}(c_{j+1}),$$

which proves (1) by induction; the factor M^{-j} comes from applying Theorem 10.10 j times. The minima are taken for real coarse fields and real free coordinates, and the critical-value identities extend holomorphically, as stated in Theorem 10.10.

For (2), we first show that $\widehat{c}_0$ is critical on its fiber. The tangent space at a configuration on a lattice of one averaging step decomposes according to the coordinates of Theorem 10.10. These coordinates gauge the configuration by the transports along the root paths of the block trees, take the remaining free logarithmic coordinates, and solve the eliminated edges by the inverse branch. Differentiating them, we split a tangent vector into a tangent to the gauge action of the block trees, a derivative of $b(c,z)$ in the free coordinates z, and a derivative through the next coarser field c. Consider a tangent vector to the fiber $\{T_M^J V = e^\theta\}$ at $\widehat{c}_0$. At the first averaging step, the gauge part has zero derivative of E_{d_0} by the local gauge invariance of Lemma 10.8. The free part is killed by the critical equation of the conditional constrained minimizer. The remaining derivative

is the derivative of the partially minimized value $\Phi_1 = M^{-1}E_{d_0+1}$ in the next coarser field. Repeating this at each of the J averaging steps, and using that the coarsest field e^θ is fixed, we find that the derivative vanishes. This proves the first assertion. The same induction, preceded by one more step, applies to $\widehat{U}$. A variation of $\widehat{U}$ at fixed coarse field splits into the variation of $U^{\mathrm{ord}}_{d_0}$ induced by the variation of its field on the fine lattice of the step, and a variation that keeps that field fixed. The latter has zero derivative of the action by Theorem 10.6. The former has derivative DE_{d_0} applied to the induced variation, up to the fixed scale factor, and this vanishes by the first assertion. We conclude that every tangent to the fiber $\{T_M^{d_0+J}U = e^\theta\}$ at $\widehat{U}$ has zero first variation.

Changing from units in which the fine lattice of the step has spacing one to coarse units multiplies potentials by δ^{-1} and first differences by δ^{-2}, which are fixed factors for fixed J. The potential of $\widehat{U}(\theta)$ therefore has C^1 norm at most $C_J\|\theta\|_\infty$ in coarse units. By (1), its action in coarse units is M^J times $\Phi_J = M^{-J}E_{d_0+J}$, that is, $E_{d_0+J}(e^\theta)$. Let r'_J be so small that the gauge slice of Theorem 9.9, with prescribed coarse gauge logarithm zero, places $\widehat{U}(\theta)$ in the larger domain of Theorem 9.7. The argument of Step 6 in the proof of Theorem 11.6 transfers the constrained criticality to that domain. The uniqueness in Theorem 10.6 then identifies the gauge orbit of $\widehat{U}(\theta)$ with that of the classical background field of depth $d_0 + J$.

Finally, we write $\widehat{U} = (e^{\varepsilon A_{d_0+J}})^g$ for a fine gauge transformation g, where $\varepsilon = M^{-d_0-J}$. By gauge covariance of T_M, $\widehat{c}_0 = T_M^{d_0}\widehat{U}$ is the gauge transform of $T_M^{d_0}e^{\varepsilon A_{d_0+J}}$ by the restriction of g, and by (11.1) the latter is gauge equivalent to D_0. Thus $\widehat{c}_0(\theta)$ and $D_0(\theta)$ are gauge equivalent, and after reducing r'_J both lie in B_ρ with $\rho \le \rho_{\mathrm{ov}}$. Theorem 11.6 then implies that $E_{d_0}(\widehat{c}_0) = E_{d_0}(D_0)$. □

We write $\mathscr{C}_{\mathrm{raw}\,d_0,J}(\theta, 0) = \widehat{c}_0(\theta)$ for the zero-fluctuation reconstruction of the step before gauge transformation. It is built from the successive conditional constrained minimizers of Theorem 10.10 and their normalization by the positive inverse square roots of the constrained Hessians, with every normalized fluctuation variable equal to zero.

Lemma 11.9. *Let $J \ge 1$, $d_0 \ge 0$, and $m \ge 4$, and put $\delta = M^{-J}$.*

1. *On a common complex ball $\|\theta\|_\infty < r_{\mathrm{cen}}$ there is an analytic representative*

$$C_{d_0,J}(\theta) = e^{\delta\overline{A}_{d_0,J}(\theta)}, \qquad T_M^J C_{d_0,J}(\theta) = e^\theta, \qquad \overline{A}_{d_0,J}(0) = 0,$$

   of the gauge orbit of the classical background field of the step.

2. *There exist $r_{\mathrm{cen}}, a_{\mathrm{cen}}, C_{\mathrm{cen}} > 0$, depending only on M and the fixed domains and independent of J, d_0, and m, such that for every integer $s \ge 1$ and every $\|\theta\|_\infty < r_{\mathrm{cen}}$,*

$$\|D^s_\theta(\overline{A}_{d_0,J}, \nabla_\delta\overline{A}_{d_0,J})\|_{a_{\mathrm{cen}},\mathrm{out}} + \|D^s_\theta(\overline{A}_{d_0,J}, \nabla_\delta\overline{A}_{d_0,J})\|_{a_{\mathrm{cen}},\mathrm{input};\delta^3} \le C_{\mathrm{cen}}^{s+1}s!.$$

   In particular $\|\overline{A}_{d_0,J}(\theta)\|_{C^1_\delta} \le C_{\mathrm{cen}}\|\theta\|_\infty$.

3. *The representative is $C_{d_0,J} = D_0^L$, where L is the smooth interpolation, by the cardinal weights of Lemma 10.8, of the accumulated gauge transformation G at the coarse vertices that relates the gauge-corrected and the ordinary block averages of D_0; at the coarse vertices $L = G$ (not G^{-1}), the multiplication order being forced by $(U^k)^l = U^{lk}$. The real gauge path connecting D_0 to $C_{d_0,J}$ has logarithms of the fine link variables bounded by $C\delta\|\theta\|_\infty$.*
4. *After one fixed reduction of r_{cen} with $Cr_{\mathrm{cen}} < 1/2$,*

$$\mathscr{R}_{a_{\mathrm{cen}}}\big((\overline{A}_{d_0,J}, \nabla_\delta \overline{A}_{d_0,J}); u\big) \preccurlyeq Z(u) = \frac{Cu}{1 - Cu}, \qquad \mathscr{C}_{a_{\mathrm{cen}},\delta^3}\big((\overline{A}_{d_0,J}, \nabla_\delta \overline{A}_{d_0,J}); u\big) \preccurlyeq Z'(u),$$

on $0 \le u < r_{\mathrm{cen}}$, with C and r_{cen} independent of J, d_0, and m. The accumulated gauge transformation G, its inverse, and its interpolation L have bounds of the same type, uniform in J. This item gives no bound uniform in J for the full reconstruction in coarse and free coordinates or for the gauge transformation F_J of item (6), and no column bound for arbitrary fine inputs to these gauge transformations.
5. *For each fixed J, the representative $C_{d_0,J}$, the gauge transformation L and its inverse, and the gauge transformation F_J of item (6) have weighted absolute coefficient bounds of factorial type, with every index fixed in turn, on a fixed larger domain of radius $r_J > 0$, with constants C_J. A positive spatial decay rate for these bounds can be chosen before J; r_J and C_J may depend on J and on the chosen analytic domains, but not on d_0, m, L, or γ. These constants are not used to choose J.*
6. *For the same fixed J, after reducing r_J only, let $F_J(\theta)$ be the gauge transformation obtained from $C_{d_0,J}(\theta)$ by imposing, in the order $j = J-1, J-2, \dots, 0$, the block axial gauge of the level-j blocks of the field after the preceding gauge transformations, each factor being extended constantly through the finer block partitions. With $(U^k)^l = U^{lk}$ its ordered product is $F_J = K_0 K_1 \cdots K_{J-1}$, and*

$$F_J = I \text{ at the coarse vertices}, \qquad F_J(0) = I, \qquad C_{d_0,J}(\theta)^{F_J(\theta)} = \mathscr{C}_{\mathrm{raw}\, d_0,J}(\theta, 0).$$

This identity holds on the complex ball of radius r_J, with strict margins in all intermediate charts. The gauge transformations F_J and F_J^{-1} depend only on θ and satisfy the bounds of item (5), uniformly in d_0, m, L, and γ; no bound on F_J uniform in J is asserted.

The bounds of item (2) hold at every order s; the reconstruction maps of Section 15 use only finitely many orders of such uniform bounds. Table 11.1 lists the order in which the constants of this section enter the choice of parameters.

Proof of Lemma 11.9. Steps 1–6 construct $C_{d_0,J}$ and prove items (1)–(4) with constants independent of J. Step 7 constructs F_J and proves item (5), and Step 8 proves the identity in item (6).

Constants	Dependence and role
a_*, C_*, r_*, m_0; $r_{\mathrm{CK}}, \rho_{\mathrm{ov}}$	Fixed geometry, decay rates, and classical coefficient bounds (Theorems 10.10, 10.11, 11.2, and 11.6); independent of J.
$a_{\mathrm{cen}}, r_{\mathrm{cen}}, C_{\mathrm{cen}}$ and Z	Items (2)–(4) of Lemma 11.9; independent of J, d_0, and m.
a, $\rho_0(a), \delta_0(a), C_P(a)$	Theorem 11.10; for the application to $C_{d_0,J}$, $0 < a < a_{\mathrm{cen}}/8$, $2\rho_0 < \min(r_{\mathrm{cen}}, r_*)$, and δ_0 chosen so that the image condition holds for both D_0 and $C_{d_0,J}$; independent of J, d_0, m, and of the later choice of $\rho \le \rho_0$.
J	Chosen after the preceding constants, for instance so that $C_P(a)M^{-J} < 1/4$ (Theorem 13.5; see also Theorem 23.2).
r_J, C_J	Items (5)–(6) of Lemma 11.9; depend on J but not on d_0, m, L, or γ; never used to choose J.
Later radii and coupling bounds	Chosen in Parts IV and VI, after J.

Table 11.1. Order of the constants in Section 11.

Step 1: conventions. We use the representatives D_l described before Lemma 11.8, with their common factorial majorant from Theorem 10.11. Fix $0 < a_{\mathrm{cen}} < a_*/32$. The larger multiples of this rate used below give spatial decay rates strictly larger than the working rate, which we use to sum columns. This choice does not depend on J, d_0, or m.

Step 2: the accumulated gauge transformation. We bound the gauge transformation relating the ordinary and the gauge-corrected block averages, rather than replacing the block averaging constraint by the gauge-corrected one. At level l, the vertex factor of the gauge-corrected average at a block center r is

$$H_l(r) = \exp\Big\{-M^{-3} \sum_{x \in \mathsf{B}_M(r)} \operatorname{Log} D_l(\sigma_{r,x})\Big\},$$

the identity-background factor of Lemma 8.10; by its definition, $D_{l+1} = (T_M D_l)^{H_l}$. By gauge covariance of T_M, the accumulated gauge transformations G_l satisfy

$$G_0 = I, \qquad G_{l+1} = H_l\,(G_l|_{\text{next coarser vertices}}), \qquad D_l = (T_M^l D_0)^{G_l};$$

the last identity follows by induction from $(U^k)^l = U^{lk}$. In particular, with $G = G_J$,

$$e^{\theta} = (T_M^J D_0)^G, \qquad T_M^J D_0 = (e^{\theta})^{G^{-1}}. \tag{11.12}$$

We now bound the coefficients of $\kappa = \operatorname{Log} G$ by a series that does not depend on J. Each path in H_l has at most C_M edges with variables $e^{\delta_l A_{l,e}}$. Expanding the product, the logarithm, and the exponential, we obtain the coefficientwise bound

$$H_l - I \preccurlyeq \delta_l \beta(Z(t)), \qquad \beta(z) \le \frac{Cz}{1 - Cz}, \quad \beta(0) = 0, \tag{11.13}$$

where $Z(t) = Ct/(1-Ct)$ is the majorant of the pairs $(A_l, \nabla_{\delta_l} A_l)$ and $\preccurlyeq$ refers to absolute output-row sums at a specified smaller decay rate. The factor δ_l appears because every nonconstant monomial of the local word contains at least one exponent $\delta_l A_l$, and $\delta_l^k \le \delta_l$. The finitely many path variables contribute a fixed factor per degree. The paths lie in a collar of radius $C_M \delta_l$, and joining it to the output vertex contributes another fixed factor per degree, absorbed in C. The absolute exponential, logarithm, and product series converge for one small fixed t. This proves (11.13) as an estimate on coefficients.

Restriction to coarser vertices cannot increase an output row. Using $\sum_{l=0}^{J-1} \delta_l < 1/(M-1)$, we obtain

$$G - I \preccurlyeq \prod_{l=0}^{J-1} (1 + \delta_l \beta(Z)) - 1 \preccurlyeq \exp\Big(\frac{\beta(Z)}{M-1}\Big) - 1,$$

and we denote the right side by $Q(t)$. Fix a radius of coarse logarithms such that $Q(t) < 1/2$. The logarithm series then bounds the absolute row series of κ by $\sum_{k\ge 1} Q(t)^k/k$. This series converges, vanishes at zero, and is dominated coefficientwise by $Ct/(1-Ct)$ after enlarging C. Indeed, the coefficient of degree s of a series with nonnegative coefficients that converges at $t_0 > 0$ is at most its value at t_0 times t_0^{-s}. The radius and the constants are independent of J, d_0, and m. The inverse needs no implicit differentiation: since $\det G = 1$, for 2×2 matrices

$$G^{-1} = \operatorname{adj} G, \qquad \operatorname{adj}(I + X) - I = (\operatorname{tr} X) I - X. \tag{11.14}$$

This is linear in X, with absolute rows at most a fixed multiple of those of its argument, and on the common branch $\operatorname{Log} G^{-1} = -\kappa$. Enlarging the constant of the rational majorant, we bound κ, $G - I$, and $G^{-1} - I$ simultaneously, at every order, before J is chosen.

Step 3: from rows to columns. We work with row bounds at twice the decay rate used in the conclusion. For an output vertex x and a fixed coarse input u, the length of a shortest connecting network is at least $\operatorname{dist}(x, u)$. We remove the sum over that input from an absolute output row and use half of the rate. Then the remaining weighted sum of order s is at most $C^{s+1} s! e^{-a \operatorname{dist}(x,u)}$. For the meshes that occur here,

$$\sup_u \sup_{\substack{\varepsilon = M^{-j} \\ j \in \mathbb{Z}_{\ge 0}}} \varepsilon^3 \sum_{x \in \varepsilon \mathbb{Z}^3/(m\mathbb{Z})^3} e^{-a \operatorname{dist}(x,u)} \le C_a, \tag{11.15}$$

where m is an integer, $m/\varepsilon = mM^j \in \mathbb{N}$, and u is a vertex of the fine lattice; this covers the coarse spacing 1 and every intermediate spacing δ_l. To prove (11.15), we take the shortest periodic representatives and bound the torus sum by the sum over the infinite lattice. By equivalence of the fixed lattice metrics, this reduces to a product of three one-dimensional sums. For $b > 0$, by monotonicity of e^{-bt} we have $\varepsilon \sum_{k \in \mathbb{Z}} e^{-b\varepsilon|k|} \le$

$1 + 2\int_0^\infty e^{-bt}dt = 1 + 2/b$, uniformly in the side. Hence κ has bounded counting columns with coarse outputs, and the same argument gives volume-normalized columns for outputs on a lattice of spacing ε. The input in this argument is the coarse logarithm θ, through the representatives D_l.

Step 4: the interpolated gauge transformation and the exact constraint. With the smooth periodic cardinal weights χ_r of Lemma 10.8, we define on the fine vertices

$$\lambda_x(\theta) = \sum_r \chi_r(x)\kappa_r(\theta), \qquad L_x(\theta) = e^{\lambda_x(\theta)}, \qquad C_{d_0,J}(\theta) = D_0(\theta)^{L(\theta)}. \tag{11.16}$$

Since $L = G$ at the coarse vertices, gauge covariance of T_M^J and (11.12) give $T_M^J C_{d_0,J} = ((e^\theta)^{G^{-1}})^G = e^\theta$ exactly. This is why we interpolate G, and not G^{-1}. The interpolation need not be the identity at the coarse vertices, since it corrects the block average; the gauge transformation F_J constructed in Step 7 will be the identity there.

The weights and their first two spatial derivatives have bounded absolute rows and volume-normalized columns, with a fixed collar of support. Integrating these derivatives, we obtain the same bounds for the first and second divided differences of their restrictions to the lattice. By Steps 2 and 3, λ, $\nabla_\delta\lambda$, and all second divided differences of λ have factorial rows and columns in θ, uniformly in J. If $Y(u)$ is their common row majorant, the exponential series bounds $L - I$ by $e^{Y(u)} - 1$. Since $\det L = 1$, (11.14) applies to L and bounds $L^{-1} - I$. Differentiating the exponential series spatially once or twice inserts a first difference of λ, or a second difference and products of first differences, which have convergent majorant series of the same type. Row bounds at a spatial decay rate strictly larger than the working rate, together with (11.15), give their columns with one fixed coarse input and output volume δ^3. For G, the output measure is counting measure on the coarse lattice. This proves the bounds of item (4) for G, its inverse, and its interpolation, all with the coarse logarithm θ as input.

Step 5: removal of the inverse mesh. We remove the inverse mesh in the gauge word before taking spatial or θ derivatives. For $u = \lambda_x$, $v = (\lambda_{x+\delta e_i} - \lambda_x)/\delta$, and $a = A_{0,i}(x)$, we define

$$F_\delta(u, v, a) = \delta^{-1}\operatorname{Log}(e^u e^{\delta a} e^{-u-\delta v}). \tag{11.17}$$

The product equals I at $\delta = 0$, for all small u, v, a. The absolutely convergent exponential and logarithm series are jointly analytic in (δ, u, v, a) on a small ball, also for $|\delta| \le 2$, and the zero at $\delta = 0$ makes the division removable. After division, the absolute series have a common majorant for $0 \le \delta \le 1$. Differentiating at $\delta = 0$, we find

$$F_0(u, v, a) = \operatorname{Ad}(e^u)a - \int_0^1 \operatorname{Ad}(e^{su})v\, ds, \tag{11.18}$$

as follows from $De^X[Y] = \int_0^1 e^{(1-s)X} Y e^{sX} ds$. Thus $F_\delta = F_0 + \delta R_\delta$ with a uniformly convergent absolute analytic remainder. We define

$$\overline{A}_{d_0,J,i}(x) = F_\delta(\lambda_x, \nabla_{\delta,i}\lambda_x, A_{0,i}(x)).$$

Since $L_x e^{\delta A_{0,i}(x)} L^{-1}_{x+\delta e_i} = e^{\lambda_x} e^{\delta A_{0,i}(x)} e^{-\lambda_x - \delta \nabla_{\delta,i}\lambda_x}$, this is the logarithmic potential of $C_{d_0,J}$ in (11.16). Its first divided difference is the integral of the derivative of F_δ along the segment between the neighboring lists of arguments, whose differences are $\nabla_\delta \lambda$, $\nabla^2_\delta \lambda$, and $\nabla_\delta A_0$. All of these have the majorants established above. Composing majorant series with the counting of Lemma 11.1, we obtain factorial rows for $(\overline{A}, \nabla_\delta \overline{A})$ at one fixed smaller decay rate. Here the union of the local collars and of the input networks connects every external index. Applying (11.15) to rows at a strictly larger rate gives the columns with output volume δ^3. All decay rates are chosen before J, and no rate is reduced from one averaging step to the next.

Step 6: one majorant for all bounds. We work first at twice the final rate a_{cen}. Let $Y(u) = C_0 u/(1 - C_0 u)$ dominate the absolute rows of $(A_0, \nabla_\delta A_0, \lambda, \nabla_\delta \lambda, \nabla^2_\delta \lambda)$, where C_0 is increased to account for the finitely many types of components. For a suitable fixed c, the series of F_δ and of its first derivative in its local arguments are bounded by $cz/(1-cz)$ and $c/(1-cz)^2$. Using the integral representation of the spatial difference, we obtain

$$\mathscr{R}_{2a_{\mathrm{cen}}}((\overline{A}, \nabla_\delta \overline{A}); u) \preccurlyeq P(u), \qquad P(u) = \frac{cY(u)}{1 - cY(u)} + \frac{cY(u)}{(1 - cY(u))^2}, \tag{11.19}$$

by multiplication of absolute Taylor series and Lemma 11.1. In the second term, the last factor Y accounts for the spatial difference of a local argument. The majorant is independent of δ and of J. At order s, since the rows are bounded at a larger rate than the columns, (11.15) bounds the column by $C_{a_{\mathrm{cen}}}$ times the row; in the notation (11.2),

$$\mathscr{C}_{a_{\mathrm{cen}},\delta^3}((\overline{A}, \nabla_\delta \overline{A}); u) \preccurlyeq C_{a_{\mathrm{cen}}} P'(u).$$

The same conversion applies to the series for G, G^{-1}, and L. We add all these row majorants, together with P and the fixed constants of the column conversions, into one series $S(u) = \sum_{s \geq 1} S_s u^s$ with nonnegative coefficients, convergent at some $u_* > 0$ independent of J, d_0, and m. Then $S_s \leq S(u_*) u_*^{-s}$. Choosing $C \geq \max\{1, u_*^{-1} \max\{1, S(u_*)\}\}$, we have $S_s \leq C^s$ for every $s \geq 1$, and hence

$$\begin{aligned} \mathscr{R}_{a_{\mathrm{cen}}}((\overline{A}, \nabla_\delta \overline{A}); u) &\preccurlyeq Z(u) = \frac{Cu}{1 - Cu}, \\ \mathscr{C}_{a_{\mathrm{cen}},\delta^3}((\overline{A}, \nabla_\delta \overline{A}); u) &\preccurlyeq Z'(u). \end{aligned} \tag{11.20}$$

The same Z and Z' dominate the nonconstant parts of the series of G, G^{-1}, and L, with output volume 1 for coarse outputs and δ^3 for fine outputs. The final Z may be larger than

the majorant used in (11.13); all earlier estimates remain valid on the smaller common ball.

With this rate, let $r_{\mathrm{cen}} > 0$ be such that the series just used converge on a ball strictly larger than $\|\theta\|_\infty < r_{\mathrm{cen}}$ and $Cr_{\mathrm{cen}} < 1/2$. These constants are fixed before J. The bounds also hold at every point of the ball, not only at its center. Indeed, if a tensor of order k at zero is bounded by $C^{k+1}k!$, then translating the argument by θ bounds the tensor of order s at θ by

$$\sum_{l\geq 0} \frac{\|\theta\|_\infty^l}{l!} C^{s+l+1}(s+l)! = \frac{C^{s+1}s!}{(1-C\|\theta\|_\infty)^{s+1}}.$$

Since contracting l inputs only shortens the external network, the same inequality holds for each coefficient bound with a fixed external index and for each volume-normalized column. A fixed reduction of the radius bounds the right side by $C_{\mathrm{cen}}^{s+1}s!$ for every $s \geq 1$, with no loss in the radius or the decay rate that depends on s. Enlarging C_{cen}, we also bound the first derivative itself. Since the pair $(\overline{A}, \nabla_\delta \overline{A})$ and the nonconstant parts of the gauge transformations vanish at $\theta = 0$, integrating the first derivative, we find $\|\overline{A}\|_{C^1_\delta} \leq C_{\mathrm{cen}}\|\theta\|_\infty$. Replacing λ by $t\lambda$ in (11.17), uniformly for $0 \leq t \leq 1$, we find that the real gauge path from D_0 to $C_{d_0,J}$ has fine logarithms at most $C\delta\|\theta\|_\infty$. This completes the proof of items (1)–(4); item (1) refers to this gauge orbit because $C_{d_0,J}$ is a gauge transform of D_0.

Step 7: the block axial gauge transformation for fixed J. For a configuration V on the fine lattice of one averaging step, we define on each block with center r

$$f(V)_x = V(\sigma_{r,x}), \qquad f(V)_r = I.$$

For each edge (x, y) of the block tree, oriented away from the center, the root path gives $f(V)_y = f(V)_x V_{xy}$, and hence $(V^{f(V)})_{xy} = I$. Starting from $V = C_{d_0,J}(\theta)$, we perform the following finite procedure for $j = J-1, J-2, \ldots, 0$. We compute $V_j = T_M^j V$ for the field V after the preceding gauge transformations, form $f(V_j)$, extend this gauge transformation constantly through the j finer block partitions to the fine vertices, and apply the resulting gauge transformation K_j to V. The factor K_j is the identity at the vertices of level $j+1$. By gauge covariance, it therefore leaves unchanged every coarser iterated block average and each block axial gauge condition already imposed there. The resulting gauge transformation is

$$F_J = K_0 K_1 \cdots K_{J-1}, \qquad F_J = I \text{ at the coarse vertices.} \tag{11.21}$$

Each factor is evaluated on the field transformed by the preceding factors, and the order of the product is forced by $(U^k)^l = U^{lk}$.

For fixed J, these operations are finite products and the local logarithms of the block averaging map. At $\theta = 0$, every intermediate field and every factor is the identity. Finite-word absolute series and the uniform series of $C_{d_0,J}$ therefore give a radius $r_J > 0$ with

strict margins in all intermediate charts. The lengths of the words depend on M and J, not on d_0 or m, and all factorial row constants may depend on J. The collars are bounded by a fixed multiple of $\sum_{j<J} M^{j-J} < 1/(M-1)$; extension through finer block partitions enlarges them only by the same geometric sum. The union of networks preserves a chosen positive decay rate at every composition, and the number of variables per coarse unit cell is finite for fixed J. Row bounds at a spatial decay rate strictly larger than the working rate and (11.15) give the volume-normalized columns. Since inversion of a matrix of determinant one is a fixed polynomial in its entries, the same statements hold for F_J^{-1}, for L, and for L^{-1}. This proves item (5).

Step 8: identification with the zero-fluctuation reconstruction. The stationarity and convexity arguments below use real coarse fields and real free coordinates; the final identity is then continued holomorphically. Consider the free logarithmic coordinates $z = (z_0, \dots, z_{J-1})$ of the J averaging steps in the nested coordinates of Theorem 10.10. Consider also the function of z obtained by composing E_{d_0} with the reconstruction of the fine field of the step from θ and z. By part (1) of Lemma 11.8, partial minimization over the first j steps gives $M^{-j}E_{d_0+j}$. At $\theta = 0$, let δz_j be a free tangent vector of step j, let δc_{j+1} be the induced tangent vector of the next coarser field, and set

$$\eta_j = \delta z_j - Dz^*_{d_0+j}(I)[\delta c_{j+1}].$$

We complete the square at each step. The critical equation of the conditional minimizer removes the mixed term, and differentiating the identity of part (1) gives the remaining term. We obtain the Hessian of this function at $\theta = 0$, $z = 0$:

$$\sum_{j=0}^{J-1} M^{-j} \langle \eta_j, K^0_{d_0+j} \eta_j \rangle, \qquad \delta c_J = 0, \tag{11.22}$$

where $K^0_{d_0+j}$ are the constrained Hessians of Theorem 10.10 at the identity. For a quadratic form $\langle z, Kz\rangle/2 + \langle z, Bc\rangle + \langle c, Dc\rangle/2$, the derivative of the minimizer is $-K^{-1}B$. Substituting $z = \eta - K^{-1}Bc$ leaves $\langle \eta, K\eta\rangle/2 + \langle c, (D - B^{\mathsf{T}}K^{-1}B)c\rangle/2$, where the last matrix, the Schur complement, is the Hessian of the partially minimized value. Iterating gives (11.22). In particular, the blocks are $M^{-j}K^0_{d_0+j}$, not $K^0_{d_0+j}$.

The map from (δz_j) to (η_j) is triangular with identity diagonal. Its inverse is given by backward substitution and involves only finitely many compositions of the mixed derivatives of the minimizers and of the geometric one-step maps. By their row and column bounds in Theorems 10.10 and 10.11, the rows and columns of the inverse are bounded by C_J. Its ℓ^2 norm is then at most C_J, since by the Cauchy–Schwarz inequality

$$\|Tv\|_2^2 \le \Big(\sup_x \sum_y |T_{xy}|\Big)\Big(\sup_y \sum_x |T_{xy}|\Big)\|v\|_2^2.$$

Since $K^0_{d_0+j} \geq m_0 I$, the Hessian (11.22) is bounded below by $m_0 M^{-(J-1)} C_J^{-2} I$. By the bounds on third derivatives for fixed J, with each external index fixed in turn, the Hessian at (θ, z) differs from this one by at most $C_J(\|\theta\|_\infty + \max_j \|z_j\|_\infty)$ in row and column norm. We reduce the radius for this fixed J so that this is less than half the lower bound. Then the function is strictly convex on a smaller real convex ball of coordinates, uniformly in d_0 and m.

The successive conditional constrained minimizers give a critical point of this function. Indeed, at the first minimizer the derivative in its free variables vanishes. The derivative in the remaining variables is the derivative of $M^{-1}E_{d_0+1}$, whose derivative in the next free variables vanishes at its minimizer, and so on through the J steps. This critical point corresponds to $\widehat{c}_0(\theta) = \mathscr{C}_{\mathrm{raw}\, d_0, J}(\theta, 0)$. On the other hand, by part (2) of Lemma 11.8, $C_{d_0,J}(\theta)$ is a gauge transform of $\widehat{c}_0(\theta)$, by a gauge transformation whose restriction to the coarse vertices fixes e^θ. Since $\widehat{c}_0(\theta)$ is critical for E_{d_0} on the fiber $\{T^J_M V = e^\theta\}$ and E_{d_0} is gauge invariant on D_ρ (Theorem 11.6), so is $C_{d_0,J}(\theta)$. The gauge transformation $F_J(\theta)$ is the identity at the coarse vertices and preserves this criticality. The field $C_{d_0,J}(\theta)^{F_J(\theta)}$ satisfies the block axial gauge condition at every level. It is therefore the reconstruction of the step from θ and some free coordinates z, and it is a critical point of the function above. It lies in the ball of strict convexity when r_J is small, because it equals the identity at $\theta = 0$ and its coordinates have rows bounded for fixed J. By strict convexity, it is the unique critical point, so

$$C_{d_0,J}(\theta)^{F_J(\theta)} = \widehat{c}_0(\theta) = \mathscr{C}_{\mathrm{raw}\, d_0, J}(\theta, 0)$$

for real θ. The identity extends to the complex ball by the coordinatewise uniqueness argument of Lemma 11.4. Thus F_J^{-1} is the gauge transformation, depending only on θ and equal to the identity at the coarse vertices, that takes the zero-fluctuation reconstruction to the representative $C_{d_0,J}$. The gauge transformations F_J, F_J^{-1} have the bounds of item (5). We shrink r_J inside a larger domain on which these bounds hold, so that they remain available later. Their constants depend only on M, J, and the chosen domains and rates, never on d_0, m, L, or γ. The constants r_{cen}, a_{cen}, and C_{cen} were fixed without them, so the constants of item (5) are not used to choose J. □

11.5 Contraction of the interaction under the classical background field

In the renormalization group step of Section 13, the effective interaction R of the fine lattice is evaluated at the classical background field of the step. We show that this evaluation contracts the weighted analytic norm by a factor $O(\delta)$, $\delta = M^{-J}$, at the same radius and the same decay rate. A term of degree k in the link logarithms ξ of the fine lattice, evaluated at $\xi = \delta A$ with A of order one, gains δ^k. The sum over the position of a fixed fine index, measured against the coarse lattice, contributes a factor δ^{-3}. Terms

of degree at least four therefore gain $\delta^{k-3} \leq \delta$. The quadratic and cubic terms need additional cancellations. Gauge invariance and spatial inversion make the quadratic term a quadratic form in first differences of ξ, up to an exponentially small finite-period remainder. Each first difference of δA gains an extra factor δ. Spatial inversion and translation invariance make the first derivative of the cubic term vanish at fields that are constant in each orientation, which yields one first difference. This use of gauge invariance is standard in renormalization group analyses of gauge theories; we prove the absolute kernel factorization, the cubic cancellation, and the composition estimate at unchanged radius below.

We use the following notation. On the fine lattice of side $q = m/\delta$, in units in which its spacing is one, ∇ denotes the collection of all componentwise first differences of link fields, $(\nabla v)_{\ell,i}(x) = v_i(x + e_\ell) - v_i(x)$ for each direction ℓ and each orientation and color component i. Its adjoint is ∇^*. We write grad for the lattice gradient from vertex fields to link fields, $(\operatorname{grad}\lambda)_{xy} = \lambda_y - \lambda_x$, and I for spatial inversion acting on link fields, $(\mathsf{I}v)_i(x) = -v_i(-x - e_i)$, as in Lemma 8.6. For a link logarithm ξ and a vertex field λ, let $\mathcal{D}_\xi\lambda$ be the infinitesimal gauge variation, that is, the derivative of $t \mapsto \operatorname{Log}\big((e^{\xi})^{e^{t\lambda}}\big)$ at $t = 0$; then $\mathcal{D}_0\lambda = -\operatorname{grad}\lambda$. In this section the letter q denotes the side of the fine lattice; the plaquette energy $q(U)$ does not occur. For a translation-invariant kernel K, $\|K\|_{b,\mathrm{row}+\mathrm{col}}$ denotes the sum of its weighted absolute row and column norms at rate b, using the periodic Euclidean distance between initial vertices, consistently with Definition 4.6. The sum convention agrees with Lemma 8.6; that lemma uses the periodic ℓ^1 distance instead, so its rate must be converted when we apply it. These kernels act on a single lattice, so their columns carry no volume factor. For the same distance, the sum lies between the maximum of the row and column norms, used in Sections 4, 14, and 31, and twice that maximum; in particular, the upper bounds on the sum proved below also hold for the maximum.

Theorem 11.10. *Let a_* be the decay rate of Theorem 10.11 and fix $0 < a < a_*/8$. There exist $\rho_0(a), \delta_0(a), C_P(a) > 0$, depending on a and on the fixed classical data (including M), and independent of the later choice of $0 < \rho \leq \rho_0$, of J, of d_0, and of the side of the lattice, with the following property. Let $\delta = M^{-J} \leq \delta_0$, let $m \geq 4$ be the side of the coarse lattice, so that the fine lattice of the renormalization group step has side m/δ. Let R be a scalar function, holomorphic in the logarithms ξ of the fine link variables on $\|\xi\|_\infty < \rho$, such that*

$$DR(I) = 0, \qquad \mathcal{B}_{\rho,a}(R) \leq \epsilon,$$

and such that R is invariant under translations of the fine lattice, under constant gauge transformations, and under spatial inversion, and satisfies the infinitesimal gauge-invariance identity $DR(\xi)[\mathcal{D}_\xi\lambda] = 0$ for all ξ in its domain and all vertex fields λ. These hypotheses concern the function R as a whole, not the individual terms of an expansion of R.

1. *Set $w_q = (1+q)^3 e^{-c_a q}$, where $c_a > 0$ is fixed using part of the spatial decay rate. Then, exactly on the finite torus,*

$$D^2 R(I) = \nabla^* W \nabla + \mathsf{E}_{\mathrm{per}},$$
$$\|W\|_{a/2,\mathrm{row+col}} \le C_a \epsilon, \qquad \|\mathsf{E}_{\mathrm{per}}\|_{a/2,\mathrm{row+col}} \le C_a \epsilon w_{m/\delta}.$$

2. *Let R_3 be the cubic term of the Taylor expansion of R at I. The first derivative of R_3 vanishes at every field that is constant in each orientation and color component, and it has the exact representation through first differences along coordinate paths given in* (11.26) *and* (11.27) *below.*
3. *Let $e^{\delta A_{d_0,J}(\theta)}$ be the representative $D_0(\theta)$ of the gauge orbit of the classical background field of the step from Section 11.4, with the bounds of Theorem 10.11 on the output rows and volume-normalized columns of $(A_{d_0,J}, \nabla_\delta A_{d_0,J})$. Assume that the image of $\|\theta\|_\infty \le 2\rho$, measured by absolute Taylor series, lies in the ball of radius $\rho/2$ of fine link logarithms; a sufficient condition is $\delta Z(2\rho) \le \rho/2$, where $Z(u) \le Cu/(1-Cu)$ is the majorant series of $(A_{d_0,J}, \nabla_\delta A_{d_0,J})$. Set $\mathcal{P}_\delta R(\theta) = R(e^{\delta A_{d_0,J}(\theta)})$. Then*

$$\mathcal{B}_{\rho,a}(\mathcal{P}_\delta R) \le C_a[\delta + \delta^{-1} w_{m/\delta}] \mathcal{B}_{\rho,a}(R) \le C_P(a)\delta\, \mathcal{B}_{\rho,a}(R).$$

   The radius ρ and the rate a are the same on both sides; in the norm of R distances are measured in units of the fine lattice, and in the norm of $\mathcal{P}_\delta R$ in units of the coarse lattice. The constant $C_P(a)$ includes the bound on the finite-period remainder, uniformly for $m \ge 4$.
4. *More generally, let $e^{\delta \widetilde{A}(\theta)}$ be another representative of the gauge orbit of the classical background field of the step (for instance one satisfying $T_M^J(\cdot) = e^\theta$ exactly), holomorphic on $\|\theta\|_\infty < \widetilde{r}$, and suppose that for some rate $b > 8a$ the output rows and the volume-normalized columns, with one fixed coarse input and output volume δ^3, of the Taylor coefficients at $\theta = 0$ of $(\widetilde{A}, \nabla_\delta \widetilde{A})$ are dominated at rate b by a series $\widetilde{Z}(u) \le \widetilde{C}u/(1-\widetilde{C}u)$ and by its derivative $\widetilde{Z}'$, where $\widetilde{r}$ and $\widetilde{C}$ do not depend on J, d_0, or m. Then the conclusion of item (3) holds with $e^{\delta \widetilde{A}}$ in place of $e^{\delta A_{d_0,J}}$, provided $2\rho_0 < \widetilde{r}$ and the image condition holds with $\widetilde{Z}$ in place of Z. The constants ρ_0, δ_0, and C_P then depend also on b, $\widetilde{C}$, and $\widetilde{r}$, and they remain independent of J, d_0, m, and of the later choice of $\rho \le \rho_0$. No conclusion is asserted at output rates $a \ge b/8$. The equality of $\mathcal{P}_\delta R$ with the evaluation of R at a specified reconstruction in block axial gauge coordinates requires, in addition, either a real gauge path inside the domain of R connecting the two representatives, or the invariance of R under the gauge transformations between overlapping charts.*

We record the application to the representative $C_{d_0,J}$ of Lemma 11.9. By items (2) and (4) of that lemma, $C_{d_0,J}$ satisfies the hypotheses of item (4) with $b = a_{\mathrm{cen}}$, $\widetilde{Z} = Z$, and $\widetilde{r} = r_{\mathrm{cen}}$. For $C_{d_0,J}$, the theorem therefore gives the estimate of item (3) at every output rate $0 < a < a_{\mathrm{cen}}/8$, and at no larger rate. Since $a_{\mathrm{cen}} < a_*/32$, such an a also satisfies $a < a_*/8$, and the estimate for D_0 holds at the same rate. To treat both representatives

with one set of constants, let $0 < a < a_{\mathrm{cen}}/8$ and $2\rho_0 < \min(r_{\mathrm{cen}}, r_*)$, where r_* is the radius of Theorem 10.11. We use one enlarged majorant $Cu/(1-Cu)$ at rate a_{cen} for both pairs; the bounds of Theorem 10.11 at rate a_* imply the same bounds at the smaller rate a_{cen}. Finally, δ_0 is chosen so that the image condition holds for both pairs for every $\rho \le \rho_0$. Steps 3–9 of the proof then give constants independent of J, d_0, and m for both representatives, before J is chosen. This is the form in which the theorem is used in Theorem 13.5. The proof of item (1) rests on the following kernel factorization, which strengthens the quadratic-form bound of Lemma 8.6 to a factorization with exponentially decaying kernels.

Lemma 11.11. *Fix $a > 0$ and a finite number of color components. Let $q \ge 4$, and let H be a real self-adjoint translation-invariant kernel on the link fields of the periodic lattice of side q such that*

$$H \operatorname{grad} = 0 = \operatorname{grad}^{\mathsf{T}} H, \qquad H\mathsf{I} = \mathsf{I}H, \qquad \|H\|_{a,\mathrm{row+col}} \le b.$$

Then there exist translation-invariant kernels W and E such that, exactly on the torus of side q,

$$H = \nabla^* W \nabla + \mathsf{E}, \qquad \|W\|_{a/2,\mathrm{row+col}} \le C_a b, \qquad \|\mathsf{E}\|_{a/2,\mathrm{row+col}} \le C_a b w_q.$$

The differences act on every orientation and color component, and the constants depend only on a, the fixed dimension, and the norm conventions, not on q, H, or b. The conclusion also holds for a complex symmetric kernel whose real and imaginary parts satisfy these hypotheses.

Proof. A bound on the quadratic form would not suffice here, since we need a factorization of the kernel. We write $h_{ij}(r)$ for the translation kernel, with color indices suppressed, and attach each positive link to its lower endpoint. The midpoint displacement of this entry is $p = r + (e_j - e_i)/2$. We lift it from the torus by its shortest representatives, splitting tied representatives equally, and use opposite lifts for the entry related by inversion. Since spatial inversion gives $h_{ij}(r) = h_{ij}(-r + e_i - e_j)$, this midpoint interpolation is even. It preserves every allowed Fourier sample: two lifts differ by qz with $z \in \mathbb{Z}^3$, and $e^{\mathrm{i}k\cdot qz} = 1$ at the allowed frequencies k. The lifted integer coefficients, attached to lower endpoints, have absolute exponentially weighted sum at most $C_a b$, since moving an endpoint to a midpoint changes distances by a fixed amount. We denote by $H(k)$ the trigonometric interpolation of the lower-endpoint coefficients and by $\widetilde{H}(k)$ that of the midpoint coefficients. Entrywise,

$$\widetilde{H}_{ij}(k) = e^{\mathrm{i}k\cdot(e_j-e_i)/2} H_{ij}(k), \qquad D_\ell \widetilde{H}(0) = 0,$$

so $D_\ell H_{ij}(0) = -\mathrm{i}(e_j - e_i)_\ell H_{ij}(0)/2$. Write d_2 and d_1 for the periodic Euclidean and ℓ^1 distances. Since $d_2 \le d_1 \le \sqrt{3} d_2$, the hypothesis at Euclidean rate a implies the same kernel bound at ℓ^1 rate $a/\sqrt{3}$. Applying the estimate on the Fourier block at zero frequency in part (1) of Lemma 8.6 at that rate, with $c_a = c(a/\sqrt{3}) > 0$ in w_q, we obtain

$$\|H(0)\| + \sum_{\ell} \|D_\ell H(0)\| \le C_a b w_q. \tag{11.23}$$

Since the symmetric choice of lifts preserves self-adjointness, $H(k)$ and its derivatives are Hermitian at real k. We set

$$E(k) = H(0) + \sum_{\ell=1}^{3} \sin(k_\ell) D_\ell H(0).$$

This is a Hermitian trigonometric polynomial of range one with the same value and first derivatives at zero as H, and its kernel norm is at most $C_a b w_q$. Let $h'(r)$ be the finitely supported lifted coefficients of $H - E$. They satisfy the two exact moment cancellations $\sum_r h'(r) = 0$ and $\sum_r r_\ell h'(r) = 0$.

Next, we divide by two differences, with an absolute bound. Let $t_i = e^{\mathrm{i}k_i}$ and $z_i = t_i - 1$. For each integer m, we write $t^m - 1 = z S_m(t)$ and $t^m - 1 - mz = z^2 B_m(t)$. For $m \geq 0$,

$$S_m(t) = \sum_{j=0}^{m-1} t^j, \qquad B_m(t) = \sum_{j=0}^{m-2} (m-1-j) t^j,$$

with empty sums equal to zero, and for $m = -p < 0$,

$$S_{-p}(t) = -\sum_{j=1}^{p} t^{-j}, \qquad B_{-p}(t) = \sum_{j=1}^{p} (p-j+1) t^{-j}.$$

Multiplying by $t - 1$, respectively $(t-1)^2$, we verify all four identities term by term. The sums of the absolute coefficients are at most $|m|$ and $C(1+|m|)^2$. We now telescope $t^r - 1 = \sum_i (t_i^{r_i} - 1) \prod_{j<i} t_j^{r_j}$. Substituting $t_i^{r_i} - 1 = r_i z_i + z_i^2 B_{r_i}(t_i)$ and telescoping each $\prod_{j<i} t_j^{r_j} - 1$ in the same way, we obtain

$$t^r - 1 - \sum_i r_i z_i = \sum_{i,j} z_i z_j P_{r,ij}(t). \tag{11.24}$$

The sum of the absolute coefficients of all $P_{r,ij}$ is at most $C(1+|r|)^2$: the pure terms contribute $\sum_i C(1+|r_i|)^2$ and the mixed terms $\sum_{j<i} |r_i||r_j|$. Their supports lie in the coordinate box from 0 to r, enlarged by a fixed distance, so their displacements are at most $|r| + C$ in the usual lattice metrics, with a fixed comparison of metrics absorbed in the constants.

By the moment cancellations, we may apply (11.24) termwise in $\sum_r h'(r) t^r$. The unused half of the exponential weight absorbs the factor $(1+|r|)^2$, since $\sup_{u \geq 0} (1+u)^2 e^{-au/2} < \infty$. Hence the coefficients in $H - E = \sum_{i,j} z_i L_{ij} z_j$ have weighted absolute sum at most $C_a b$ at rate $a/2$. Since $z_i = -t_i(t_i^{-1} - 1)$, setting $W_{ij} = -t_i L_{ij}$ gives $H - E = \nabla^* W \nabla$. Hermitian symmetrization of W preserves this identity and its bound. We periodize these kernels. Their Fourier samples, and hence their kernels, agree exactly with those of the original operator on the torus. Periodization does not increase the periodic weighted

absolute sums, because each distance on the torus is at most the distance of its lift. Taking E to be the periodized kernel of E proves the lemma. For a complex kernel, we apply the argument to the real and imaginary parts, each of norm at most b, and add the two factorizations. □

Proof of Theorem 11.10. We first prove the two cancellations, items (1) and (2), then the composition estimate of item (3), and finally item (4). Throughout, the norm of R is taken in units of the fine lattice, and $q = m/\delta$.

Step 1: the quadratic term. We subtract the constant $R(I)$, which does not enter $\mathcal{B}_{\rho,a}$, and write $T_k = D^k R(I)$ in the logarithmic coordinates of the fine lattice. By the definition of $\mathcal{B}_{\rho,a}$, we have

$$\frac{1}{k!}\|T_k\|_{a,\mathrm{root}} \le \epsilon\rho^{2-k} \qquad (k \ge 2). \tag{11.25}$$

We differentiate the identity $DR(\xi)[\mathcal{D}_{\tilde\xi}\lambda] = 0$ in $\tilde\xi$ at $\tilde\xi = 0$. The term containing the derivative of $\mathcal{D}_{\tilde\xi}\lambda$ is multiplied by $DR(0) = 0$, and we are left with $T_2\,\mathrm{grad} = 0 = \mathrm{grad}^{\mathsf{T}}\,T_2$. Translation invariance and invariance under spatial inversion give the remaining hypotheses of Lemma 11.11, with $b \le C\epsilon$. Since both norms use the periodic Euclidean distance, the constant accounts only for the color components and for adding the row and column bounds. For a complex-valued R, the real and imaginary parts of the coefficients satisfy the same linear identities. Lemma 11.11 then implies the factorization and the remainder bound in item (1). Its constant c_a is fixed in that proof from the rate $a/\sqrt{3}$ in Lemma 8.6, and is independent of all later radii.

Step 2: the cubic term. Let $R_3(\xi) = T_3[\xi,\xi,\xi]/6$. By linearity of I and of the translations, R_3 has the same invariances as R. On a field a that is constant in each orientation and color component, spatial inversion acts as $\mathsf{I}a = -a$. Hence $R_3(a) = R_3(-a) = -R_3(a)$, and $R_3(a) = 0$. By translation invariance, the first derivative of R_3 at such a field is the same at every link of a given orientation and color component. Differentiating the vanishing restriction with respect to one constant component gives q^3 times this common value, which therefore vanishes. We conclude that $DR_3(a) = 0$ at every link. For a link e with lower endpoint x_e, let $a_i = \xi_i(x_e)$ and let a be the corresponding constant field. Subtracting $DR_3(a) = 0$, we obtain componentwise the exact identity

$$(DR_3(\xi))_e = \frac{1}{2}\sum_{f,g}(T_3)_{efg}(\xi_f\xi_g - a_{i_f}a_{i_g}), \tag{11.26}$$

where i_f is the orientation of the link f and the products denote the bilinear color contractions with the tensor. We expand the bracket as $(\xi_f - a_{i_f})\xi_g + a_{i_f}(\xi_g - a_{i_g})$. For a coordinate path $x_0 = x_e, x_1, \dots, x_l = x_f$ on the fine lattice,

$$\xi_f - a_{i_f} = \sum_{j=0}^{l-1}(\xi_{i_f}(x_{j+1}) - \xi_{i_f}(x_j)). \tag{11.27}$$

We use shortest coordinate displacements on the torus, with one fixed choice in case of ties. The path and its reverse stay within a fixed multiple of the length of a shortest network connecting the three links. Together with Euler's identity $3R_3 = \sum_e \xi_e (DR_3)_e$, (11.26) and (11.27) are the representation asserted in item (2).

Step 3: majorants of the background field and power counting. We write $A = A_{d_0,J}$. For real θ, this is the potential of the representative of item (3); for complex θ, we use its holomorphic continuation and make no variational comparison. By Theorem 10.11, the Taylor tensors of $(A, \nabla_\delta A)$ have output rows, and columns with one fixed coarse input and output volume δ^3, that are dominated at a decay rate larger than the one used here by one series

$$Z(t) \le \frac{Ct}{1 - Ct}, \qquad A(0) = \nabla_\delta A(0) = 0. \tag{11.28}$$

We enlarge C to cover both members of the pair and the finitely many orientation and color types. The derivative $Z'(t)$ bounds the series with one fixed coarse input, because a Taylor coefficient of order s then has denominator $(s-1)!$ instead of $s!$.

We expand each vertex $T_k[\xi, \dots, \xi]/k!$, with $\xi = \delta A(\theta)$, and replace each argument by its Taylor series in θ. Lemma 11.1 implies that the resulting absolute coefficients are controlled by products of the argument series, with no factorials beyond those of the Taylor coefficients, for any fixed external index. For the spatial and volume bookkeeping, at a vertex we fix the relative positions of its fine indices and sum the remaining position with the fixed-index coefficient bound of T_k. We use output rows for every argument except the one containing the fixed coarse input; for that argument, its volume-normalized column bounds the sum over the translated fine index by $\delta^{-3} Z'(t)$. Since the union of the network of the coefficient and the networks of the arguments connects all external coarse indices, the external weight is at most the product of the weights. A fine displacement has length δ times its length in fine units. Let δ_0 be smaller than a fixed geometric constant, so that half of the fine weight remaining after a polynomial or path moment controls the same output rate a. The networks of the arguments need only the rate a, which is smaller than the rate a_* of their bounds, since $a < a_*/8$. Any enlargement caused by coordinate paths is absorbed by decreasing this fixed δ_0, independently of the order. In particular, no decay rate depends on the number of Taylor inputs. Table 11.2 summarizes the resulting powers of δ, which are verified in Steps 4–6.

Step 4: the quadratic contribution. A first difference of $\xi = \delta A$ over one fine step, in fine units, is exactly δ^2 times a component of $\nabla_\delta A$, translated and with a sign if the step is negative. The two difference factors in $\nabla^* W \nabla$ therefore supply δ^4, and the single sum over a fine index supplies δ^{-3}. We find that the quadratic contribution to the series with one fixed coarse input is at most $C_a \epsilon \delta Z(t) Z'(t)$. Since the finite-period remainder has two undifferentiated factors δA, it contributes $C_a \epsilon \delta^{-1} w_q Z(t) Z'(t)$.

Contribution	Field factors	Sum over a fine index	Result
Quadratic term, two differences	$\delta^2 \cdot \delta^2$	δ^{-3}	δ
Cubic term, one difference	$\delta^2 \cdot \delta \cdot \delta$	δ^{-3}	δ
Degree $k \geq 4$	δ^k	δ^{-3}	δ^{k-3}
Finite-period remainder	$\delta \cdot \delta \cdot w_{m/\delta}$	δ^{-3}	$\delta^{-1} w_{m/\delta} = O(\delta)$

Table 11.2. Powers of $\delta = M^{-J}$ in the proof of Theorem 11.10.

Step 5: the cubic contribution. In the representation of Step 2, the factor given by (11.27) supplies $\delta^2 \nabla_\delta A$, and the two other field factors supply δ^2. The counting column again supplies δ^{-3}. The length of the path and the number of its vertices are absorbed by a polynomial moment of the unused fine weight, since $l \leq C(1 + \mathrm{t})$. If the fixed coarse derivative falls on one of the undifferentiated factors, we use the column of that factor. If it falls on the difference factor, we first fix the relative fine configuration and the position along the path, and then translate the summed fine index to that vertex of the path. This translation is a bijection of the periodic lattice. Translation invariance of T_3 leaves the coefficient unchanged, and the same column with volume δ^3 controls the sum. By (11.25), we find the bound $C_a \epsilon \delta \rho^{-1} Z(t)^2 Z'(t)$, for every choice of the fixed external input.

Step 6: terms of degree at least four. No cancellation is needed. The k field factors and the one counting column give exactly δ^{k-3}. The vertex is bounded by (11.25), and the fixed derivative can fall on any of the k slots. Thus these terms are bounded by

$$C_a \epsilon \delta \rho^{-2} Z(t)^3 Z'(t) \sum_{k \geq 4} k \big(\delta Z(t)/\rho\big)^{k-4}.$$

Combining Steps 4–6, we find that the majorant $\mathcal{D}(t)$ of the series of the composed function with one fixed coarse input satisfies

$$\mathcal{D}(t) \leq C_a \epsilon \delta \Big\{ Z Z' + \rho^{-1} Z^2 Z' + \rho^{-2} Z^3 Z' \sum_{k \geq 4} k (\delta Z/\rho)^{k-4} \Big\} + C_a \epsilon \delta^{-1} w_q Z Z', \qquad (11.29)$$

where all series are evaluated at t. We used only symmetries of the tensors T_k, never symmetries of an individual term of an expansion of R.

Step 7: summation. Let $\rho_0(a) > 0$ lie inside the domain of Theorem 10.11 and satisfy $Z(2\rho) \leq C_1 \rho$ and $Z'(\rho) \leq C_1$ for $0 < \rho \leq \rho_0$. Let $\delta_0(a)$ be smaller than the geometric threshold of Step 3 and satisfy $\delta_0 C_1 \leq 1/2$. Through the sufficient condition $\delta Z(2\rho) \leq \rho/2$, these choices give the image condition of item (3) simultaneously for all later $\rho \leq \rho_0$. At $t = \rho$, the series in (11.29) converges, because $\delta Z(\rho)/\rho \leq 1/2$. Since $DR(I) = 0$ and $A(0) = 0$, we also have $D\mathcal{P}_\delta R(0) = 0$. Since a coefficient of order s with one fixed input

has denominator $(s-1)!$, the series $\rho^{-1}\mathcal{D}(\rho)$ dominates $\sum_{s\geq 2}\rho^{s-2}\|D^s\mathcal{P}_\delta R(0)\|_{a,\mathrm{root}}/s!$. Using $Z(\rho)\leq C_1\rho$ in each term of (11.29), we obtain

$$\mathcal{B}_{\rho,a}(\mathcal{P}_\delta R)\leq C_a(\delta+\delta^{-1}w_{m/\delta})\epsilon.$$

These constants do not depend on the later reduction of ρ. Replacing ϵ by $\mathcal{B}_{\rho,a}(R)$ gives the first inequality of item (3); the case $\mathcal{B}_{\rho,a}(R)=0$ follows by continuity.

Step 8: the finite-period remainder. Since $q=m/\delta\geq 4/\delta$,

$$\delta^{-2}w_q\leq\frac{1}{16}q^2(1+q)^3e^{-c_aq}\leq C_a.$$

The last supremum is finite, for example because $q^je^{-c_aq}\leq j!c_a^{-j}$ by the exponential series. Thus $\delta^{-1}w_q\leq C_a\delta$, uniformly for $m\geq 4$, and we enlarge $C_P(a)$ to include this constant. This proves the second inequality of item (3).

Step 9: other representatives. About the representative, Steps 3–8 used only its domain of holomorphy, the output rows and volume-normalized columns of $(A,\nabla_\delta A)$, their majorant Z, and the fact that these bounds hold at a rate larger than $8a$. Repeating Steps 3–8 with $\widetilde{A}$, $\widetilde{Z}$, $\widetilde{r}$, and the rate $b>8a$ in place of A, Z, r_*, and a_*, we obtain the estimate in item (4), with constants depending on these data and independent of J, d_0, and m. To compare with the evaluation of R at a specified reconstruction, we integrate the infinitesimal gauge-invariance identity along a real gauge path inside the domain of R. Even if the path is only continuous, at each of its points the strict margin of the domain allows all sufficiently small exponential gauge increments. Integrating the identity along each such increment, we find that R is constant on that neighborhood in the gauge variable. Continuity of the path and a finite subcover of its parameter interval identify the values at the two endpoints, and their holomorphic continuations agree by the uniqueness argument of Lemma 11.4. Alternatively, invariance of R under the gauge transformations between overlapping charts identifies the values at the two real endpoints directly. Neither conclusion follows from the bound on the image alone, which concerns only $e^{\delta A}$. This proves item (4). □

PART IV

Fluctuation integration and conditional measures

SECTION 12

Fluctuation integration and cluster expansions

In this section, we integrate out the fluctuations of a bounded number of averaging steps around the classical background field. We consider $s \leq J$ consecutive averaging steps, from a lattice of side $M^s m$ to a coarse lattice of side $m \geq 4$, starting from the effective classical action E_{d_0} of some depth $d_0 \geq 0$; for $s = J$ this is one renormalization group step. Given a coarse field c, the fine configurations whose average is c are described by free logarithmic coordinates at each intermediate scale. We center these coordinates at the conditional constrained minimizer, normalize them by the coupling and the constrained Hessian, and integrate the resulting normalized fluctuation variables w over a fixed product Ω_p of three-dimensional balls.

There are three main results. The first is an exact formula for this integral, for one averaging step in Lemma 12.3 and for $s \leq J$ averaging steps in Theorem 12.13. The second is a convergent polymer expansion of the logarithm of the fluctuation partition function, with volume-independent bounds on all its derivatives of positive order (Theorems 12.6 and 12.7 and Proposition 12.10). The third, Lemma 12.16, concerns an input effective interaction R, produced by the integrations at finer scales. It shows that integrating out the fluctuations replaces R by its value on the zero-fluctuation reconstruction plus a correction of second order in the coupling. We do not estimate the probability of the domain of integration under the Wilson measure here; this is done in Section 23.

We use the conventions of Section 4, the absolute coefficient calculus of Lemma 5.3, the constraint coordinates and the exact Haar disintegration of Lemma 6.3, and the conditional constrained minimizers, the nested minimization identity, and the coefficient bounds for E_d of Theorems 10.10 and 10.11. In Section 13, the results are used to construct the renormalization group recursion on the small-field event and to describe the conditional fluctuation kernel; they are also used in Sections 14, 15, and 23. Sections 18 and 20 reuse the triangular change of variables and the graph combinatorics, and Sections 31, 33, and 35 use the coordinates of Theorem 12.13 and its dimension counts.

The integral over one averaging step. We first describe the identity of Lemma 12.3 informally. Let $b(c, z)$ be the fine configuration with average c and free logarithmic coordinates z, and let $F(c, z) = E_{d_0}(b(c, z))$. Let $z^*(c)$ be the minimizer of $F(c, \cdot)$ and $K(c) = D_z^2 F(c, z^*(c))$ the constrained Hessian. The substitution

$$z = z^*(c) + gK(c)^{-1/2} w$$

has Jacobian $g^{3f} \det K(c)^{-1/2}$, where $3f$ is the number of real free logarithmic coordinates. Since z^* is stationary and $K^{-1/2} K K^{-1/2} = I$, we have

$$\frac{F(c,z)}{g^2} = \frac{F(c,z^*(c))}{g^2} + \frac{1}{2}|w|^2 + O(g|w|^3),$$

and $F(c,z^*(c))/g^2 = E_{d_0+1}(c)/(Mg^2)$ by the nested minimization identity. The Haar density of the free logarithmic coordinates is a reference constant times $e^{-\mathcal{L}_c(z)}$, and $\mathcal{L}_c(z) = \mathcal{L}_c(z^*(c)) + O(g|w|)$. Thus the integral over $w \in \Omega_p$ is the product of three factors that depend on c (the exponential of the effective classical action at the coarse scale, the determinant $\det K(c)^{-1/2}$, and the Haar density at the minimizer) and of the integral of $e^{-|w|^2/2 - U(c,w)}$, where U is small on Ω_p. The determinant and the Haar density at the minimizer become part of the effective interaction as functions of c, and $E_{d_0+1}/(Mg^2)$ remains a separate term. We control the integral of $e^{-|w|^2/2-U}$ by a polymer expansion about the product of truncated Gaussian measures on the balls. This product is only a reference measure. The conditional law of w, the conditional fluctuation kernel studied in Section 13, has density proportional to $e^{-|w|^2/2-U}$.

For several averaging steps the change of variables is triangular, from the coarsest intermediate scale to the finest. The minimizers, Hessians, and Haar densities at a finer scale depend on the fluctuations at all coarser scales, and the exact formula of Theorem 12.13 keeps these dependences.

Organization. Section 12.1 defines the coefficient norms and proves the exact formula for one averaging step. Section 12.2 proves the cluster expansion in an absolute coefficient algebra, in a form that applies to arbitrary interactions with connected supports. Section 12.3 constructs connected supports for the interaction of one averaging step and estimates the resulting effective interaction. Section 12.4 treats $s \le J$ averaging steps, and Section 12.5 treats an input effective interaction. The order in which the constants are chosen is summarized in Remark 12.17.

Conventions. All results of this section concern the periodic torus without a fixed complement. Distances are measured in units of the coarse lattice spacing. Unless stated otherwise, constants in the statements about one averaging step have the dependence described in item (2) of Definition 4.14. That is, they depend only on M, on the fixed larger domains of the classical and Haar disintegration charts, and on fixed radius ratios, spatial decay rates, and norm bounds. They are independent of the depth d_0, of the side m, and of the coupling and cutoff parameters satisfying the stated inequalities. For $s \le J$ averaging steps, the constants may also depend on J, on the finitely many changes of scale between the lattices involved, and on the fixed box geometry, and no uniformity as $J \to \infty$ is claimed. Every factor that is independent of the field, and every factor that depends only on the coarse field, is kept explicitly in the formulas.

We recall the coefficient norms of Definition 4.6. A tensor is bounded *at every fixed index* if, at the spatial decay rate b, its output-fixed absolute row sum and each of its input-fixed absolute column sums, the latter with the volume normalization of Definition 4.6, are bounded. Every sum carries the weight $e^{b\mathsf{t}}$, where t is the length of a shortest connected network joining the locations of all indices of the coefficient; internal vertices are allowed. For a scalar function, we fix any one input index and sum over the others with the same weight, and we write $\|\cdot\|_{b,\mathrm{root}}$ for the resulting norm of a derivative tensor. Scalar values are never included in these norms. A *majorant series* of a family of tensors is a power series with nonnegative coefficients that dominate the corresponding sums of absolute coefficients.

Attribution. The organization of the integral into an effective classical action and connected local fluctuation terms follows Bałaban's renormalization group analysis of lattice gauge theories [17, 19]; its three-dimensional antecedent is the stability analysis in [15]. We adapt this organization to the block averaging map, the constraint coordinates, and the truncated domains used here, and we prove the expansion below. In particular, we do not use the four-dimensional coupling renormalization of [17]. The cluster expansion combines the Mayer expansion with a convergence criterion of the type of Kotecký and Preiss [120]. The bound on connected graph sums by spanning trees comes from Penrose's partition [136], in the form described by Fernández and Procacci [87, Section 4.1]; see also Brydges' exposition [38]. Dimock records the finite graph estimate in the constructive renormalization group setting [68, Appendix B, Theorem 27, p. 39, and (323), p. 42]. His analysis concerns a scalar field, and no other result of [68] is used. The weighted resolvent bounds use the Combes–Thomas method [61], as in Lemma 5.3.

12.1 Coefficient norms and normalized fluctuation coordinates

Definition 12.1. Let $\mathscr{L} \geq 1$ be an integer, the box scale; it is unrelated to the side length L of the torus. Partition each periodic coordinate direction of the coarse lattice into integer intervals of lengths between $\mathscr{L}$ and $2\mathscr{L}$; a direction that is too short for such a partition forms a single interval. The products of these intervals are the *boxes*. A *support* is a nonempty connected set X of boxes; sets that wind around the torus are allowed, and $|X|$ denotes the number of boxes in X. A function is *supported in* X if it depends only on coordinates θ and w (or θ and q, when those variables are used) whose locations lie in X.

For a convergent series $f(\theta, w) = \sum_\nu f_\nu(w)\theta^\nu$ in the coarse-field coordinates θ, whose coefficients are functions of w on a fixed product Ω_p, and for a family $\{f_X\}$ indexed by supports, set

$$\|f\|_{u,\mathrm{coeff};p} = \sum_\nu u^{|\nu|} \sup_{w\in\Omega_p} |f_\nu(w)|, \qquad \|\{f_X\}\|_{u,\kappa;p} = \sup_x \sum_{X\ni x} e^{\kappa|X|}\|f_X\|_{u,\mathrm{coeff};p}, \tag{12.1}$$

where x ranges over the boxes. The coefficients are taken in the scalar link and color coordinates and include the Taylor factorials, that is, f_ν is the coefficient of the monomial θ^ν; replacing the scalar absolute value by a fixed norm on the three color components changes only fixed constants. When the functions do not depend on w we omit p from the notation.

For an extensive scalar holomorphic function $f(\theta, q)$ of the coarse-field coordinates θ and of variables q, with $q_i = g_i w_i$ in the applications below, set

$$\mathcal{J}_{u,v,b}(f) = \sum_{r+s\geq 1} \frac{u^r v^s}{r!\, s!} \| D_\theta^r D_q^s f(0,0) \|_{b,\mathrm{root}}, \tag{12.2}$$

where the tensor norm fixes any one index of θ or of q, sums over all other indices, and uses the weight $e^{b\mathfrak{t}}$ and the volume normalization of Definition 4.6. The constant coefficient of f is not restricted by $\mathcal{J}_{u,v,b}$. For a reconstructed field, which is vector valued, we use the analogous majorant series for the output-fixed rows and for all input-fixed volume-normalized columns. In a composition of s averaging steps the variables w_i and q_i of the i-th step have mesh M^{i-s}, $0 \leq i < s$, and the number of their indices, for all these steps, located in a unit cube is at most $C_M s M^{3s}$.

In (12.1), we take the supremum over $w \in \Omega_p$ of each coefficient in θ and then sum with the weights $u^{|\nu|}$. This norm dominates the supremum of the function. The symbol $\mathcal{J}_{u,v,b}$ is unrelated to the Haar disintegration densities $\mathcal{J}_c$ introduced below.

We now fix one averaging step, from side Mm to side $m \geq 4$, with input action E_{d_0} of depth $d_0 \geq 0$. By Lemma 6.3 and Theorem 10.10, the fine configuration with average c is $b(c,z) = e^{\Gamma_c(z)} U_0(c)$, where $U_0(c)$ is the coarse-field lift, Γ_c solves the block averaging constraint for the eliminated edges e_a^*, $a \in \mathcal{E}_m$, and z are the free logarithmic coordinates. We write

$$B(\theta,z) = \operatorname{Log} b(e^\theta, z), \qquad F(\theta,z) = E_{d_0}(b(e^\theta,z)), \qquad \mathcal{L}(\theta,z) = -\log \frac{\mathcal{J}_{e^\theta}(z)}{\mathcal{J}_I(0)},$$

where $\mathcal{J}_c(z)$ is the Haar disintegration density of Lemma 12.3 below; when c rather than θ is the variable we also write $F(c,z)$. Let $z^*(c)$ be the conditional constrained minimizer of Theorem 10.10 and $K(\theta) = D_z^2 F(\theta, z^*(e^\theta))$.

Lemma 12.2. *There exist $a, A, R > 0$, with the dependence described in item (2) of Definition 4.14 and independent of $d_0 \geq 0$ and $m \geq 4$, and fixed products of coarse-field coordinates and free logarithmic coordinates, contained with fixed positive margins in the domains of Lemma 6.3 and Theorems 10.10 and 10.11, on which the following bounds hold at the spatial decay rate a.*

1. *The map $B(\theta,z)$ has output-fixed absolute row sums and input-fixed volume-normalized column sums whose coefficients of order k are bounded by $A^{k+1}k!$.*

2. *The scalar functions $F(\theta, z)$ and $\mathcal{L}(\theta, z)$ have coefficients of every order $k \geq 1$ bounded by $A^{k+1}k!$ with any one input index fixed.*
3. *The minimizer $z^*(e^\theta)$ vanishes at $\theta = 0$ and has majorant series for its rows and its columns of all orders, with the same factorial bounds.*
4. *The coefficients of positive degree in θ of $K(\theta)$ may be bounded with either matrix index fixed, or with one coarse-field index fixed; in the latter case both matrix indices are summed. Their generating series is bounded by $Ax/(1 - Ax)$ for $0 \leq x < R$.*

Proof. The output side is $m \geq 4$, and the input action lives on the side $Mm \geq 4$ and has depth $d_0 \geq 0$, so Theorems 10.10 and 10.11 apply. We fix $R > 0$ such that the products $\|\theta\|_\infty \leq 2R$, $\|z\|_\infty \leq 2R$ lie inside the domain of the constraint coordinates and the domain of Theorem 10.10, and such that $\|B(\theta, z)\|_\infty < r_*/2$ there, where r_* is the radius of Theorem 10.11. Such a choice exists since $B(0, 0) = 0$ and by the first-order bounds of Lemma 6.3. The last condition places the argument of E_{d_0}, and not only the coarse field, in the domain where its coefficient bounds hold. The resulting margins depend only on the data of one averaging step, and all later reductions of R in this proof are made before J, g, and p are chosen.

Recall that if $\sum_\nu a_\nu z^\nu$ converges on a neighborhood of a product of circles of radii R_j, then by Cauchy's formula $|a_\mu| \prod_j R_j^{\mu_j}$ is at most the supremum of the function on these circles. The same holds for coefficients with values in a Banach space.

Each component of the solution Γ in Lemma 6.3 depends on a finite stencil of at most n_M scalar coordinates, of diameter at most d_M in the output lattice. At fixed M there are only finitely many local types of such stencils, and the periodic identifications only identify members of this finite list. On a closed complex product strictly inside the domain, the holomorphic solutions are bounded by a fixed constant A_0. If the circle radius in each scalar coordinate is R_0, the coefficient of a multiindex ν is then at most $A_0 R_0^{-|\nu|}$. There are $\binom{n_M+k-1}{k} \leq (2n_M)^k$ multiindices of degree $k \geq 1$. Summing absolute coefficients therefore introduces a factor exponential in k, and multiplying by $k!$ gives the bound $A^{k+1}k!$ for the ordered derivative tensors. A fixed input belongs to at most C_M stencils, which gives the column bounds. A tree on the $k + 1$ locations of a coefficient has length at most $d_M k$, so the exponential weight contributes another factor exponential in k. This proves the row and column bounds; no bound on directional derivatives is used. Finite products, exponentials, and the logarithm in the identity chart preserve such bounds, since their majorant series are dominated by products, by e^x, and by $\sum_{j\geq 1} x^j/j$ on a fixed small disc.

These are volume-normalized column bounds as well as counting bounds. In units of the coarse lattice spacing, the two meshes are 1 and M^{-1}. The column factor, the output volume divided by the input volume, is therefore 1, M^{-3}, or M^3, and we include these fixed factors in A. In compositions we use these factors as in Lemma 5.3, and the

intermediate volumes cancel at each contraction. Since lengths measured in the units of the input lattice are multiplied by M^{-1}, the exponential bounds of the input lattice still hold at one fixed positive rate.

The same reasoning applies to each term of $\mathcal{L}$. Each nonforest link contributes $-\log j_H(\Gamma_e)$, and each coarse link a contributes $\log\det(M^2 D_{X_{c_a^*}} \mathsf{C}_a)$. Here $j_H(0) = 1$, and the matrix in the second logarithm equals I at $z = 0$. On a smaller product, their differences from 1 and from I have norm less than $1/2$, which ensures that the scalar and matrix logarithm series converge with uniform local coefficient bounds. The constant $\mathcal{J}_I(0)$ cancels exactly these values at zero. Each index belongs to a bounded number of these local terms, which gives the asserted bounds for their sum with one index fixed. This argument also specifies the real logarithms and their holomorphic continuations.

For F, the product chosen above places every argument B inside the radius r_*, and we use the factorial bounds for E_{d_0} of Theorem 10.11. In a coefficient of the composition, we join the network of the outer tensor to the networks of the inserted B tensors. If an input index is fixed, we use the column of the insertion containing it and rows for the other insertions. The contraction rule of Lemma 5.3 then sums every internal index without a volume factor, and the exponential generating series is bounded by the composition of two convergent majorant series. Differentiating twice to form a Hessian introduces a factor $(k+1)(k+2)$ at coefficient degree k, which is absorbed on a fixed smaller radius.

To bound all orders of the minimizer, let $K^0 = D_z^2 F(0,0)$ and write the stationarity equation as the implicit system

$$z = \Phi(\theta, z), \qquad \Phi(\theta, z) = -(K^0)^{-1}\{D_z F(\theta, z) - K^0 z\}. \tag{12.3}$$

We have $\Phi(0,0) = 0$, and the linear part of Φ in z vanishes at the origin. Its part linear in θ is bounded by $A\|\theta\|$, and the remaining majorant series is bounded by $A(\|\theta\| + x)^2/[1 - A(\|\theta\| + x)]$ when the unknown has majorant x. The rows and columns of $(K^0)^{-1}$ are bounded uniformly by Theorem 10.10. We apply the implicit-series clause of Lemma 5.3 with the majorant

$$x = A\|\theta\| + \frac{A(\|\theta\| + x)^2}{1 - A(\|\theta\| + x)},$$

that is, with $\kappa = 0$ in its notation, and we obtain a convergent majorant at every fixed index. Its unique small solution is the minimizer of Theorem 10.10, by the uniqueness statement there.

Finally we compose the tensor $D_z^2 F$, which has two indices of z, with the minimizer. A coefficient of positive degree in θ contains a coarse-field index either in the outer tensor or in an inserted copy of z^*. Fixing that index and using the appropriate columns along its path, we sum over the two indices of z. The contractions and the majorant series just described prove the stated bound for $K - K^0$. Throughout the contractions we keep the

shortest connected networks, and we replace them by trees on the external indices only once, as permitted by Lemma 5.3. This fixes one positive rate for every order. □

In the next lemma, U denotes a scalar function of the coarse field and of w, not a configuration.

Lemma 12.3. *Fix an odd integer $M \geq 3$. There exist $u_0, v_0, b, m_0, C, \sigma_0 > 0$ and $p_0 \geq 1$, with the dependence described in item (2) of Definition 4.14 and independent of $d_0 \geq 0$ and $m \geq 4$, such that the following holds for the reconstruction $b(c,z)$ of Theorem 10.10. Put*

$$F(c,z) = E_{d_0}(b(c,z)), \quad z^*(c) = z^*_{d_0}(c), \quad K(c) = D_z^2 F(c, z^*(c)), \quad S(c) = K(c)^{-1/2}.$$

1. *There are $f = 2(M^3-1)m^3$ independent $\mathrm{SU}(2)$ variables, hence $3f$ real free logarithmic coordinates. Their density relative to the product Haar measure on the coarse configuration, including the Haar factors of the eliminated edges, is the Haar disintegration density*

$$\mathcal{J}_c(z) = c_{\mathrm{Haar}}^f \frac{\prod_{e \text{ nonforest}} j_H(\Gamma_{c,e}(z))}{\prod_{a \in \mathcal{E}_m} \det D_{X_{e_a^*}} \mathsf{C}_{c,a}(\Gamma_c(z))},$$

   where $j_H(X) = \mathrm{sinc}^2(|X|/2)$; its value at $c = I$, $z = 0$ is $\mathcal{J}_I(0) = c_{\mathrm{Haar}}^f M^{6|\mathcal{E}_m|}$. The integral over the forest variables has mass one. Set $\mathcal{L}_c(z) = -\log(\mathcal{J}_c(z)/\mathcal{J}_I(0))$ and $\mathcal{L}_0(c) = \mathcal{L}_c(z^*(c))$.
2. *For real c the matrix $S(c)$ is real, symmetric, and positive definite, and S extends holomorphically to $c = e^\theta$, $\|\theta\|_\infty < u_0$. With $K^0 = K(I)$, for every real $x \geq 0$,*

$$\|(K^0 + xI)^{-1}\|_{b,\mathrm{row+col}} \leq \frac{C}{m_0 + x}, \qquad S(c) = \frac{1}{\pi} \int_0^\infty x^{-1/2} (K(c) + xI)^{-1}\, dx.$$

   The coefficients of S satisfy factorial bounds at every fixed index, with exponentially weighted rows and columns, and each coefficient of positive degree in θ may also be bounded with one coarse-field index fixed and both matrix indices summed.
3. *There exist $a_1, A, R > 0$, chosen before J and independent of d_0, m, g, p, and fixed products of radius R contained with fixed positive margins in the larger classical and Haar disintegration domains, on which $B(\theta, z)$, $F(e^\theta, z)$, $\mathcal{L}_{e^\theta}(z)$, and $z^*(e^\theta)$ satisfy the bounds of Lemma 12.2 at the rate a_1, with coefficients of order $k \geq 1$ bounded by $A^{k+1}k!$; for B these are output-fixed rows and all input-fixed volume-normalized columns, and for the scalar functions any one input index is fixed. Scalar values are excluded, and no coupling or cutoff enters. The coefficients of positive degree of $K(e^\theta)$, $K^{1/2} = KS$, and $S = K^{-1/2}$ are bounded by $A^{k+1}k!$ with either matrix index fixed, or with a coarse-field index fixed and then both matrix indices and all other inputs summed; their series of positive degree are bounded by $Au/(1-Au)$. All these bounds also hold after translation to any background point of a fixed smaller product. The volume normalizations are those of Definition 4.6 for this pair of lattices.*

4. *Let $g > 0$, $p \geq p_0$, and $\|\theta\|_\infty < u_0$, and assume*

$$Cgp < \tfrac{1}{2}, \qquad \sigma = C\Big\{\frac{gp^3}{1 - Cgp} + gp\Big\} \leq \sigma_0. \tag{12.4}$$

Then, for every $w \in \Omega_p = \prod_{e=1}^f \{w_e \in \mathbb{R}^3 : |w_e| \leq p\}$, the point $z = z^*(c) + gS(c)w$ satisfies $\|z\|_\infty < v_0/2$, and $b(c, z)$ lies in the domain of the classical coefficient bounds. Let $z_p = \int_{|w| \leq p} e^{-|w|^2/2}\, d^3w$, let π_p be the product reference measure on Ω_p with density $z_p^{-f} \prod_e \mathbf{1}_{|w_e| \leq p} e^{-|w_e|^2/2}$, and set

$$U(c, w) = \frac{F(c, z^* + gSw) - F(c, z^*)}{g^2} - \frac{1}{2}|w|^2 + \mathcal{L}_c(z^* + gSw) - \mathcal{L}_0(c). \tag{12.5}$$

Then, with $g_+^2 = Mg^2$,

$$\int_{z^* + gS\Omega_p} e^{-F(c,z)/g^2}\, \mathcal{J}_c(z)\, dz = \mathcal{J}_I(0) g^{3f} e^{-E_{d_0+1}(c)/g_+^2} \det S(c)\, e^{-\mathcal{L}_0(c)} z_p^f\, \Xi(c), \tag{12.6}$$

where $\Xi(c) = \mathbb{E}_{\pi_p} e^{-U(c,w)}$. These identities are exact for real c. For complex c the left side is defined as the holomorphic continuation obtained by integrating over the same real product of w.

Proof. We take $p_0 = 1$; any fixed larger p_0 also works. We use the products of Lemma 12.2 inside the domain of Theorem 10.10, and we reduce their radii as follows.

Step 1: the weighted resolvent at the identity. Let $\lambda = m_0$ be the uniform lower bound of Theorem 10.10 for the Hessian K^0 on the real space of free logarithmic coordinates; it holds for every $m \geq 4$. The indices of z have bounded density and polynomial growth, with constants depending only on M. We apply the weighted inverse clause of Lemma 5.3 to $K^0 + xI$, $x \geq 0$. Its lower bound is $\lambda + x$, and its off-diagonal entries are those of K^0. We fix $0 < \beta_0 < a$ by the condition of that clause for the lower bound λ; this choice works for every $x \geq 0$. We obtain

$$|(K^0 + xI)^{-1}_{ef}| \leq \frac{2e^{-\beta_0 \operatorname{dist}(e,f)}}{\lambda + x}.$$

For $0 < b_0 < \beta_0$, summing with the weight $e^{b_0 \operatorname{dist}(e,f)}$ and using the polynomial growth just recalled, we obtain the row and column bound $C/(\lambda + x)$. The constant and the rate are independent of x, d_0, and m.

Step 2: the inverse square root. Let $\Delta K = K(c) - K^0$. On a smaller coarse-field product, Lemma 12.2(4) implies that $\|(K^0 + xI)^{-1}\Delta K\|_{b_0} < 1/2$ simultaneously for all $x \geq 0$. Hence

$$(K(c) + xI)^{-1} = \sum_{j \geq 0} \big[-(K^0 + xI)^{-1}\Delta K\big]^j (K^0 + xI)^{-1} \tag{12.7}$$

converges in the weighted matrix algebra. We may integrate its majorant against $\pi^{-1}x^{-1/2}\,dx$, since $x^{-1/2}/(\lambda+x)$ is integrable. For a real eigenvalue $k>0$, the substitution $x=ky^2$ and $2\int_0^\infty(1+y^2)^{-1}dy=\pi$ give $\pi^{-1}\int_0^\infty x^{-1/2}(k+x)^{-1}dx=k^{-1/2}$. Diagonalizing the real symmetric matrix $K(c)$, we find that the integral is its positive symmetric inverse square root. The same integral of the normally convergent series defines the holomorphic continuation. By continuation from real data we have $S^{\mathsf T}=S$ and $S^{\mathsf T}KS=I$, with the transpose rather than the Hermitian adjoint.

Step 3: coefficients of S. Each coefficient of positive degree in θ of (12.7) differentiates at least one factor ΔK. We fix the coarse-field index on that factor, sum both of its matrix indices by Lemma 12.2(4), and contract the remaining resolvents using their rows and columns. Integrating the resulting convergent majorant series proves the asserted bounds for S, including the sum over both matrix indices when a coarse-field index is fixed. The undifferentiated term needs only the rows and columns of $(K^0+xI)^{-1}$. All radius reductions and the final rate are chosen here, before g and p.

Step 4: joint bounds and the positive square root. The tensors of B, F, $\mathcal{L}$, and z^* in part (3) are those of Lemma 12.2; no fluctuation variable or cutoff enters their construction. For the matrix products, we fix $a_1>0$ such that $2a_1$ is at most both the rate of Lemma 12.2 and b_0; this leaves the factor two needed to replace a shortest connected network by a tree on the external indices. Since S is a function of K, it commutes with K. The holomorphic matrix

$$P(c)=K(c)S(c) \tag{12.8}$$

equals the positive symmetric square root $K(c)^{1/2}$ for real data, and $P^2=K$ on the complex product since $S^2K=I$. Then P is the continuation of the positive square root, and its row and column bounds follow from submultiplicativity.

We check the coefficient bounds for P. For a coarse-field multiindex ν we have $P_\nu=\sum_{\mu\le\nu}K_\mu S_{\nu-\mu}$, with the Taylor factorials included in the coefficients. If a matrix index is fixed, we use the row or column bound of the factor containing it and the compatible bound of the other factor. If a coarse-field index is fixed, we distinguish its position in the convolution. If it belongs to K_μ, we use the bound for K summing both matrix indices and then a row of S at the common index. If it belongs to $S_{\nu-\mu}$, we use the corresponding bound for S and the column of K at the common index. Each contraction joins two networks at the shared index of z, so the exponential weight and the volume normalization are those of Lemma 5.3.

To treat all orders at once, let $k(x),s(x)$ be majorant series of the coefficients of K and S with a matrix index fixed, including their constant terms, and let $k_{\mathrm t}(x),s_{\mathrm t}(x)$ be majorant series of their coefficients of positive degree with a coarse-field index fixed and both matrix indices summed. These four series converge, and the last two have no

constant term. The contractions just described bound the coefficients of positive degree of P by those of

$$k(x)s(x) - k(0)s(0), \qquad k_{\mathrm{t}}(x)s(x) + k(x)s_{\mathrm{t}}(x), \tag{12.9}$$

for a fixed matrix index and a fixed coarse-field index, respectively. If such a series is bounded by C_0 on a circle of radius r_0, its coefficient of degree k is at most $C_0 r_0^{-k}$. Enlarging A beyond $\max\{1, (1 + C_0)/r_0\}$ for the finitely many series involved, we bound these coefficients by A^k for $k \geq 1$. This bounds the series of positive degree by $Au/(1 - Au)$ and the ordered tensors of order k by $A^{k+1}k!$. The same enlargement covers B, F, $\mathcal{L}$, z^*, K, and S.

These bounds persist after translation to any background point of a fixed smaller product. Indeed, suppose that a tensor of order n, with one index fixed, is bounded by $C^{n+1}n!$. Expanding at a background point of radius r, we obtain for $k \geq 1$ the order-k bound

$$\sum_{j \geq 0} \frac{r^j}{j!} C^{k+j+1}(k + j)! = \frac{C^{k+1}k!}{(1 - Cr)^{k+1}} \leq (2C)^{k+1}k! \qquad (Cr \leq 1/2).$$

The fixed index remains a differentiated input or a matrix index, and the other legs at the background point are summed using the same rows or columns; removing these legs cannot increase the length of the remaining network. Thus one radius reduction and one enlargement of A cover all orders and all these background points, without changing a_1. We take the least common radius R and the least rate a_1, and we reduce u_0 to this radius if necessary. This proves part (3), with constants chosen before J, g, and p.

Step 5: the Haar disintegration. By Lemma 6.3 there are $f = 2((Mm)^3 - m^3) = 2(M^3 - 1)m^3$ independent SU(2) variables, and the density is exactly $\mathcal{J}_c$. At $c = I$ and $z = 0$ each of the $|\mathcal{E}_m|$ determinants $\det D_{X_{e_a^*}} \mathsf{C}_{I,a}(0) = \det(M^{-2} I_3)$ equals M^{-6}, and each factor j_H equals one, which gives $\mathcal{J}_I(0) = c_{\mathrm{Haar}}^f M^{6|\mathcal{E}_m|}$. The Haar probability measure on the gauge transformations of the block forests has mass one. The forest integral contributes no further factor, since the integral uses the action at the representative in the block axial gauge. This proves part (1).

Step 6: the domain. By the bound $\|z^*(c)\| \leq C\|\theta\|$ and the row bound for S, we have $\|z^* + gSw\| \leq C(u_0 + gp)$. We choose u_0 and the threshold for gp such that this is less than half of the least chart radius v_0 and the reconstruction stays inside the domain of the classical coefficient bounds. We achieve these requirements by enlarging the constant C in (12.4) before it is fixed; none of them depends on p, g, d_0, or m.

Step 7: the change of variables. For real c, the change of variables $z = z^* + gSw$ has Jacobian $g^{3f} \det S$. Stationarity removes the linear term of $F(c, \cdot)$ at z^*, and $S^{\mathsf{T}} K S = I$ turns its quadratic term into $|w|^2/2$. By the nested minimization identity $E_{d_0+1}(c) = MF(c, z^*(c))$ of Theorem 10.10 and $g_+^2 = Mg^2$, we have $F(c, z^*)/g^2 = E_{d_0+1}(c)/g_+^2$. Substituting

$\mathcal{J}_c(z) = \mathcal{J}_I(0)e^{-\mathcal{L}_c(z)}$ and extracting $e^{-\mathcal{L}_0(c)}$ leaves the integrand $e^{-|w|^2/2-U(c,w)}$, whose integral over Ω_p is $z_p^f \Xi(c)$ by the definition of π_p. This proves (12.6), with every scalar factor displayed. For complex c, we integrate over the same real product of w. Since the uniform chart margins and the convergent series justify integrating coefficient by coefficient, the result is the holomorphic continuation of the real identity. □

12.2 Polymer expansions in the coefficient algebra

In this subsection, we fix a finite set of boxes as in Definition 12.1. A *polymer* is a support, that is, a nonempty connected set of boxes. We prove the cluster expansion of a hard-core polymer gas whose activities take values in the coefficient algebra of (12.1). We then prove a version for arbitrary interactions with connected supports, which includes holomorphic dependence on the interaction and an estimate for the derivative with respect to an inserted interaction. These statements use only the norms and the independence of fluctuation variables in disjoint supports. They are applied to one averaging step in Section 12.3 and to several in Section 12.4. The weighted incidence condition below is a version of the convergence criterion of Kotecký and Preiss [120], and we prove the bound we need by majorizing with rooted trees. The successive support weights $e^{8|X|}$, $e^{5|P|}$, and $e^{2|Y|}$ below are chosen for convenience; only the gaps between them matter.

Lemma 12.4. *Let $\mathcal{S}$ be a finite family of nonempty sets of boxes, not necessarily connected, with nonnegative weights h_X, $X \in \mathcal{S}$. Let $\kappa \geq 0$ and suppose*

$$\eta = \sup_x \sum_{X \ni x} h_X e^{(\kappa+1)|X|} \leq 1.$$

Put $a_X = h_X e^{\kappa|X|}$. For $X \in \mathcal{S}$ let T_X be the sum over finite rooted trees whose vertices carry elements of $\mathcal{S}$, repetitions allowed, whose root carries X, and in which the sets carried by adjacent vertices intersect, of the product of the weights a_Y of all vertices, where a vertex with j children receives the factor $1/j!$. Then $T_X \leq a_X e^{|X|}$, and $\sum_{X \ni x} T_X \leq \eta$ for every box x. In particular, the sum of $e^{\kappa|\cup \mathcal{F}|} \prod_{X \in \mathcal{F}} h_X$ over all families $\mathcal{F}$ of distinct elements of $\mathcal{S}$ whose union contains x and whose intersection graph is connected is at most η.

Proof. For trees of height zero, we set $T_X^{(0)} = a_X$, and we define iteratively

$$T_X^{(n+1)} = a_X \exp\Big(\sum_{Y:\, Y \cap X \neq \varnothing} T_Y^{(n)} \Big). \tag{12.10}$$

Expanding the exponential assigns the factor $1/j!$ to the j children of each vertex, and induction on the height shows that $T_X^{(n)}$ is the sum over the trees of height at most n described in the statement. Equivalently, for trees with k vertices and a fixed root, one may label the other vertices $2, \dots, k$ and divide by $(k-1)!$; grouping the labels among

the subtrees of the root gives exactly the same factors $1/j!$. This verifies the count also when several vertices carry the same set.

If $T_Y^{(n)} \le a_Y e^{|Y|}$ for all Y, then

$$\sum_{Y:\, Y\cap X\neq\varnothing} T_Y^{(n)} \le \sum_{x\in X}\sum_{Y\ni x} a_Y e^{|Y|} \le \eta|X| \le |X|,$$

which implies $T_X^{(n+1)} \le a_X e^{|X|}$. Their limit T_X satisfies the same bound, since the iterates increase. Summing over $X \ni x$, we obtain $\sum_{X\ni x} T_X \le \sup_x \sum_{X\ni x} h_X e^{(\kappa+1)|X|} = \eta$. A family $\mathcal{F}$ of k distinct sets with connected intersection graph and union containing x has a member containing x and an intersection spanning tree rooted at it. Listing its other members in all orders cancels the factor $1/(k-1)!$, so the rooted tree sum counts $\prod_{X\in\mathcal{F}} a_X$ at least once. Finally, the inequality $|\cup\mathcal{F}| \le \sum_{X\in\mathcal{F}}|X|$ transfers the weight of the union to the vertex weights. □

Lemma 12.5. *For every finite simple graph G,*

$$\Big|\sum_{H}(-1)^{|E(H)|}\Big| \le \#\{\textit{spanning trees of } G\},$$

where the sum is over the connected spanning subgraphs H of G.

This inequality is used by Dimock in [68, Appendix B, Theorem 27, p. 39, and (323), p. 42]. We prove it with the partition of connected subgraphs introduced by Penrose [136]; see also [87, Section 4.1].

Proof. For a graph with one vertex both sides equal one, and for a disconnected graph both sides vanish. Otherwise we order the vertices and root the graph at vertex 1. For a connected spanning subgraph H, let $d_H(v)$ be the graph distance from v to 1 in H, and join each $v \neq 1$ to its least neighbor in H in the preceding distance layer. These edges form a spanning tree $T(H)$ with the same distances to 1. For a spanning tree T, let $R(T)$ consist of the edges of T, of every edge of G joining two vertices in the same distance layer of T, and of every edge of G joining successive layers whose endpoint in the lower layer is not smaller than the parent in T of its endpoint in the upper layer. No other edge belongs to $R(T)$. Then

$$T(H) = T \quad\Longleftrightarrow\quad T \subset H \subset R(T).$$

Indeed, an edge of H cannot skip a distance layer of H, and it cannot be joined to a smaller vertex of the preceding layer than the chosen parent. Conversely, adding edges of $R(T)\setminus T$ to T changes no distance, since each such edge changes the layer by at most

one, and it does not change the least parent. Thus the connected spanning subgraphs are partitioned into these intervals, and each interval contributes

$$\sum_{T\subset H\subset R(T)} (-1)^{|E(H)|} = (-1)^{k-1}(1-1)^{|E(R(T))\setminus E(T)|},$$

where k is the number of vertices. Its absolute value is at most one, and summing over spanning trees proves the inequality. □

Theorem 12.6. *Fix a finite set of boxes and $u > 0$. For each polymer P let $\mathfrak{z}(P)$ be a convergent power series in the coarse-field coordinates located in P, with $\|\mathfrak{z}(P)\|_{u,\mathrm{coeff}} < \infty$, and assume*

$$\sup_x \sum_{P\ni x} e^{5|P|}\|\mathfrak{z}(P)\|_{u,\mathrm{coeff}} \le 2\sigma, \tag{12.11}$$

where $\sigma \le \sigma_0$ for an absolute constant $\sigma_0 > 0$. Let

$$\Xi = \sum_{\{P_1,\dots,P_k\}\ \text{pairwise disjoint}} \prod_{i=1}^{k} \mathfrak{z}(P_i)$$

be the partition function of the hard-core polymer gas, in which two polymers are compatible if they are disjoint; the empty family contributes one. Then the following statements hold.

1. *We have $\log\Xi = \sum_Y \Psi_Y$, where*

$$\Psi_Y = \sum_{k\ge 1}\frac{1}{k!}\sum_{P_1\cup\cdots\cup P_k = Y} \varphi^T(P_1,\dots,P_k)\prod_{i=1}^{k}\mathfrak{z}(P_i).$$

   The inner sum is over ordered tuples of polymers, repetitions allowed, and $\varphi^T(P_1,\dots,P_k) = \sum_H (-1)^{|E(H)|}$, the sum being over the connected spanning subgraphs H of the incompatibility graph on $\{1,\dots,k\}$, in which $i \ne j$ are joined if $P_i \cap P_j \ne \varnothing$. A single polymer has coefficient one, and $|\varphi^T|$ is at most the number of spanning trees of the incompatibility graph by Lemma 12.5. All these series converge absolutely in the coefficient algebra.

2. *Each Ψ_Y depends only on the coarse-field coordinates located in Y, and*

$$\sup_x \sum_{Y\ni x} e^{2|Y|}\|\Psi_Y\|_{u,\mathrm{coeff}} \le C\sigma.$$

3. *$\Xi \ne 0$ on $\|\theta\|_\infty < u$, and $\log\Xi$ is the branch that vanishes at zero activity.*

4. *Suppose that the number of coordinate labels in each box is bounded and that, for every support Y, all labels located in Y can be joined by a network of length at most $C_{\mathrm{geom}}|Y|$. Then there exists $b > 0$ such that, on $\|\theta\|_\infty \le u/2$, for every $s \ge 1$,*

$$\|D_\theta^s \log\Xi\|_{b,\mathrm{root}} \le C^s s!\,\sigma.$$

The constants in (1)–(3) are absolute; in particular they do not depend on the number of polymers. In (4) the constants depend in addition on C_{geom}, on the bound on the number of labels per box, and on u, but not on the number of boxes or on s.

Proof. We take $\sigma_0 = 1/4$.

Step 1: the formal identity. We give each polymer P a formal variable z_P. The partition function is

$$\sum_{k\geq 0}\frac{1}{k!}\sum_{P_1,\dots,P_k}\prod_i z_{P_i}\prod_{i<j}(1-\mathbf{1}_{P_i\cap P_j\neq\varnothing}),$$

since the last product removes all tuples with an intersecting pair, including repeated polymers. Expanding this product gives a sum over all graphs on $\{1,\dots,k\}$, with the weight $-\mathbf{1}_{P_i\cap P_j\neq\varnothing}$ for each edge. Each graph has a unique partition of its vertices into connected components. For components of sizes $k_1,\dots,k_l$, distributing the labels gives the factor $k!/(l!\prod_j k_j!)$, where the factor $1/l!$ accounts for equal components. Hence the sum over all graphs is the exponential of the sum over connected graphs, and comparing coefficients, we obtain the formula for Ψ_Y.

Step 2: the bound. Let $h_P = \|\mathfrak{z}(P)\|_{u,\mathrm{coeff}}$ and $a_P = h_P e^{2|P|}$. For every tuple, the incompatibility graph is a finite simple graph on the distinct indices $1,\dots,k$, even if some of the listed polymers coincide, and its edges are the intersecting pairs. Thus Lemma 12.5 applies to every coefficient φ^T. If the union contains x, we choose a root polymer containing x, which replaces the factor $1/k!$ by the larger factor $1/(k-1)!$. By Lemma 12.4 with $\kappa = 2$, we have

$$\sup_x \sum_{Y\ni x} e^{2|Y|}\|\Psi_Y\|_{u,\mathrm{coeff}} \leq \sup_x \sum_{P\ni x} h_P e^{3|P|} \leq 2\sigma,$$

provided $2\sigma \leq 1$. This proves the absolute convergence in the coefficient algebra, the bound in (2), and the fact that Ψ_Y depends only on coordinates in Y.

Step 3: the analytic branch. We replace every activity by $\alpha\mathfrak{z}(P)$ with $\alpha \in \mathbb{C}$. Since $\sigma \leq 1/4$, the bound of Step 2 holds for $|\alpha| \leq 2$. Since the sum of all these bounds is finite at finite volume, the connected series and its exponential are convergent power series in α on this disc. By Step 1, their exponential and the polynomial $\Xi(\alpha)$ have the same Taylor coefficients at $\alpha = 0$, which implies that they agree on the whole disc. At $\alpha = 1$, this proves $\Xi = \exp(\sum_Y \Psi_Y)$, which gives $\Xi \neq 0$ and identifies the branch. This argument does not use a volume-independent bound on the scalar $\log \Xi$.

Step 4: derivatives. For a scalar series $f_Y(\theta) = \sum_\nu f_{Y,\nu}\theta^\nu$ and $\|\theta\|_\infty \leq u/2$, the sum over all ordered derivative indices of order s of the absolute values of the derivatives of f_Y is bounded by

$$\sum_{n\geq s}\sum_{|\nu|=n}|f_{Y,\nu}|(n)_s(u/2)^{n-s} \leq 2^{s+1}s!\,u^{-s}\|f_Y\|_{u,\mathrm{coeff}}, \tag{12.12}$$

where $(n)_s = n(n-1)\cdots(n-s+1)$. To check the constant, we write $n = s+j$ and bound each $\binom{s+j}{s}2^{-j}$ by $\sum_{j\geq 0}\binom{s+j}{s}2^{-j} = 2^{s+1}$. Fixing one derivative index only reduces the sum, and makes it zero unless that index is located in Y. By hypothesis, all distinct labels in Y can be joined by a network of length $C_{\mathrm{geom}}|Y|$, and repeated labels add no length. We choose b with $bC_{\mathrm{geom}} \leq 1$, multiply (12.12) by the weight $e^{bt} \leq e^{|Y|}$, and

use the bound in (2), in which the fixed index determines a box. This proves (4), with a single factorial. For the boxes of Definition 12.1, whose labels have bounded density, the geometric hypothesis holds. Indeed, we join the centers of adjacent boxes of Y and, inside each box, join its finitely many labels by a fixed tree; the total length is at most $C_{M,\mathscr{L}}|Y|$. □

In the next theorem, we apply two expansions to an arbitrary interaction with connected supports: first the connected-component expansion of $\prod_X (1 + (e^{-U_X} - 1))$, which produces a hard-core polymer gas, and then the cluster expansion of Theorem 12.6.

Theorem 12.7. *Fix a finite set of boxes, a fixed product domain Ω for the fluctuation variables, each fluctuation variable being located in one box, and a product probability measure π on Ω. Fix $u > 0$, and let $\mathscr{A}$ be the algebra of convergent series $f(\theta, w) = \sum_\nu f_\nu(w)\theta^\nu$ with bounded measurable coefficients and finite norm $\|f\|_{\mathscr{A}} = \sum_\nu u^{|\nu|} \sup_{w\in\Omega} |f_\nu(w)|$. For $h \geq 0$ let $\mathscr{S}_h$ be the Banach space of families $\boldsymbol{U} = (U_X)$, indexed by supports, such that each $U_X \in \mathscr{A}$ depends only on the fluctuation and coarse-field coordinates located in X, with the norm*

$$\|\boldsymbol{U}\|_{\mathscr{S}_h} = \sup_x \sum_{X \ni x} e^{h|X|} \|U_X\|_{\mathscr{A}}.$$

Constant coefficients are allowed. There exist absolute constants $\eta_0, C > 0$, independent of the number of boxes, of the dimension of the fluctuation variables, of u, and of π, such that the following holds for $\|\boldsymbol{U}\|_{\mathscr{S}_8} < \eta_0$. Define the polymer activities

$$\mathfrak{z}(P) = \sum_{\mathcal{F}} \mathbb{E}_\pi \prod_{X\in\mathcal{F}} \big(e^{-U_X} - 1\big), \tag{12.13}$$

the sum being over the families $\mathcal{F}$ of distinct supports whose intersection graph is connected and whose union is P, and set

$$\mathcal{L}_Y(\boldsymbol{U}) = -\sum_{k\geq 1} \frac{1}{k!} \sum_{P_1\cup\cdots\cup P_k = Y} \varphi^T(P_1, \dots, P_k) \prod_{i=1}^k \mathfrak{z}(P_i),$$

with φ^T as in Theorem 12.6. Then $\mathcal{L}_Y(\boldsymbol{U})$ depends only on the coarse-field coordinates located in Y, and

$$\sum_Y \mathcal{L}_Y(\boldsymbol{U}) = -\log \mathbb{E}_\pi e^{-\sum_X U_X}, \qquad \|\boldsymbol{\mathcal{L}}(\boldsymbol{U})\|_{\mathscr{S}_2} \leq C\|\boldsymbol{U}\|_{\mathscr{S}_8}, \tag{12.14}$$

where $\boldsymbol{\mathcal{L}}(\boldsymbol{U}) = (\mathcal{L}_Y(\boldsymbol{U}))_Y$. Here $\mathbb{E}_\pi e^{-\sum_X U_X} \neq 0$, and the logarithm is the branch that vanishes at $\boldsymbol{U} = 0$. Thus each connected cluster of interactions is assigned to the union of their supports. The map $\boldsymbol{U} \mapsto \boldsymbol{\mathcal{L}}(\boldsymbol{U})$, from the open ball of radius η_0 in $\mathscr{S}_8$ to $\mathscr{S}_2$, is Fréchet holomorphic. For $\|\boldsymbol{U}\|_{\mathscr{S}_8} \leq \eta_0/2$ and every $\boldsymbol{A} \in \mathscr{S}_8$,

$$\|D\boldsymbol{\mathcal{L}}(\boldsymbol{U})[\boldsymbol{A}]\|_{\mathscr{S}_2} \leq C\|\boldsymbol{A}\|_{\mathscr{S}_8}. \tag{12.15}$$

If the segment $\boldsymbol{U} + s\boldsymbol{A}$, $0 \le s \le 1$, lies in the closed ball of radius $\eta_0/2$, then $\boldsymbol{\mathcal{L}}(\boldsymbol{U}+\boldsymbol{A}) - \boldsymbol{\mathcal{L}}(\boldsymbol{U})$ is the integral of this derivative along the segment, and its $\mathscr{S}_2$ norm is at most $C\|\boldsymbol{A}\|_{\mathscr{S}_8}$. If $\boldsymbol{U}$ depends holomorphically on a parameter in a Banach space, so does $\boldsymbol{\mathcal{L}}(\boldsymbol{U})$. If θ is real and all U_X and A_X are real valued, then

$$\sum_Y D\mathcal{L}_Y(\boldsymbol{U})[\boldsymbol{A}] = \frac{\mathbb{E}_\pi\big[(\sum_X A_X)e^{-\sum_X U_X}\big]}{\mathbb{E}_\pi e^{-\sum_X U_X}}.$$

The supports of the A_X may lie anywhere relative to the box at which the norm $\mathscr{S}_2$ is evaluated. The constants are absolute, as in item (1) of Definition 4.14; when these norms are converted to the torus norms of Definition 4.6, the conversion constants have the dependence described in item (2).

Proof. By coefficient convolution, we have $\|fg\|_{\mathscr{A}} \le \|f\|_{\mathscr{A}}\|g\|_{\mathscr{A}}$. The coefficientwise expectation $\mathbb{E}_\pi$ has norm at most one, and functions of the fluctuation variables in disjoint sets of boxes are independent under π, so their product has the product expectation. These are the operations of Lemma 5.3. At a fixed finite number of boxes, the spaces $\mathscr{S}_h$ are complete, since they are finite products of closed subspaces of weighted ℓ^1 spaces of bounded measurable functions, with an equivalent finite maximum norm.

Step 1: the connected-component expansion. We write $F_X = e^{-U_X} - 1$, $h_X = \|F_X\|_{\mathscr{A}}$, and $\eta = \|\boldsymbol{U}\|_{\mathscr{S}_8}$. For η_0 small, the exponential series in $\mathscr{A}$ implies that $h_X \le e^{\|U_X\|_{\mathscr{A}}} - 1 \le 2\|U_X\|_{\mathscr{A}}$, and therefore $\sup_x \sum_{X\ni x} e^{8|X|}h_X \le 2\eta$. Since there are finitely many supports, we may expand $\mathbb{E}_\pi e^{-\sum_X U_X} = \mathbb{E}_\pi \prod_X (1+F_X)$ as the sum over families of distinct supports of $\mathbb{E}_\pi \prod_{X\in\mathcal{F}} F_X$. Each family has a unique decomposition into components whose intersection graphs are connected. Different components have disjoint unions, hence disjoint fluctuation variables, and the expectation factors. Grouping the families according to the unions of their components, we obtain exactly the hard-core gas with the activities (12.13); the empty family contributes one, and the coarse-field variables enter only as parameters. Since the expectation contracts the norm and $\sup_x \sum_{X\ni x} h_X e^{6|X|} \le 2\eta \le 1$, Lemma 12.4 with $\kappa = 5$ gives

$$\sup_x \sum_{P\ni x} e^{5|P|}\|\mathfrak{z}(P)\|_{\mathscr{A}} \le 2\eta.$$

Step 2: the cluster expansion. Taking $\eta_0 \le \sigma_0$, we apply Theorem 12.6 to these activities, with $\sigma = \eta$. We obtain the absolute convergence of the series defining $\mathcal{L}_Y$, the statement about their supports, the nonvanishing of $\mathbb{E}_\pi e^{-\sum_X U_X}$, the branch, and (12.14). The repetitions are those of Theorem 12.6. Since each connected union is fixed before the coefficients are summed, these formulas define a family, although its sum could also be distributed over the supports in other ways.

Step 3: holomorphy. At a fixed number of boxes the activities are finite sums of products of entire functions of the U_X in $\mathscr{A}$, hence holomorphic. We choose η_0 so small that the bounds of Step 2 still hold after every activity is multiplied by 2, uniformly for $\|\boldsymbol{U}\|_{\mathscr{S}_8} \le \eta_0$. Then the sum of all terms of the logarithm with $k \ge n$ polymers has $\mathscr{S}_2$ norm at most $C\eta_0 2^{-n}$. Each sum with fixed k is finite and holomorphic, and by this bound the series converges uniformly on the ball. To see that the limit is holomorphic, we fix around any point of the open ball a closed ball of radius r inside it. By Cauchy's formula, the homogeneous Taylor polynomial of degree j of each partial sum is bounded by $C\eta_0(\|v\|/r)^j$, uniformly in the increment v. The uniform convergence implies that these polynomials converge uniformly on smaller balls, and the limits are continuous homogeneous polynomials, since polarization of the partial sums passes to the limit. For $\|v\| < r$, their series converges geometrically, and by the one-variable Cauchy formula on the line through v, it equals the limit. This proves Fréchet holomorphy, and holomorphy after composition with holomorphic parameter families.

Step 4: the derivative. Let $a = \|\boldsymbol{A}\|_{\mathscr{S}_8} > 0$ and $r_v = \eta_0/(4a)$. For $|v| \le r_v$, the output has norm at most $C\eta_0$, since the input $\boldsymbol{U} + v\boldsymbol{A}$ has norm at most $3\eta_0/4$. By Cauchy's formula, we have

$$D\boldsymbol{\mathcal{L}}(\boldsymbol{U})[\boldsymbol{A}] = \frac{1}{2\pi i}\int_{|v|=r_v} \frac{\boldsymbol{\mathcal{L}}(\boldsymbol{U}+v\boldsymbol{A})}{v^2}\,dv, \qquad \|D\boldsymbol{\mathcal{L}}(\boldsymbol{U})[\boldsymbol{A}]\|_{\mathscr{S}_2} \le 4Ca.$$

For $a = 0$ there is nothing to prove. Renaming C, we obtain (12.15), and integrating along the segment proves the statement about differences. The norm sums all supports containing the chosen box after the circle integral. An inserted interaction need not contain that box, since the derivative acts at every position of the inserted interaction within a connected cluster.

Step 5: real data. At a fixed number of boxes the coefficient sums bound $\sum_X U_X$ and $\sum_X A_X$ uniformly on Ω. The integrable constant envelope $|\sum_X A_X| e^{|\sum_X U_X| + v_0|\sum_X A_X|}$ justifies differentiating $-\log \mathbb{E}_\pi e^{-\sum_X (U_X + vA_X)}$ under the integral at $v = 0$, and the sum of the components of $D\boldsymbol{\mathcal{L}}(\boldsymbol{U})[\boldsymbol{A}]$ is this derivative, which is the displayed formula. The envelope depends on the volume; we use it only to identify this sum, not in the estimates for the family. □

The derivative with respect to an inserted interaction gains a second power of a small parameter when the first-order term of the insertion has mean zero under π on every support. This is the mechanism behind Lemma 12.16.

Corollary 12.8. *Assume the setting of Theorem 12.7. For $s \in [0,1]$ let $\zeta \mapsto \boldsymbol{U}_s(\zeta)$ and $\zeta \mapsto \boldsymbol{A}(\zeta)$ be holomorphic maps into $\mathscr{S}_8$ on a neighborhood of the closed disc $|\zeta| \le R$ such that, uniformly in s,*

$$\|\boldsymbol{U}_s(\zeta)\|_{\mathscr{S}_8} \le \eta_0/2, \qquad \|\boldsymbol{A}(\zeta)\|_{\mathscr{S}_8} \le a|\zeta|, \qquad \boldsymbol{U}_s(0) = \boldsymbol{A}(0) = 0.$$

Assume that $\mathbb{E}_\pi A'_X(0) = 0$ *for every support* X*, as an identity of coefficients in* θ*, where* $A' = dA/d\zeta$*. Set* $\boldsymbol{F}_s(\zeta) = D\boldsymbol{\mathcal{L}}(\boldsymbol{U}_s(\zeta))[\boldsymbol{A}(\zeta)]$*. Then* $F_{s,Y}(0) = F'_{s,Y}(0) = 0$ *for every* s *and every support* Y*, coefficient by coefficient, and*

$$\|\boldsymbol{F}_s(t)\|_{\mathscr{S}_2} \le \frac{2Ca\,t^2}{R}, \qquad 0 < t \le R/2, \tag{12.16}$$

where C *is the constant of Theorem 12.7. The same conclusion holds if the uniform bounds are assumed only on an open disc.*

Proof. By (12.15), we have $\|\boldsymbol{F}_s(\zeta)\|_{\mathscr{S}_2} \le Ca|\zeta|$. At zero interaction the derivative of the family is $\mathbb{E}_\pi A_Y$, support by support: in the first expansion $e^{-U_X} - 1 = -U_X + O(U_X^2)$, and in the second only the terms with a single polymer are linear. Terms with two interaction factors are of degree at least two in ζ. Since $\boldsymbol{U}_s(0) = \boldsymbol{A}(0) = 0$, the coefficient of ζ in $\boldsymbol{F}_s(\zeta)$ is $(\mathbb{E}_\pi A'_Y(0))_Y = 0$. Thus $F_{s,Y}(0) = F'_{s,Y}(0) = 0$ for every support and every coefficient in θ; no cancellation between different supports is used.

The family $\boldsymbol{B}_s(\zeta) = \boldsymbol{F}_s(\zeta)/\zeta$ extends holomorphically to $\zeta = 0$, vanishes there, and has norm at most Ca. By Cauchy's formula for Banach-valued functions, we have $\|[\zeta^k]\boldsymbol{B}_s\|_{\mathscr{S}_2} \le CaR^{-k}$. For $0 < t \le R/2$, summing the series, we find

$$\|\boldsymbol{F}_s(t)\|_{\mathscr{S}_2} \le \frac{Ca\,t^2}{R(1 - t/R)} \le \frac{2Ca\,t^2}{R}.$$

If the bounds hold only on an open disc, we apply this on smaller circles and pass to the limit. No regularity in s is used. □

12.3 Connected supports and the effective interaction of one averaging step

We now return to the fluctuation interaction $U(c, w)$ of one averaging step, defined in (12.5). The coarse-field coordinates and the normalized fluctuation variables have locations on the lattice, and the coefficient bounds of Lemmas 12.2 and 12.3 decay exponentially in the length of a network joining these locations. In the next lemma, we convert this decay into a decomposition of U into pieces supported on connected sets of boxes, with the summability over supports required by the norm (12.1), as needed to apply Theorems 12.6 and 12.7. A large box scale $\mathscr{L}$ makes the factor $e^{8|X|}$, exponential in the number of boxes met by a network, compatible with the available spatial decay.

Lemma 12.9. *Assume the setting of Lemma 12.3. Choose the box scale* $\mathscr{L}$ *sufficiently large, using a fixed part of the spatial decay rate of the classical coefficient bounds, and then reduce the coarse-field radius* u *and the threshold for* gp*, once. Assign every joint Taylor monomial of* U*, in* θ *and* w*, to the set of boxes met by a rectilinear tree joining the locations of all its coarse-field coordinates and normalized fluctuation variables, chosen by a fixed deterministic rule described in*

the proof. This yields an exact decomposition $U = \sum_X U_X$ *into functions supported on connected sets of boxes, including sets winding around the torus, with the following properties.*

1. *For degree* r *in* θ *and degree* s *in* w*, the absolute coefficient sums with one index of* w *fixed and with the exponential weight of a connecting network at a fixed rate are bounded by*

$$C^{r+s} g^{s-2} \quad (s \geq 3) \text{ for the classical part}, \qquad C^{r+s} g^{s} \quad (s \geq 1) \text{ for the part from } \mathcal{L}.$$

   The classical part of U*, the first two terms of* (12.5)*, has no terms of degree zero, one, or two in* w*, and every term of* U *has degree at least one in* w*.*

2. *The support assigned to a monomial satisfies* $|X| \leq C(r + s + 1 + \mathtt{t}/\mathscr{L})$*, and*

$$\|\{U_X\}\|_{u,8;p} \leq \sigma = C\Big\{\frac{gp^3}{1 - Cgp} + gp\Big\}.$$

3. *If* $\sigma \leq \sigma_0$*, then, with* $F_X = e^{-U_X} - 1$*, the fluctuation partition function is the hard-core polymer gas*

$$\Xi = \sum_{\{P_1,\dots,P_k\} \text{ disjoint}} \prod_{i=1}^{k} \mathfrak{z}(P_i), \qquad \mathfrak{z}(P) = \sum_{\mathcal{F}} \mathbb{E}_{\pi_p} \prod_{X \in \mathcal{F}} F_X, \qquad \|\{\mathfrak{z}(P)\}\|_{u,5} \leq 2\sigma,$$

   where $\mathcal{F}$ *ranges over the families of distinct supports whose intersection graph is connected and whose union is* P*. The empty family contributes one, and each activity depends only on coarse-field coordinates located in* P*.*

4. *Statements (1)–(3) remain valid, with* g *replaced by* $|\zeta|$ *in all bounds and in* (12.4)*, for the interaction*

$$U(c, w; \zeta) = \frac{F(c, z^* + \zeta S w) - F(c, z^*)}{\zeta^2} - \frac{1}{2}|w|^2 + \mathcal{L}_c(z^* + \zeta S w) - \mathcal{L}_0(c)$$

   with a complex parameter ζ*, extended holomorphically across* $\zeta = 0$*; at* $\zeta = g > 0$ *this is* $U(c, w)$*.*

The constants have the dependence described in item (2) of Definition 4.14; they are independent of d_0*, of* m*, of* g, p *satisfying* (12.4)*, and of the number of supports. The only independence used is that of the fluctuation variables in distinct boxes under the product measure* π_p*. The exact formula* (12.6) *concerns real* g *only.*

Proof. We write $c = e^{\theta}$ and proceed in four steps.

Step 1: expansion in the fluctuation variables. At fixed θ, we expand in the increment gSw and obtain the normally convergent series

$$\frac{F(c, z^* + gSw) - F(c, z^*)}{g^2} - \frac{1}{2}|w|^2 = \sum_{s \geq 3} \frac{g^{s-2}}{s!} D_z^s F(c, z^*)[Sw, \dots, Sw], \tag{12.17}$$

$$\mathcal{L}_c(z^* + gSw) - \mathcal{L}_c(z^*) = \sum_{s \geq 1} \frac{g^s}{s!} D_z^s \mathcal{L}_c(z^*)[Sw, \dots, Sw]. \tag{12.18}$$

The classical terms of degree one and two vanish by stationarity and by $S^{\mathsf{T}} K S = I$. Both series vanish at $w = 0$ for every coarse field.

Step 2: coefficient bounds. We expand the coefficients further in θ and apply Lemmas 12.2 and 12.3 and the contraction rule of Lemma 5.3. If an index of w is fixed, the column of the factor S containing it carries the fixed index to a tensor of F or of $\mathcal{L}$ with one index fixed, and all other insertions use rows. The networks of the factors meet at the contracted indices, so their union joins all external locations. The joint coefficient of degree (r, s) has the generating factor $1/(r!\, s!)$, and passing from total derivatives gives only the factor $(r+s)!/(r!\, s!) \le 2^{r+s}$. Summing the composed majorant series proves the two coefficient bounds in (1), at one fixed rate $a > 0$. The choice of the fixed occurrence of w, including multiplicities and colors, contributes at most another factor exponential in $r + s$, which is absorbed into C.

Step 3: the supports. Let $\mathscr{L} \ge 1$ be an integer. If a periodic direction of the coarse lattice has length at least $2\mathscr{L}$, we divide it into integer intervals of lengths between $\mathscr{L}$ and $2\mathscr{L}$; this is possible by distributing the remainder among $\lfloor m/\mathscr{L} \rfloor$ intervals. A shorter direction forms one interval. The resulting boxes have bounded adjacency degree and contain at most $D_{M,\mathscr{L}}$ scalar labels.

Consider a monomial with $k = r + s \ge 1$ coordinate locations. We order all metric spanning trees of these locations and all shortest periodic coordinate paths by one fixed rule, choose a shortest metric spanning tree, and replace each of its edges by the chosen rectilinear path. The resulting network has length at most a fixed multiple of the length t of a shortest connected network joining the locations. Indeed, traversing every edge of such a network twice gives a closed walk of length $2\mathsf{t}$ through all locations. Shortcutting this walk yields a metric spanning tree of length at most $2\mathsf{t}$, and replacing an edge by a coordinate path changes its length by at most a factor depending on the dimension. We add the intersection points of the paths as vertices, delete cycles by the fixed rule, and prune branches that contain no location. The result is a rectilinear tree of no greater length. Let X be the set of boxes met by this tree, including the boxes of the locations. It is connected, since the fixed rule assigns boundary points to adjacent boxes. A coordinate segment of length l meets at most $C(1 + l/\mathscr{L})$ boxes. The unpruned paths consist of at most $3(k-1)$ segments, and the deletions do not add boxes. Applying the bound to these segments, we obtain

$$|X| \le C_0\big(k + 1 + \mathsf{t}/\mathscr{L}\big). \tag{12.19}$$

Supports winding around the torus occur, since the paths are periodic. If $x \in X$ and e is the location of the fixed index of w, then

$$\operatorname{dist}(x, e) \le C_1\big\{\mathsf{t} + \mathscr{L}(k+1)\big\},$$

where the distance to a box is measured to its center; another choice changes the constant by the diameter of a box.

We choose $\mathscr{L}$ so large that $8C_0/\mathscr{L} < a/4$, and then $b_1 > 0$ so small that $b_1 C_1 < a/4$. Combining the two geometric bounds, we obtain the support-weight estimate

$$\mathbf{1}_{x\in X} e^{8|X|} \le C D_{\mathscr{L}}^{k} e^{a\mathrm{t}/2} e^{-b_1 \operatorname{dist}(x,e)}, \tag{12.20}$$

with $D_{\mathscr{L}} = e^{8C_0 + b_1 C_1 \mathscr{L}}$. Since the indices of w have bounded density and polynomial growth, we have $\sup_x \sum_e e^{-b_1 \operatorname{dist}(x,e)} \le C_{M,\mathscr{L},b_1}$, uniformly in the side of the torus. This includes the case of a short direction, in which the number of labels in that direction is bounded by the box scale.

Step 4: summation and the polymer gas. We group the monomials, with their coefficients, according to their supports X; the sum U_X depends only on coordinates located in X. We apply (12.20) before summing over the location e of the fixed index of w, and then the coefficient bounds of Step 2. This bounds the norm with support weight $e^{8|X|}$ by

$$C \sum_{r\ge 0} (Cu)^r \Big\{ \sum_{s\ge 3} C^s g^{s-2} p^s + \sum_{s\ge 1} (Cgp)^s \Big\},$$

where the constants include the factors $D_{\mathscr{L}}^{r+s}$. We reduce u until $Cu \le 1/2$ and the threshold for gp until $Cgp < 1/2$. Summing the geometric series and enlarging the constant in (12.4), we obtain the bound $C\{gp^3/(1 - Cgp) + gp\}$. The absolute convergence proves both the identity $U = \sum_X U_X$ and the bound in (2). This estimate controls the sum of the separate coefficient suprema required by (12.1).

The bounds of Steps 1–4 use g only through the factors g^{s-2} and g^s of the series (12.17) and (12.18), and the domain condition $\|gSw\| \le C|g|p$. For a complex parameter ζ in place of g, the same series define $U(c, w; \zeta)$, which is holomorphic across $\zeta = 0$ since the classical series starts at ζ^1. The same estimates hold with $|\zeta|$ in place of g. This proves (4) for the bounds in (1) and (2), and the argument for (3) below applies without change.

For (3), we apply Step 1 of the proof of Theorem 12.7 with $\pi = \pi_p$ and with η replaced by σ. We obtain $\|F_X\|_{u,\mathrm{coeff};p} \le 2\|U_X\|_{u,\mathrm{coeff};p}$, the hard-core representation of Ξ with the displayed activities, and the bound $\|\{\mathfrak{z}(P)\}\|_{u,5} \le 2\sigma$. This requires only the independence of the fluctuation variables in disjoint sets of boxes under π_p; the coarse-field variables are parameters. All constants were chosen using M, the fixed domains, and the spatial decay rates, so they have the stated dependence. □

We now combine the exact formula (12.6) with the cluster expansion. We define the effective interaction newly generated by the averaging step as

$$Q_{d_0}^{\mathrm{w}}(c) = \mathcal{L}_0(c) + \tfrac{1}{2} \log\det K(c) - f \log z_p - \log \Xi(c). \tag{12.21}$$

Since $\det S(c) = (\det K(c))^{-1/2}$, Lemma 12.3 can be written as

$$\int_{z^*+gS\Omega_p} e^{-F(c,z)/g^2}\, \mathcal{J}_c(z)\, dz = \mathcal{J}_I(0) g^{3f} \exp\Big(-\frac{E_{d_0+1}(c)}{g_+^2} - Q^{\mathrm{w}}_{d_0}(c)\Big).$$

Proposition 12.10. *Assume the setting of Lemma 12.9, with $\sigma \le \sigma_0$. There exist $u_* \in (0, u_0]$ and $b > 0$, with the dependence described in item (2) of Definition 4.14, such that the following holds on $\|\theta\|_\infty \le u_*$, uniformly in d_0, m, and in g, p satisfying* (12.4).

1. *For every $s \ge 1$,*
$$\|D^s_\theta Q^{\mathrm{w}}_{d_0}\|_{b,\mathrm{root}} \le C^s s!.$$
The value of $Q^{\mathrm{w}}_{d_0}$ is not bounded uniformly in the volume.
2. *For real c and $w \in \Omega_p$, the Hessian of $w \mapsto |w|^2/2 + U(c,w)$ is $I + E$, where E is bounded by $C(gp + g^2)$ in a fixed exponentially weighted row-plus-column norm.*

Proof. By Lemma 12.9(3), the activities satisfy (12.11), and the labels have bounded density. Thus Theorem 12.6(4) implies that $\|D^s_\theta \log \Xi\|_{b,\mathrm{root}} \le C^s s! \sigma$ on $\|\theta\|_\infty \le u/2$.

We next treat the determinant. Let $A(\theta) = (K^0)^{-1}(K(c) - K^0)$, and reduce the coefficient radius such that the row and column series of A have norm less than $1/2$. On this radius, we have

$$\tfrac{1}{2} \log\det K(c) = \tfrac{1}{2} \log\det K^0 + \tfrac{1}{2} \sum_{j \ge 1} \frac{(-1)^{j+1}}{j} \operatorname{tr} A(\theta)^j, \tag{12.22}$$

where the logarithm is the branch that is real for real c. To verify this, we replace A by hA. Differentiating the determinant along its columns, we find $(d/dh) \log\det(I + hA) = \operatorname{tr}[(I + hA)^{-1} A]$, and integrating the Neumann series from $h = 0$ to $h = 1$ gives the formula. A coefficient of positive degree in θ differentiates at least one factor A. We fix the coarse-field index on such a factor and sum over its two matrix indices using Lemma 12.2(4) and the rows and columns of $(K^0)^{-1}$; every other factor is contracted by rows and columns. The choice of the distinguished factor cancels the factor $1/j$. If $a(x) = Cx/(1 - Cx)$ is a majorant series for A, the trace coefficients with one coarse-field index fixed are bounded by those of $Ca'(x)/(1 - a(x))$ on a fixed smaller disc, and these coefficients are at most C_1^{k+1}. Translating to a background point in a fixed smaller product, we obtain factorial bounds for all derivatives of positive order. The network of a trace may contain a cycle. Deleting an edge leaves a network joining the same locations, so the weight of a shortest connected network is still available. The constant $\log\det K^0$ is extensive and is not estimated. The term $\mathcal{L}_0$ is the composition of $\mathcal{L}$ with the minimizer, and by Lemma 12.2 it has the same bounds with one index fixed. The constant $f \log z_p$ has no derivatives of positive order. Combining these bounds on $\|\theta\|_\infty \le u_*$, where u_* is the smaller of $u/2$ and the radius chosen for A, we obtain (1). Here the determinant term enters (12.21) with the positive sign, and the constant $-f \log z_p$ is kept.

For (2), we fix a real coarse field. Up to a term independent of w, the potential is $g^{-2}F(c, z^* + gSw) + \mathcal{L}_c(z^* + gSw)$. Since S depends only on c, its Hessian minus the identity is

$$S^{\mathsf{T}}\{D_z^2 F(c, z^* + gSw) - K(c)\}S + g^2 S^{\mathsf{T}} D_z^2 \mathcal{L}_c(z^* + gSw)S.$$

The third derivative of F and the second derivative of $\mathcal{L}_c$ have fixed weighted bounds on the product, and $\|gSw\| \le Cgp$ by the row bound for S. We conclude that the displayed matrix is bounded by $C(gp + g^2)$ in a fixed weighted row-plus-column norm. □

The last result for one averaging step concerns symmetries.

Proposition 12.11. *In the setting of Lemma 12.3, there exist fixed products of coarse-field logarithms θ, free logarithmic coordinates z, and gauge parameters κ, independent of d_0 and m and contained in the domains of that lemma, on which both the original and the transformed reconstructed configurations lie in the domains of Lemma 6.3 and Theorems 10.10 and 10.11. We call them the common symmetry domains; they are constructed in the proof. Let $c = e^{\theta}$ be real, with θ in the common symmetry domain, and let τ be one of the following real operations on coarse fields: a translation by a vector of the coarse lattice; the spatial inversion, under which reversed links carry inverted matrices; a constant color conjugation; or a coarse gauge transformation $c \mapsto c^k$ with $\mathrm{SU}(2)$-valued $k = e^{\kappa}$ and κ real in the corresponding fixed parameter product. Then there exists an orthogonal map $O(c)$ of the free logarithmic coordinates, which permutes the three-component blocks, acts on each block by an orthogonal matrix, and does not depend on z, such that*

$$z^*(\tau c) = O(c)z^*(c), \qquad K(\tau c) = O(c)K(c)O(c)^{\mathsf{T}}, \qquad S(\tau c) = O(c)S(c)O(c)^{\mathsf{T}}.$$

The induced map $w \mapsto O(c)w$ of the normalized fluctuation variables preserves Ω_p, $|w|^2$, Lebesgue measure, and π_p, and the Haar disintegration density and $\det K$ *are preserved. Consequently the integral* (12.6) *and $Q^{\mathrm{w}}_{d_0}$ take the same values at c and at τc. The resulting identities between analytic functions of the coarse field extend to the corresponding common complex domains.*

Proof. At depth zero the Wilson action is invariant under periodic gauge transformations, translations, the spatial inversion, and constant color conjugations: the plaquette variables are conjugated, relabeled, or inverted, and $q(U^{-1}) = q(U)$. The transformations of the constraint coordinates in Lemma 6.3 intertwine the reconstruction, and on the common symmetry domains they send z to $O(c)z$, where $O(c)$ is as in the statement.

We first prove the invariance of E_d as an identity of analytic germs at the identity, by induction on the depth d. If the germ at depth d is invariant, then the intertwining of the constraint coordinates carries the constrained objective to the transformed objective near $(c, z) = (I, 0)$. The transformed stationary point is $O(c)z^*(c)$, which lies in the neighborhood where the minimizer of Theorem 10.10 is unique. The two stationary values agree, and multiplying by M gives the invariance of the germ at depth $d + 1$. Only

a nonempty neighborhood is used in this induction, and no uniform radius is inferred from it.

To obtain a uniform domain, we use the common holomorphic domains of Lemma 6.3 and Theorems 10.10 and 10.11. We choose fixed smaller products in (θ, z, κ) on which both the original and the transformed reconstructed fields lie in these domains; these are the common symmetry domains of the statement. The finite-word bounds for the reconstruction and the local gauge word $e^{\kappa_x} e^{\theta_{xy}} e^{-\kappa_y}$ allow this choice independently of the depth. The differences between the two action values, and between the two constrained objectives, are holomorphic there and have zero germ by the induction. We claim that they vanish on the whole smaller product. Indeed, we restrict such a difference to the complex line $h \mapsto h(\theta, z, \kappa)$ through a fixed point of the product. The fixed margins allow a disc $|h| < 1 + \eta$ for some $\eta > 0$. Its Taylor series vanishes near $h = 0$, and continuation through overlapping discs along $[0, 1]$ shows that it vanishes at $h = 1$. Translations and the spatial inversion are treated in the same way without κ, and a constant color conjugation preserves the radii and is kept fixed in the induction. Thus the identity of the objectives holds on the fixed products, and the uniqueness of the minimizer there implies that $z^*(\tau c) = O(c) z^*(c)$ on the common domain, without a loss of radius depending on the depth.

Differentiating the objective identity twice, we obtain $K(\tau c) = OKO^{\mathsf{T}}$, and the integral formula for the inverse square root implies that $S(\tau c) = OSO^{\mathsf{T}}$. Then $w = S^{-1}(z - z^*)/g$ transforms as $w \mapsto O(c) w$, which preserves the product of balls, $|w|^2$, Lebesgue measure, and the product reference measure π_p. By the exact Haar disintegration of Lemma 6.3 and $\det(OKO^{\mathsf{T}}) = \det K$, every remaining factor of the integral is preserved. This proves the identities for the integral and for $Q^{\mathrm{w}}_{d_0}$ at real coarse fields, without requiring the individual pieces U_X to be invariant. The statements about balls, Lebesgue measure, and π_p concern the real change of variables. The identities for z^*, K, S, and $Q^{\mathrm{w}}_{d_0}$ hold between functions that are holomorphic on the common complex symmetry domains, so they extend there by the identity theorem. □

The gauge parameter κ in Proposition 12.11 ranges over a fixed small product, and Theorem 12.13(6) imposes this restriction at every scale. Transitions between coarse fields in the comparison domains of Section 13 that are related by an arbitrary periodic gauge transformation are given by Theorem 13.4(3).

12.4 Several averaging steps

We now compose $s \le J$ averaging steps. At each scale, from the coarsest to the finest, we perform the change of variables of Lemma 12.3 with the coarse field of that scale, which depends on the fluctuations already introduced. The following example shows the structure of the resulting change of variables in the simplest case.

Example 12.12. Let $s = 2$, and let $c_2 = e^\theta$ be the coarse field. The coordinates of the coarser intermediate scale are $z_1 = z_1^*(c_2) + g_1 S_1(c_2) w_1$, and they determine the field $c_1 = b_1(c_2, z_1)$, so that $c_1 = c_1(w_1)$. The coordinates of the finer scale are

$$z_0 = z_0^*(c_1(w_1)) + g_0 S_0(c_1(w_1)) w_0.$$

In the order (w_1, w_0) the derivative of $w \mapsto (z_1, z_0)$ is block lower triangular,

$$D_w z = \begin{pmatrix} g_1 S_1(c_2) & 0 \\ D_{w_1} z_0 & g_0 S_0(c_1(w_1)) \end{pmatrix}, \qquad D_{w_1} z_0 = D z_0^*(c_1) D_{w_1} c_1 + g_0 D S_0(c_1)[D_{w_1} c_1] w_0.$$

We write D_i for the number of real coordinates of z_i, $i = 0, 1$. The off-diagonal block does not change the determinant, $\det D_w z = g_1^{D_1} \det S_1(c_2)\, g_0^{D_0} \det S_0(c_1(w_1))$, but it enters all later derivatives. The determinant of the finer scale depends on w_1. Let $\widehat{c}_1 = c_1(0) = b_1(c_2, z_1^*(c_2))$ be the zero-fluctuation reconstruction of c_1. We split

$$\log\det K_0(c_1(w_1)) = \log\det K_0(\widehat{c}_1) + \big[\log\det K_0(c_1(w_1)) - \log\det K_0(\widehat{c}_1)\big].$$

The first term depends only on c_2 and becomes part of the function $\mathsf{B}_{\mathrm{ref}}$ of Theorem 12.13. The second depends on w_1 and is part of the fluctuation interaction $H_{d_0,2}$. The negative logarithmic Haar density at the minimizer of the finer scale is split in the same way. Replacing $c_1(w_1)$ by $\widehat{c}_1$ in these terms would not give an exact formula. Under the product reference measure, w_1 and w_0 are independent, but the interacting density need not factor. Its classical and Haar-density remainders can involve both variables, while the determinant and minimizer-density corrections displayed here depend only on w_1 and change its marginal weight.

In the theorem below, the field c_i lives on the lattice of side mM^{s-i}, $0 \le i \le s$, so that c_0 is the finest field and $c_s = e^\theta$ is the coarse field. The i-th averaging step, from side mM^{s-i} to side mM^{s-i-1}, has input action E_{d_0+i}; we write $b_i(c, z)$ for its reconstruction, $\mathcal{J}_i(c, z)$ for its Haar disintegration density, and $z_i^*(c)$ for its conditional constrained minimizer, as in Lemma 12.3. The coupling of the coarsest integrated scale is t, and the couplings decrease by the factor $M^{-1/2}$ toward finer scales.

Theorem 12.13. *Fix an odd integer $M \ge 3$ and an integer $J \ge 1$. There exist $u_J, v_J, b_J, c_J, C_J, \sigma_0 > 0$, uniform in the depth $d_0 \ge 0$ and in the side $m \ge 4$, such that the following holds for every integer $1 \le s \le J$. For $0 \le i < s$ put*

$$f_i = 2(M^3 - 1)(mM^{s-i-1})^3, \qquad D_i = 3 f_i, \qquad g_i = t M^{(i-s+1)/2},$$

and $g_s^2 = M g_{s-1}^2$. Given $c_s = e^\theta$, define successively, for decreasing i,

$$F_i(c, z) = E_{d_0+i}(b_i(c, z)), \qquad K_i(c) = D_z^2 F_i(c, z_i^*(c)), \qquad S_i = K_i^{-1/2},$$
$$z_i = z_i^*(c_{i+1}) + g_i S_i(c_{i+1}) w_i, \qquad c_i = b_i(c_{i+1}, z_i).$$

Let $\Omega_p^{\mathrm{all}} = \prod_{i<s} \prod_e \{w_{i,e} \in \mathbb{R}^3 : |w_{i,e}| \le p\}$, *and let* π_p^{all} *be the product reference measure on it with density proportional to* $e^{-\sum_i |w_i|^2/2}$. *Assume* $p \ge p_0$, $\|\theta\|_\infty < u_J$, *and*

$$C_J t p < \tfrac{1}{2}, \qquad \sigma_J = C_J \frac{t p^3 + t p}{1 - C_J t p} \le \sigma_0. \tag{12.23}$$

Then the following statements hold.

1. *For every* $w \in \Omega_p^{\mathrm{all}}$ *the reconstruction lies, with fixed margins, in every classical and Haar disintegration chart, and the recursion is a jointly holomorphic map of* θ *and of the variables* $q_i = g_i w_i$ *on a common larger product.*
2. *In the order from coarser to finer scales,*

$$\det D_w z = \prod_{i=0}^{s-1} g_i^{D_i} \det S_i(c_{i+1}).$$

3. *Put*

$$U_i^{\mathrm{cl}} = \frac{F_i(c_{i+1}, z_i) - F_i(c_{i+1}, z_i^*(c_{i+1}))}{g_i^2} - \frac{1}{2}|w_i|^2.$$

Then, exactly,

$$\frac{E_{d_0}(c_0)}{g_0^2} = \frac{E_{d_0+s}(c_s)}{g_s^2} + \frac{1}{2}\sum_i |w_i|^2 + \sum_i U_i^{\mathrm{cl}}.$$

4. *Put* $\mathcal{L}_i(c, z) = -\log(\mathcal{J}_i(c, z)/\mathcal{J}_i(I, 0))$ *and*

$$\mathsf{B}_i(c) = \mathcal{L}_i(c, z_i^*(c)) + \tfrac{1}{2}\log\det K_i(c).$$

Let $\widehat{c}_s = c_s$ *and* $\widehat{c}_i = b_i(\widehat{c}_{i+1}, z_i^*(\widehat{c}_{i+1}))$ *be the zero-fluctuation reconstruction, and set* $\mathsf{B}_{\mathrm{ref}}(c_s) = \sum_i \mathsf{B}_i(\widehat{c}_{i+1})$. *Define the fluctuation interaction*

$$H_{d_0,s}(\theta, w) = \sum_i \Big[U_i^{\mathrm{cl}} + \mathcal{L}_i(c_{i+1}, z_i) - \mathcal{L}_i(c_{i+1}, z_i^*(c_{i+1})) + \mathsf{B}_i(c_{i+1}) - \mathsf{B}_i(\widehat{c}_{i+1}) \Big]. \tag{12.24}$$

If $\mathscr{D}_s(c_s)$ *is the image of* Ω_p^{all} *under* $w \mapsto (z_i)_{i<s}$, *then*

$$\begin{aligned} &\int_{\mathscr{D}_s(c_s)} e^{-E_{d_0}(c_0)/g_0^2} \prod_i \mathcal{J}_i(c_{i+1}, z_i)\, dz_i \\ &\qquad = \Big(\prod_i \mathcal{J}_i(I, 0) g_i^{D_i} \Big) e^{-E_{d_0+s}(c_s)/g_s^2 - \mathsf{B}_{\mathrm{ref}}(c_s)} z_p^{\sum_i f_i}\, \Xi_{d_0,s}(c_s), \end{aligned} \tag{12.25}$$

where $\Xi_{d_0,s} = \mathbb{E}_{\pi_p^{\mathrm{all}}} e^{-H_{d_0,s}}$.

5. *There is an exact decomposition* $H_{d_0,s} = \sum_X H_X$ *into functions supported on connected sets of boxes with* $\|\{H_X\}\|_{u_J', 8; p} \le \sigma_J$, *for a fixed coarse-field radius* $u_J' \in (0, u_J]$ *that also lies*

inside the domain of the coefficient series of $\mathsf{B}_{\mathrm{ref}}$ *described in the proof. Both expansions of Theorem 12.7 apply;* $\Xi_{d_0,s} \neq 0$ *on* $\|\theta\|_\infty < u'_J$*, and the effective interaction*

$$Q^{\mathrm{w}}_{d_0,s} = \mathsf{B}_{\mathrm{ref}} - \Big(\sum_i f_i\Big) \log z_p - \log \Xi_{d_0,s}$$

satisfies, on $\|\theta\|_\infty \le u'_J/2$, $\|D^k_\theta Q^{\mathrm{w}}_{d_0,s}\|_{b_J,\mathrm{root}} \le C_J^{k+1} k!$ *for every* $k \ge 1$*. The function* $\mathsf{B}_{\mathrm{ref}}$ *of the coarse field is kept in full.*

6. *Let* c_s *be real, and let* τ *be one of the operations of Proposition 12.11, applied to* c_s*. Assume that, for every* $w \in \Omega^{\mathrm{all}}_p$ *and every* i*, the field* c_{i+1} *and the operation induced by* τ *on it satisfy the hypotheses of Proposition 12.11 for the averaging step* i*, that is, they lie in the common symmetry domains of that step. Then the induced changes of variables* $w'_i = O_i(c_{i+1}) w_i$ *are triangular, orthogonal at each scale for fixed coarser variables, preserve every ball, and have absolute joint Jacobian one; their dependence on the coarser fluctuations is retained. They transport every factor of* (12.25)*.*

The constants depend only on M*,* J*, the larger chart margins, the box geometry, and the spatial decay rates; they do not depend on* d_0*,* m*, or on* t*,* p *satisfying* (12.23)*.*

In the proof, we first construct one product of coordinates on which all compositions are controlled, before any integration. We then compute the Jacobian and the integral exactly, and finally we estimate the fluctuation interaction and apply the expansions.

Proof. For each $0 \le i < s$ the averaging step i has output side $m_i = mM^{s-i-1} \ge 4$, input side Mm_i, and depth $d_0 + i \ge 0$. Thus Lemmas 12.2 and 12.3 apply to every step, and the construction below checks their domain conditions at every argument reached by the reconstruction.

Step 1: a common product. In logarithmic coordinates, we define the map of one step

$$T_i(x, q) = \mathrm{Log}\, b_i\big(e^x, z_i^*(e^x) + S_i(e^x) q\big).$$

Its value at $(0, 0)$ is zero. By Lemmas 12.2 and 12.3, its output rows and all its input columns are bounded by one convergent majorant series, which we enlarge to $P(h) = Ah/(1 - Ah)$; these bounds are uniform in $d_0 + i$ and in m_i. We choose a smaller domain for each step, with a fixed positive margin R_1 to every classical and Haar disintegration boundary and to every denominator in these series.

For a scalar variable h, we set $x_s(h) = h$ and successively $x_i(h) = P(x_{i+1}(h) + h)$. There are only $s \le J$ compositions, and their denominators equal one at $h = 0$. We choose $r_J > 0$ such that, for every $s \le J$ and $0 \le i < s$, all denominators are at least $1/2$ and $x_{i+1}(h) + h < R_1/4$ for $0 \le h \le 2r_J$. These are finitely many continuous inequalities that hold strictly at $h = 0$, so such an r_J exists; it depends only on the data listed in the statement. By coefficientwise composition and the contraction rule of Lemma 5.3, these

scalar series majorize the recursion with independent variables q_i. At a fixed input index, we use the column along its path to the output and the rows on the other branches, and the scalar compositions enumerate the partitions of the other inputs with their Taylor factorials. Thus all joint absolute coefficients are controlled, not only the values of the maps at real arguments.

Step 2: units and volumes. The output mesh of step i is M^{i+1-s} in units of the coarse lattice spacing. A length l in the units of step i therefore becomes $M^{i+1-s}l$, and the exponential bound of that step yields a bound at a fixed smaller rate in coarse units. The meshes of all inputs and outputs belong to the finite set $\{M^{-J}, \dots, 1\}$. The column factors are the ratios of the corresponding volumes, as in Lemma 5.3. Passing between counting sums and volume-normalized sums introduces at most a factor M^{3J} for each participating index, hence at most $M^{3J(k+1)}$ for a coefficient of order k, which is absorbed by a fixed smaller joint radius. The number of indices of the variables q_i of the finitely many scales per unit cube is at most $C_M s M^{3s}$. In particular, no factor M^{d_0} and no factor of the total volume occurs. We keep the composed networks until a single final replacement by trees on the external indices, which gives one fixed rate $a_J > 0$.

Step 3: the domain of the fluctuation variables. We choose u_J and v_J below r_J and below the last radius reduction. For $\|\theta\|_\infty < u_J$ and $\max_i \|q_i\|_\infty \le tp$, we enlarge C_J so that (12.23) implies $tp < v_J/2$. By Step 1, all charts then have fixed margins for every $w \in \Omega_p^{\mathrm{all}}$, and the recursion is jointly holomorphic in (θ, q) on the larger product. Taking maxima over $1 \le s \le J$ fixes all these choices at once. This proves (1).

Step 4: the Jacobian. By Lemma 6.3, the scale i has $2(M^3-1)(mM^{s-i-1})^3 = f_i$ independent $\mathrm{SU}(2)$ variables, hence $D_i = 3f_i$ real coordinates. We order the scales as $s-1, s-2, \dots, 0$. The field c_{i+1} depends only on the w_l with $l > i$, so

$$D_{w_i} z_i = g_i S_i(c_{i+1}), \qquad D_{w_l} z_i = 0 \quad (l < i).$$

For $l > i$, the derivative $D_{w_l} z_i$ contains both $Dz_i^*(c_{i+1}) D_{w_l} c_{i+1}$ and $g_i DS_i(c_{i+1})[D_{w_l} c_{i+1}] w_i$, and we keep these entries. The derivative matrix is block triangular, and its determinant is as stated in (2); for real data, each diagonal determinant is positive. The recursion is one-to-one onto its image, since one recovers w_{s-1} from z_{s-1} first and proceeds to finer scales, using the invertibility of each S_i. Hence it is a change of variables on its image.

Step 5: the exact integral. By the nested minimization identity of Theorem 10.10 at scale i, and since $g_{i+1}^2 = M g_i^2$ (including $g_s = \sqrt{M}t$), we have

$$\frac{E_{d_0+i}(c_i)}{g_i^2} - \frac{E_{d_0+i+1}(c_{i+1})}{g_{i+1}^2} = \frac{F_i(c_{i+1}, z_i) - F_i(c_{i+1}, z_i^*)}{g_i^2} = \frac{1}{2}|w_i|^2 + U_i^{\mathrm{cl}}.$$

Summing over i proves (3). The product of the Haar disintegration densities and of the Jacobian is

$$\prod_i \mathcal{J}_i(I,0) g_i^{D_i} \exp\Big\{ -\sum_i \Big[\mathcal{L}_i(c_{i+1}, z_i) + \tfrac{1}{2} \log\det K_i(c_{i+1}) \Big] \Big\}.$$

For each i the exponent splits exactly as

$$\begin{aligned} \mathcal{L}_i(c_{i+1}, z_i) + \tfrac{1}{2}\log\det K_i(c_{i+1}) = {} & \mathsf{B}_i(\widehat{c}_{i+1}) + \mathcal{L}_i(c_{i+1}, z_i) - \mathcal{L}_i(c_{i+1}, z_i^*(c_{i+1})) \\ & + \mathsf{B}_i(c_{i+1}) - \mathsf{B}_i(\widehat{c}_{i+1}). \end{aligned}$$

We add the terms U_i^{cl} from (3). The first terms on the right sum to $\mathsf{B}_{\mathrm{ref}}$, and all other terms together form $H_{d_0,s}$. Integrating the Gaussian factor over each ball contributes $z_p^{\sum_i f_i}$, and the remaining expectation is $\Xi_{d_0,s}$. This proves (12.25); the off-diagonal derivatives of the triangular change of variables contribute no additional determinant. The fluctuations of the determinants and of the Haar densities at the minimizers of the finer scales are exactly the terms $\mathsf{B}_i(c_{i+1}) - \mathsf{B}_i(\widehat{c}_{i+1})$. For complex coarse fields, the formula again means integration over the same real product of the w_i.

Step 6: bounds for the fluctuation interaction. All coefficients of positive degree of B_i have factorial bounds with one index fixed; for the determinant we use the series (12.22), and for the negative logarithmic Haar density Lemma 12.2. We compose these scalar series and the other tensors of one step with the maps bounded in Step 1. Fixing a scalar coefficient at any input and propagating the fixed index along columns, we sum all intermediate indices; the bounded density of the indices of the variables q_i changes only the constants.

By (12.17), a classical term from scale i has at least three w_i inputs and the factor g_i^{k-2} for its degree $k \geq 3$ in w_i. Expanding its coarse field c_{i+1} adds one factor $g_l w_l$ for each input from a coarser scale $l > i$. Since $0 < g_i \leq t$, the sum over these degrees and over all coarse-field degrees is bounded, on a smaller fixed coarse-field radius, by $C_J t p^3/(1 - C_J t p)$. By (12.18), a difference of negative logarithmic Haar densities contains at least one factor $g_i w_i$. A difference $\mathsf{B}_i(c_{i+1}) - \mathsf{B}_i(\widehat{c}_{i+1})$ has no term independent of the fluctuations, since at $q = 0$ both arguments are the zero-fluctuation reconstruction. Each of its terms contains a factor $g_l w_l$ with $l > i$. These two kinds of differences together have the majorant $C_J t p/(1 - C_J t p)$. For each of these terms, a fixed index of q either fixes the outer scalar coefficient or reaches it through the column of an insertion, so these are bounds with one index fixed. Summing over the at most J scales, we obtain the majorant

$$C_J \frac{t p^3 + t p}{1 - C_J t p}, \tag{12.26}$$

and every monomial of $H_{d_0,s}$ contains at least one fluctuation variable.

We apply the construction of supports of Lemma 12.9, with (12.19) and (12.20), in units of the coarse lattice spacing, with a_J in place of a, and with the density of the indices of q stated above in the sum over the location of the fixed index. We choose the box scale such that $8C_0/\mathscr{L} < a_J/4$, then the rate b_1, and then we reduce the joint radius to absorb the resulting factor $D_{\mathscr{L}}^{r+k}$. The geometric series of Step 4 of that proof now has the majorants (12.26) in place of those of one step. After enlarging C_J, we obtain an exact decomposition $H_{d_0,s} = \sum_X H_X$ with norm at most σ_J for the support weight $e^{8|X|}$. All the conditions in (12.23) use this final C_J.

Step 7: the expansions and the effective interaction. The connected-component expansion uses only the coefficient bound, the exact supports, and the independence of the fluctuation variables in disjoint supports, which holds for π_p^{all}. Thus Step 1 of the proof of Theorem 12.7 yields activities with $\|\{\mathfrak{z}(P)\}\|_{u'_J,5} \le 2\sigma_J$, and by Theorem 12.6 we have $\Xi_{d_0,s} \neq 0$ and the bound with support weight $e^{2|Y|}$ for the logarithm. The bounded density of the indices also provides a network of length at most $C_J|Y|$ joining all labels of a support. Then (12.12) implies factorial bounds for the derivatives of $\log \Xi_{d_0,s}$ on $\|\theta\|_\infty \le u'_J/2$, at one fixed rate $b_J > 0$, which we take no larger than a_J.

The zero-fluctuation reconstruction is the map of Step 1 at $q = 0$. We compose its majorant series with the series of the coefficients of positive degree of the B_i. This bounds the coefficients of positive degree of $\mathsf{B}_{\mathrm{ref}}$, with one coarse-field index fixed, at the rate a_J on a fixed product of coarse fields. Translating to background points of a smaller product, we bound every derivative of positive order of $\mathsf{B}_{\mathrm{ref}}$ by $C_J^{k+1}k!$ there; the value of the extensive trace is not bounded. We choose the radius u'_J of (5) such that $\|\theta\|_\infty < u'_J$ lies inside this smaller product, and we restrict the derivative bounds to $\|\theta\|_\infty \le u'_J/2$, where (12.12) applies. Restoring this function and the truncated Gaussian constants in (12.25) proves the formula for $Q^{\mathrm{w}}_{d_0,s}$ and its bounds.

Step 8: symmetries. For each operation τ, the hypothesis of (6) allows us to apply Proposition 12.11 at scale i, which shows that $z_i^*(\tau c_{i+1}) = O_i z_i^*(c_{i+1})$, $K_i(\tau c_{i+1}) = O_i K_i O_i^{\mathsf{T}}$, and $S_i(\tau c_{i+1}) = O_i S_i O_i^{\mathsf{T}}$, with $O_i = O_i(c_{i+1})$ independent of w_i. Proceeding from coarser to finer scales, we obtain $w'_i = O_i(c_{i+1})w_i$, which depends on every coarser fluctuation. This map is a bijection of Ω_p^{all}, since one inverts the block of the coarsest scale first and proceeds to finer scales. Its diagonal Jacobian blocks are the O_i, so its absolute Jacobian is one. Each block preserves its balls and $\sum_i |w_i|^2$, and each Haar density and determinant is transported by the identity of one step. Since at zero fluctuations the transformed zero-fluctuation reconstruction is the zero-fluctuation reconstruction of τc_s, the function $\mathsf{B}_{\mathrm{ref}}$ is transported as well. This proves (6). All choices used only the fixed data and finitely many scales, which proves the stated uniformity; nothing is claimed as $J \to \infty$. □

12.5 Perturbation by an input effective interaction

In the recursion of Section 13, the density at the finer scale contains, besides the effective classical action, an input effective interaction R, produced by the integrations at still finer scales and evaluated at the reconstructed fine field. In this subsection, we fix $s = J$, so that the J averaging steps form one renormalization group step, and we compute the effect of R on the integral of Theorem 12.13. We set $\lambda_i = M^{(i-J+1)/2}$, so that $g_i = t\lambda_i$, and let $\mathscr{C}_{\mathrm{raw}}(\theta, q)$ be the fine field c_0 produced by the recursion of Theorem 12.13 with q_i in place of $g_i w_i$. That is, $z_i = z_i^*(c_{i+1}) + S_i(c_{i+1})q_i$, and the matrices S_i remain in the map. This is the reconstruction before the gauge transformation used in Section 13.

The following heuristic explains why the effect of R, beyond its value R_{ref} on the zero-fluctuation reconstruction, is of second order in the coupling.

Remark 12.14. Suppose that $H = \zeta H_1 + \zeta^2 H_2 + \cdots$ and $A = \zeta A_1 + \zeta^2 A_2 + \cdots$ are interactions depending on a small parameter ζ, and that $\mathbb{E}_\pi A_1 = 0$. Expanding the logarithms to second order gives

$$-\log \mathbb{E}_\pi e^{-H-A} + \log \mathbb{E}_\pi e^{-H} = \zeta^2 \Big(\mathbb{E}_\pi A_2 - \mathrm{Cov}_\pi(H_1, A_1) - \tfrac{1}{2} \mathrm{Var}_\pi(A_1) \Big) + O(\zeta^3).$$

For the inserted interaction $A = R(c_0) - R_{\mathrm{ref}}$, the first-order term A_1 is linear in the normalized fluctuation variables, and its mean under the symmetric reference measure vanishes. The difference of the logarithms is therefore of order ζ^2, and ζ will be set equal to t. Lemma 12.16 proves a uniform version of this statement for the families of Theorem 12.7, using Corollary 12.8 instead of a finite-order expansion.

To apply Corollary 12.8 we vary the size of the fluctuations through a complex parameter ζ, which takes the value t for the integral of Theorem 12.13.

Definition 12.15. For a complex parameter ζ, substitute $q_i = \zeta \lambda_i w_i$ in the recursion, and write $c_i(\zeta)$ and $z_i(\zeta) = z_i^*(c_{i+1}(\zeta)) + \zeta \lambda_i S_i(c_{i+1}(\zeta)) w_i$ for the resulting fields and coordinates, so that $c_i(t) = c_i$ and $c_i(0) = \widehat{c}_i$. The auxiliary fluctuation interaction $H_{d_0,J}(\theta, w; \zeta)$ is obtained from (12.24) by replacing c_{i+1} and z_i by $c_{i+1}(\zeta)$ and $z_i(\zeta)$, and the classical term U_i^{cl} by

$$\frac{F_i\big(c_{i+1}(\zeta), z_i^* + \zeta \lambda_i S_i w_i\big) - F_i\big(c_{i+1}(\zeta), z_i^*\big)}{\zeta^2 \lambda_i^2} - \frac{1}{2}|w_i|^2, \tag{12.27}$$

where z_i^* and S_i are evaluated at $c_{i+1}(\zeta)$. Thus the explicit inverse square of the coupling varies together with the increments, while the classical functions, the balls, and the cutoff are held fixed. Put

$$\Xi_0(\theta; \zeta) = \mathbb{E}_{\pi_p^{\mathrm{all}}} e^{-H_{d_0,J}(\theta, w; \zeta)}, \tag{12.28}$$

where $\log \Xi_0$ is the branch of Theorem 12.7, with $\log \Xi_0(\theta; 0) = 0$.

By stationarity and $S_i^{\mathsf{T}} K_i S_i = I$, the expression (12.27) equals

$$\sum_{k\geq 3} \frac{\zeta^{k-2}\lambda_i^{k-2}}{k!} D_z^k F_i\big(c_{i+1}(\zeta), z_i^*\big)\big[(S_i w_i)^{\otimes k}\big],$$

so it extends holomorphically across $\zeta = 0$. The differences of negative logarithmic Haar densities and of the functions B_i in $H_{d_0,J}(\theta, w; \zeta)$ are evaluated at the same arguments $c_{i+1}(\zeta)$ and $z_i(\zeta)$. At $\zeta = t$, the auxiliary interaction is the interaction $H_{d_0,J}(\theta, w)$ of Theorem 12.13, and $\Xi_0(\theta; t) = \Xi_{d_0,J}(e^\theta)$. At $\zeta = 0$, every term vanishes, since the classical series starts at ζ^1, $z_i(0) = z_i^*(\widehat{c}_{i+1})$, and $c_{i+1}(0) = \widehat{c}_{i+1}$.

Lemma 12.16. *Fix J and the products, norms, and constants of Theorem 12.13 with $s = J$, and fix $u, v, b > 0$. Let R be a scalar function of the fine field such that its pullback*

$$\widehat{R}(\theta, q) = R\big(\mathscr{C}_{\mathrm{raw}}(\theta, q)\big)$$

is holomorphic on a product $\{\|\theta\|_\infty < u_2,\ \max_i \|q_i\|_\infty < v_2\}$ with $u_2 > u$ and $v_2 > v$, contained in the common product of Theorem 12.13(1), and satisfies $\mathcal{J}_{u,v,b}(\widehat{R}) \leq \epsilon$. The constant term of $\widehat{R}$ is unrestricted. Define

$$R_{\mathrm{ref}}(\theta) = \widehat{R}(\theta, 0), \qquad A_R(\theta, w; \zeta) = \widehat{R}\big(\theta, (\zeta\lambda_i w_i)_i\big) - R_{\mathrm{ref}}(\theta),$$
$$\Xi_{J,R}(\theta; \zeta) = \mathbb{E}_{\pi_p^{\mathrm{all}}} e^{-H_{d_0,J}(\theta, w; \zeta) - A_R(\theta, w; \zeta)}, \qquad \mathcal{D}_J R(\theta; \zeta) = -\log \Xi_{J,R}(\theta; \zeta) + \log \Xi_0(\theta; \zeta),$$

both logarithms being the branches of Theorem 12.7 that vanish at $\zeta = 0$. All parameters internal to R, the balls, and the classical functions are held fixed when ζ varies. There exist $u', b', C_J, c_J > 0$, depending only on M, J, u, v, b, the larger margins, and the spatial decay rates, and not on d_0, m, t, p, or ϵ, such that the following holds for every $p \geq p_0$, with $R_\zeta = c_J/(p^3 + \epsilon p)$.

1. *For every complex ζ with $|\zeta| \leq R_\zeta$ and every $w \in \Omega_p^{\mathrm{all}}$, the variables $q_i = \zeta\lambda_i w_i$ satisfy $\|q_i\|_\infty \leq c_J \leq \min\{v, v_J\}/2$. Consequently, for $\|\theta\|_\infty \leq u'$, the point (θ, q) lies in the product on which $\widehat{R}$ is holomorphic and in the common product of Theorem 12.13(1), and $H_{d_0,J}(\theta, w; \zeta)$ and $A_R(\theta, w; \zeta)$ are holomorphic in ζ on a neighborhood of the closed disc $|\zeta| \leq R_\zeta$.*
2. *Let $0 < t \leq c_J/[2(p^3 + \epsilon p)]$. Then the conditions* (12.23) *hold, and the integral* (12.25) *with the additional factor $e^{-R(c_0)}$ in the integrand equals the integral* (12.25) *times $\exp(-R_{\mathrm{ref}}(\theta) - \mathcal{D}_J R(\theta; t))$.*
3. *Let $\boldsymbol{\mathcal{D}}(\zeta) = \boldsymbol{\mathcal{L}}(\boldsymbol{H}(\zeta) + \boldsymbol{A}_R(\zeta)) - \boldsymbol{\mathcal{L}}(\boldsymbol{H}(\zeta))$ be the difference of the families of Theorem 12.7, at the coefficient radius u', for the supported decompositions $\boldsymbol{H}(\zeta)$ and $\boldsymbol{A}_R(\zeta)$ constructed in the proof; its sum over supports is $\mathcal{D}_J R(\theta; \zeta)$. Its constant and linear coefficients in ζ vanish, support by support. For $0 < t \leq c_J/[2(p^3 + \epsilon p)]$,*

$$\|\boldsymbol{\mathcal{D}}(t)\|_{\mathscr{S}_2} \leq C_J t^2 \epsilon (p^4 + \epsilon p^2),$$

and, on $\|\theta\|_\infty \le u'$*, for every* $k \ge 1$,

$$\|D_\theta^k \mathcal{D}_J R(\cdot;t)\|_{b',\mathrm{root}} \le C_J^{k+1} k!\, t^2 \epsilon (p^4 + \epsilon p^2).$$

The hypothesis concerns $\widehat{R}$ on a product containing all points described in (1). A bound for R on a smaller set of fine fields, which misses part of the range of the reconstruction over this product, does not suffice. The hypothesis is verified for the effective interactions of the recursion in Theorem 13.5.

Proof. We use Definition 12.15 throughout. Since $H_{d_0,J}(\theta, w; 0) = 0$ and $A_R(\theta, w; 0) = 0$ for every coarse field, both partition functions equal one at $\zeta = 0$.

Step 1: supported decompositions. We expand $\widehat{R}$ in the variables θ and q. Subtracting $\widehat{R}(\theta, 0)$ removes exactly the terms of degree zero in q. Every remaining monomial therefore contains a variable q_i, and its coefficient sum with that index fixed, including the volume normalization, is controlled by $\mathcal{J}_{u,v,b}(\widehat{R}) \le \epsilon$. The support-weight estimate (12.20), in the form used in Step 6 of the proof of Theorem 12.13, yields the bound $CD^{r+k} e^{b\mathrm{t}/2} e^{-b_1 \operatorname{dist}(x,e)}$ for the weight $e^{8|X|}$ of a monomial of degree r in θ, degree k in q, and fixed location e of an index of q. The sum over e contributes only the density of these indices. We choose $u_1 < u/(2D)$ and a radius $v_1 < v/(2D)$ for the variables q, and we reduce them further to absorb the fixed color factors and the choice of the fixed index of q, which contributes at most a factor $k \le 2^k$. A term of $\mathcal{J}_{u,v,b}(\widehat{R})$ is then multiplied by at most $(Du_1/u)^r (C_J|\zeta|p/v)^k$ with $k \ge 1$. Summing, we obtain an exact supported decomposition $\boldsymbol{A}_R(\zeta)$ of A_R with

$$\|\boldsymbol{A}_R(\zeta)\|_{\mathscr{S}_8} \le \frac{C_J \epsilon |\zeta| p}{1 - C_J|\zeta|p}, \tag{12.29}$$

an absolute coefficient bound at the coarse-field radius u_1. We use one box scale, chosen with the smaller of the two available rates, for H and A_R. Repeating the calculation of Step 6 in the proof of Theorem 12.13, with ζ in place of t, we obtain

$$\|\boldsymbol{H}(\zeta)\|_{\mathscr{S}_8} \le \frac{C_J|\zeta|(p^3 + p)}{1 - C_J|\zeta|p}. \tag{12.30}$$

Indeed, the classical terms have degree at least three in the fluctuation variables of their own scale, with the factor ζ^{k-2}. The differences of negative logarithmic Haar densities and of the functions B_i have degree at least one in the fluctuation variables. Joint composition and the support-weight estimate then give exactly these two geometric sums. The assignment of supports does not depend on ζ or on the interpolation parameter s below.

Step 2: the auxiliary disc. Let $R_\zeta = c_J/(p^3+\epsilon p)$. Since $p \geq 1$, we have $R_\zeta p \leq c_J$, $R_\zeta(p^3+p) \leq 2c_J$, and $R_\zeta \epsilon p \leq c_J$. We choose c_J so small that $C_J c_J \leq 1/2$, that $6C_J c_J \leq \eta_0/2$, that $c_J \leq \min\{v_1, v_J\}/2$, and that $4C'_J c_J \leq \sigma_0$, where η_0 is the constant of Theorem 12.7 and C'_J, σ_0 are the constants in (12.23). For $t \leq R_\zeta/2$, we have $tp \leq tp^3 \leq c_J/2$, hence $C'_J tp < 1/2$ and $C'_J(tp^3+tp)/(1-C'_J tp) \leq 2C'_J c_J \leq \sigma_0$, which are the conditions (12.23). Then (1) holds, the denominators in (12.29) and (12.30) are at least $1/2$ on a neighborhood of the closed disc $|\zeta| \leq R_\zeta$, and

$$\|\boldsymbol{H}(\zeta) + s\boldsymbol{A}_R(\zeta)\|_{\mathscr{S}_8} \leq 4C_J c_J + 2C_J c_J \leq \eta_0/2 \qquad (0 \leq s \leq 1).$$

Step 3: cancellation of the first order. By Theorem 12.7 and (12.29), the derivative family $D\boldsymbol{\mathcal{L}}(\boldsymbol{H}+s\boldsymbol{A}_R)[\boldsymbol{A}_R]$ has norm at most $C_J\epsilon p|\zeta|$ on the disc. The coefficient of ζ in A_R is $\sum_i \lambda_i D_{q_i}\widehat{R}(\theta,0)[w_i]$. Each monomial assigned to a support is linear in one fluctuation block, whose mean under the symmetric reference measure is zero. Thus its expectation vanishes before any sum over supports or coarse-field coefficients, and the hypothesis of Corollary 12.8 holds. Applying that corollary with $R = R_\zeta$, and integrating over $s \in [0,1]$, we obtain for the difference $\boldsymbol{\mathcal{D}}(\zeta)$ the bounds

$$\|\boldsymbol{\mathcal{D}}(\zeta)\|_{\mathscr{S}_2} \leq C_J\epsilon p|\zeta|, \qquad \|\boldsymbol{\mathcal{D}}(t)\|_{\mathscr{S}_2} \leq C_J\epsilon p\frac{t^2}{R_\zeta} = C_J t^2\epsilon(p^4+\epsilon p^2), \tag{12.31}$$

the second for $t \leq R_\zeta/2$. If $\epsilon = 0$, then $\widehat{R}$ is constant, $A_R = 0$, and the difference vanishes identically. Both terms $t^2\epsilon p^4$ and $t^2\epsilon^2 p^2$ in the bound are needed.

Step 4: derivatives. With $u' = u_1/2$, the bound (12.12) bounds the sum of the derivatives of order k of each support term by $2^{k+1}k!u_1^{-k}$ times its coefficient norm. All coarse-field labels in a support Y can be joined by a network of length at most $C_{\mathrm{geom},J}|Y|$, and we choose b' with $b'C_{\mathrm{geom},J} \leq 1$. Fixing a derivative index restricts the sum to the supports containing its box, and the factor $e^{2|Y|}$ dominates the network weight. This proves the bound for the derivatives, with a single factorial. Reducing the coefficient radius from u_1 to u' preserves the bound for $\boldsymbol{\mathcal{D}}(t)$.

Step 5: proof of (2). At $\zeta = t$, we have $q_i = g_i w_i$, so $R(c_0) = \widehat{R}(\theta,q) = R_{\mathrm{ref}}(\theta) + A_R(\theta,w;t)$. By Theorem 12.13, the integral with the factor $e^{-R(c_0)}$, divided by the integral without it, equals $e^{-R_{\mathrm{ref}}}\Xi_{J,R}(\theta;t)/\Xi_0(\theta;t)$, since the two integrals have the same partition function without insertion and the same classical, Haar density, determinant, and Gaussian prefactors. The negative logarithm of this ratio is $R_{\mathrm{ref}} + \mathcal{D}_J R(\theta;t)$, which proves (2). The radii and the constants C_J, c_J were chosen before p, ϵ, and t, which enter only through the conditions $p \geq p_0$ and $t \leq c_J/[2(p^3+\epsilon p)]$. □

Remark 12.17. The constants of this section are chosen in the following order. We first fix M and the larger domains of the classical and Haar disintegration charts. Next, we

choose the radii and rates of one averaging step, in Lemmas 12.2 and 12.3; these do not depend on J. Then we fix J. For this J, we choose the domain r_J of the compositions in Theorem 12.13, the box scale $\mathscr{L}$, and the rate b_1, we reduce the coefficient radius, and we fix C_J, σ_0, and the thresholds in (12.23). Finally, d_0, m, t, and p vary subject to the stated inequalities. In Lemma 12.16, the numbers u, v, b and the larger product of holomorphy are fixed before C_J and c_J, and ϵ, p, and t enter only through the final smallness conditions. This section does not close the recursion; Section 13 shows that the hypothesis of Lemma 12.16 is preserved from one renormalization group step to the next, at the same radii.

SECTION 13

Conditional measures and analytic estimates

In this section, we set up the renormalization group recursion for the Wilson measure restricted to the small-field event. We prove that the effective interactions stay in the same ball of an analytic coefficient norm at every scale, and we prove estimates for the conditional law of the normalized fluctuation variables given the coarse field. One renormalization group step consists of J consecutive applications of the block averaging map T_M, from a lattice of side mM^J to a coarse lattice of side $m \geq 4$. Its fluctuations are integrated with the results of Section 12. The probability of the restriction event under the Wilson measure and the continuum limit are treated in later sections.

The exact formula for one step. The central identity is Theorem 13.4. Let the density at the fine scale be $\mathbf{1}_{D_r} e^{-E_{d_0,\mathrm{sat}}/g_0^2 - R_{\mathrm{sat}}}$ with respect to the product Haar measure, where E_{d_0} is the effective classical action of depth d_0 and R is the input effective interaction, produced by the integrations at finer scales. Restricting to the event on which the step is defined and the fluctuations are cut off, and pushing forward by T_M^J, we obtain

$$\mathbf{1}_{D_r}(c)\, A_{\mathrm{coord}}\, e^{-E_{d_0+J,\mathrm{sat}}(c)/g_J^2 - \mathsf{B}_{\mathrm{ref,sat}}(c) - R_{\mathrm{ref,sat}}(c)} \Big(\int_{\Omega_p} e^{-V_c(w)}\, dw \Big)\, dH(c). \tag{13.1}$$

Here $\Omega_p = \prod_{i,e} \{ w_{i,e} \in \mathbb{R}^3 : |w_{i,e}| \leq p \}$, where e runs over the f_i normalized fluctuation variables of the intermediate scale i, each with three components, and dH is the product Haar measure on the coarse configuration. The factors are defined precisely in Theorem 13.4. Besides the effective classical action E_{d_0+J} at the coarse scale, the formula involves the reconstructed fine field, written through its logarithm $\varphi_\theta(w)$ in the gauge chosen in Theorem 13.2. The values at the identity of the Haar disintegration densities and Jacobians are collected in the constant A_{coord}. The terms $\mathsf{B}_{\mathrm{ref}}$ and R_{ref} are the determinant and Haar density terms and the input effective interaction, respectively, evaluated on the zero-fluctuation reconstruction. The conditional fluctuation potential V_c contains everything that depends on the fluctuations, and dividing by the integral gives the conditional fluctuation kernel $k(c, dw)$ of Theorem 13.8. The formula is first proved in local gauge charts and then glued across charts by exact, finite gauge invariance. Iterating it identifies the measures of the recursion with the conditioned Wilson measure, pushed forward to the coarse scales.

Main results. In Theorem 13.2, we construct a gauge representative of the reconstruction, depending only on the coarse field, on the whole domain of coarse fields and fluctuations. Theorem 13.4 proves (13.1) and identifies the iterated measures with the conditioned Wilson measure. Theorem 13.5 proves that one step maps the effective interaction into a fixed ball of the norm $\mathcal{B}_{\rho,a}$, at the same radius and rate. The new effective interaction is the sum of a newly generated effective interaction, a contracting pullback of the input effective interaction at zero fluctuation, and a fluctuation correction to the pullback, of second order in the coupling. Theorem 13.8 proves convexity and concentration for the conditional fluctuation kernel, and Theorem 13.10 estimates its means, its covariance, and the coefficients of the reconstruction at its mean.

The inputs are the concentration theorem on convex products of balls and the Haar measure identities of Theorem 5.4 and Lemma 5.1, the constrained minimizers and their coefficient bounds of Theorems 10.10 and 10.11, and the gauge invariance of the effective classical action, the contraction estimate, and the background field of Theorems 11.6 and 11.10 and Lemma 11.9. We also use the coordinates, exact integrals, and cluster expansions of Lemmas 12.3 and 12.16 and Theorems 12.6, 12.7, and 12.13. The results are used in Sections 14 and 15 to construct the small-field restriction and the backward reconstruction, and in Sections 16 and 17 for conditional estimates of the reconstruction. They are also used in Sections 19, 20, and 23, and, through the conditional law and its moments, in Sections 26 to 28, 31, and 35.

Domains. Several neighborhoods of the identity appear, with different roles.

Set	Role
B_r	coarse fields with link logarithms of norm less than r; here the integral is identified with the restricted Wilson measure
B_ρ	a larger set of coarse fields, $\rho \geq r$, on which the auxiliary integral and the analytic recursion are defined
$B_{\rho/2}$	contains the gauge-transformed reconstruction for all coarse fields and fluctuations in the enlarged product; the input effective interaction is evaluated here
$D_r = \mathcal{G}B_r$	the gauge-invariant small-field domain; the reconstructed fine field must lie in it

The gauge-transformed reconstruction lies in $B_{\rho/2}$ by the coefficient bounds of Theorem 13.2. That the reconstructed fine field lies in D_r, for every coarse field in B_r and every fluctuation in Ω_p, is a separate hypothesis, the support-inclusion hypothesis of Definition 13.3. A sufficient condition for it is $\mathfrak{M}_J(r, tp) < r/2$. Since the part of $\mathfrak{M}_J$ of positive degree in q does not vanish as $r \to 0$, this condition may require a further reduction of the coupling for each fixed r.

Order of choices. The parameters are chosen in the order

$$M,\ \text{initial domains and decay rates} \longrightarrow a, b, \mathscr{L}, K_*, \rho_0 \longrightarrow J \longrightarrow \rho, s_J \longrightarrow E_*, A_{\mathrm{w}}, t_*.$$

The rate a is taken below $a_{\mathrm{cen}}/8$, where a_{cen} is the rate of the bounds in Lemma 11.9, and $b > a$ is taken below the rate b_* of Theorem 13.2. No constant depending on J is used to choose J. The support radius $r \le \rho$ and its support-inclusion hypothesis are treated separately.

Conventions. All distances within a renormalization group step are measured in units of the coarse lattice spacing. The input mesh is $\delta = M^{-J}$, the normalized fluctuation variables w_i and the variables $q_i = g_i w_i$ of the intermediate scale $i \in \{0, \dots, J-1\}$ have mesh M^{i-J}, and the couplings are $g_i = t\lambda_i$ with $\lambda_i = M^{(i-J+1)/2} \in [M^{-(J-1)/2}, 1]$; also $g_J^2 = M g_{J-1}^2$. The number of scalar indices of θ and of w located in a unit cell is at most $D_J \le C_M(1+J)M^{3J}$; this is a density bound, not a bound on the number of variables. Unless a bound is stated to hold before J is chosen, a constant in this section may depend on M, J, the larger construction domains and their margins, the spatial decay rates, ρ, a, and the bound E_* on the effective interaction. Such a constant does not depend on the depth d_0, the side m, L, or γ. All results concern the whole periodic torus, not regions with fixed exterior data.

We use ordered scalar tensors with their Taylor factorials divided out; for example, a symmetric scalar tensor A of degree k contributes $A[\theta^{\otimes k}]/k!$. Fixing one input index and summing over the remaining indices defines the norm of a scalar tensor with one index fixed. For a vector tensor one may instead fix its output, or fix any input and sum over the output with its volume normalization, as in Definition 4.6. Every such sum carries the weight $e^{b\mathsf{t}}$, where t is the length of a shortest connected network joining the locations of the indices, with internal vertices allowed. At each degree we take the maximum over the positions of the fixed index. Additive constants are excluded from these norms. As in Section 12, a majorant series is a power series with nonnegative coefficients that dominates the corresponding sums of absolute coefficients.

Attribution. The construction follows Bałaban's renormalization group method for lattice gauge theories. The logarithmic averaging with reference transports adapts his averaging operations [12]; the use of small gauge representatives belongs to the program of [14]; and the constrained minimizer as a background field is the construction of [16]. The exponential decay of the propagators, used through Sections 10 and 11, adapts [10, 11, 13]. The iteration of effective densities with Gaussian-normalized fluctuations, separated normalization constants, and local effective interactions follows [15, 17, 19]; the four-dimensional coupling renormalization of [17] is not used. None of these works proves the identities for the centered block averaging map and the full periodic reconstruction used here, and we prove them below. The polymer expansions are those of Section 12, which

uses the criterion of Kotecký and Preiss [120] and the finite graph estimate recorded by Dimock [68, Appendix B, Theorem 27, p. 39, and (323), p. 42]. The variance, entropy, and covariance estimates for the conditional law come from Theorem 5.4, which belongs to the framework of Brascamp and Lieb [33], Gross [103], Bakry and Émery [8], and Helffer and Sjöstrand [109, 110]; here we verify its hypotheses for the conditional fluctuation potential.

13.1 Weighted coefficient bounds and majorant series

We first describe how the coefficient norms behave under the operations used in this section. The essential restriction is that the networks of the coefficients must be connected through shared indices.

Lemma 13.1. *Suppose that analytic tensor families have convergent majorant series, at one spatial decay rate b, for all their output-fixed rows and all their input-fixed volume-normalized columns. Consider finite products, contractions, and compositions in which the networks of the coefficients are connected through common outputs or contracted indices. Such expressions are bounded by the corresponding products and compositions of the majorant series. Products of extensive scalar interactions without such a connection are excluded: they require an additional connecting kernel with its own bounds, or separate bounds without a fixed index. To bound a composition with a specified input fixed, we use the derivative of the scalar composition of majorants with respect to the input variable, $(\widehat{F}\circ\widehat{G})' = (\widehat{F}'\circ\widehat{G})\,\widehat{G}'$, which accounts for the choice of the factor containing that input and of its position there. The volume normalization at the fixed input is that of its own lattice, and no second derivative factorial occurs. On a fixed smaller analytic product, evaluation and any fixed number of derivatives satisfy the same bounds.*

Let $T(o; i_1, \dots, i_k)$ be a tensor of fixed Taylor degree whose output-fixed rows are bounded by A at the rate $2b$, and let v_o and v_i denote the volumes of the meshes of the output and of an input. Then, for every fixed input i,

$$\sum_{o,\ \text{other inputs}} \frac{v_o}{v_i} e^{b\mathfrak{t}} |T(o; i, \dots)| \le \frac{A}{v_i} \sum_o v_o e^{-b\,\mathrm{dist}(o,i)}. \tag{13.2}$$

If i is an input of the coarse lattice, then $v_i = 1$, and if the outputs have spacing $\eta \le 1$ and bounded density, then $\eta^3 \sum_o e^{-b\,\mathrm{dist}(o,i)} \le C_b$; thus summing over the output converts the row bound into a column bound at the rate b, with a constant depending only on b and the density of the labels. An input of mesh $\eta_{\mathrm{in}} < 1$ keeps the factor η_{in}^{-3}, which within one renormalization group step is at most M^{3J}. Conversions between counting sums at the finitely many meshes of one renormalization group step cost at most a fixed factor depending on J.

Finally, for an analytic vector map $F_e(u) = \sum_\nu f_{e;\nu} u^\nu$ and a radius $r > 0$, define the entrywise envelope of its derivative

$$\mathcal{C}_{ex}(r) = \sum_{\nu:\, \nu_x > 0} \nu_x |f_{e;\nu}|\, r^{|\nu|-1}. \tag{13.3}$$

Then $\sup_{\|u\|_\infty \le r} |\partial_x F_e(u)| \le \mathcal{C}_{ex}(r)$*, and the sums of* $\mathcal{C}_{ex}(r)$ *over* x *at fixed* e*, and over* e *at fixed* x *with the volume factor* v_e / v_x*, both with the weight* $e^{b\mathsf{t}}$ *of the corresponding coefficients, are bounded by the derivatives at* r *of the majorant series of the output-fixed rows and of the input-fixed columns at* x*, respectively. This is an entrywise bound uniform on the product, not a bound on an evaluated operator norm.*

Proof. We first consider finite Taylor polynomials. For a pointwise product at a common output, we join the networks of the factors at that output; for a contraction we join them at the contracted index. Repeating these joins along the assumed connected structure, we obtain a connected union joining all uncontracted locations. Its length bounds the external t, which implies that the external exponential weight is at most the product of the weights of the factors. We fix the external index and sum over the contracted indices, starting with the factor containing the fixed index. At each attachment, we use an output row or the column at the attached input. The volume factor of that column is exactly the one needed for the contraction. This proves the bound for each connected product of coefficient tensors, with the product of their bounds. The argument gives no such bound for two scalar factors with disjoint networks and independent summed indices.

For a composition, we partition the ordered derivative indices among the inner factors. If the parts have sizes $k_1, \dots, k_l$, there are $k!/(k_1! \cdots k_l!)$ assignments, and division by $k!$ leaves the ordinary coefficients of the composition of exponential generating series. The derivative of the scalar composition bounds every coefficient series with a fixed input, including the columns, since it counts the choice of the inner factor and of the position of the fixed input in it. All bounds concern nonnegative sums, and passing to the limit of finite Taylor truncations gives the statements for the convergent series.

For the radius reduction, if $A_k \ge 0$ and $\sum_k A_k R^k < \infty$, then for $r < R$ the series obtained by l derivatives satisfies

$$\sum_{k \ge l} (k)_l A_k r^{k-l} \le R^{-l} \sup_{k \ge l} (k)_l (r/R)^{k-l} \sum_k A_k R^k < \infty,$$

where $(k)_l = k(k-1)\cdots(k-l+1)$. This applies only to series that are already absolute coefficient series; it does not infer absolute coefficients from a bound on directional values.

To prove (13.2), note that $\mathsf{t} \ge \operatorname{dist}(o, i)$ implies $e^{b\mathsf{t}} \le e^{2b\mathsf{t}} e^{-b \operatorname{dist}(o,i)}$. Applying the row bound separately at each output o, we obtain the inequality. For an input i of the coarse lattice, uniformly on periodic tori,

$$\eta^3 \sum_o e^{-b \operatorname{dist}(o,i)} \le C_b.$$

Indeed, the set of o with $k \le \operatorname{dist}(o, i) < k+1$ has counting volume, multiplied by η^3, at most $C(k+2)^3$, and $\sum_{k \ge 0} C(k+2)^3 e^{-bk}$ converges; a sum over the torus is bounded

by the corresponding periodized sum over the infinite lattice. This proves the column bound. An input of mesh $\eta_{\mathrm{in}} < 1$ keeps its factor η_{in}^{-3}, and replacing volume-normalized sums by counting sums at any of the fixed meshes changes a measure by at most M^{3J} for each conversion.

For the envelope, $|u^{\nu-\mathbf{e}_x}| \le r^{|\nu|-1}$ on the product, and the pointwise bound follows. Summing $\mathcal{C}_{ex}(r)$ over x at fixed e, we obtain $\sum_\nu |\nu||f_{e;\nu}| r^{|\nu|-1}$ with the weights, which is the derivative at r of the majorant for the output-fixed rows. At a fixed input x, for $|\nu| = k$ and $\nu_x > 0$, the remaining $k-1$ derivative indices can be ordered in $(k-1)!\,\nu_x / \prod_j \nu_j!$ ways, and each ordered derivative of $f_{e;\nu} u^\nu$ at zero has modulus $|f_{e;\nu}| \prod_j \nu_j!$; dividing by $k!$ gives $(\nu_x/k)|f_{e;\nu}|$ (see also (13.11) below). This shows that the column majorant at x has the coefficients $c_k = \sum_e \sum_{|\nu|=k} (\nu_x/k)|f_{e;\nu}|(v_e/v_x)e^{b\mathrm{t}}$, and the weighted sum of $\mathcal{C}_{ex}(r)$ over e equals $\sum_k k c_k r^{k-1}$, the derivative of this majorant at r. □

13.2 Gauge representatives on the reconstruction domain

The reconstruction $\mathscr{C}_{\mathrm{raw}\,d_0,J}(\theta, q)$ of Section 12.5 expresses the fine field in the block axial gauges of the intermediate scales. Even at zero fluctuation it need not lie in a small neighborhood of the identity in which the input effective interaction is defined. We now apply a gauge transformation, depending only on the coarse field, after which the reconstruction of the whole product of coarse fields and fluctuations lies in such a neighborhood. Here $\Omega(\theta)$ denotes a gauge transformation; it is unrelated to the product of balls Ω_p.

Theorem 13.2. *Fix an odd integer $M \ge 3$. There exist a spatial decay rate $b_* > 0$ and a majorant $Z(u) \le Cu/(1-Cu)$, both chosen before J, with the following property. Let $J \ge 1$, $d_0 \ge 0$, and $m \ge 4$, and put $\delta = M^{-J}$. There exist $r_J, C_J > 0$, independent of d_0, m, L, and γ, and a gauge transformation $\Omega_{d_0,J}(\theta)$ of the fine lattice, holomorphic in θ, with values in $\mathrm{SU}(2)$ for real θ, equal to the identity at every vertex of the coarse lattice, and with $\Omega_{d_0,J}(0) = I$, such that*

$$\Phi_{d_0,J}(\theta, q) = \mathrm{Log}\big[\mathscr{C}_{\mathrm{raw}\,d_0,J}(\theta, q)^{\Omega_{d_0,J}(\theta)}\big], \qquad T_M^J e^{\Phi_{d_0,J}(\theta,q)} = e^{\theta}, \qquad \Phi_{d_0,J}(\theta, 0) = \delta\overline{A}_{d_0,J}(\theta),$$

where $e^{\delta\overline{A}_{d_0,J}(\theta)}$ is the background field of Lemma 11.9. Here q_i replaces $g_i w_i$, and the matrices $K_i^{-1/2}$ remain inside the recursion. Moreover the following statements hold.

1. *On a fixed larger product with $u + v < r_J$, the map $\Phi_{d_0,J}$ has the majorant series*

$$\mathfrak{M}_J(u, v) = \delta Z(u) + \frac{C_J v}{1 - C_J(u+v)}$$

for its output-fixed rows. For the input-fixed columns, with the volume normalization of the fixed input, let $c_\theta(u, v)$ and $c_q(u, v)$ be the majorant series at a fixed coarse-field input and at a fixed input of q, in which every input, including the fixed one, is weighted by its

radius (u for coarse-field inputs and v for inputs of q). Then $c_\theta \le u\,\partial_u \widetilde{\mathfrak{M}}_J$ *and* $c_q \le v\,\partial_v \widetilde{\mathfrak{M}}_J$ *for a majorant* $\widetilde{\mathfrak{M}}_J(u,v) = \delta \widetilde{Z}(u) + C_J v/(1 - C_J(u+v))$ *of the same form, where* $\widetilde{Z}$ *has the properties of Z; in particular* $c_q(u,0) = 0$*. Thus the column bounds are the derivatives of majorants of the same form with respect to the variable of the fixed input, multiplied by its radius. The gauge transformation and its inverse have factorial coefficient bounds at every fixed index on the same larger product of coarse fields. After one fixed choice of radius,* Ω *has the logarithm* κ_Ω *in the identity chart, with* $\kappa_\Omega(0) = 0$*,* $\|\kappa_\Omega(\theta)\|_\infty \le C_J \|\theta\|_\infty$*, coefficient bounds of the same type, and* $\kappa_\Omega = 0$ *at every vertex of the coarse lattice. A positive spatial decay rate and the constants in the bounds for the first three derivatives in* θ *at zero fluctuation can be chosen before J; the joint constants and* r_J *may depend on J, the larger construction domains, and the decay rates.*

2. *For every constant* $u \in \mathrm{SU}(2)$*,* $\Omega(\mathrm{Ad}_u\,\theta) = u\Omega(\theta)u^{-1}$ *and* $\Phi(\mathrm{Ad}_u\,\theta, \mathrm{Ad}_u\,q) = \mathrm{Ad}_u\,\Phi(\theta,q)$*, on real data and for the holomorphic continuations on the domains above.*
3. *For every* $K_* \ge 2$*, one can choose J using only the constants chosen before J, and then* $\rho, s_J > 0$ *such that*

$$4K_*\rho < r_J, \qquad 4K_* C_J(\rho + s_J) < 1, \qquad \mathfrak{M}_J(4K_*\rho, 4K_* s_J) < \rho/2.$$

Then the image of the whole complex product with these radii consists of fields with link logarithms of norm less than $\rho/2$*, and all intermediate classical and Haar disintegration maps have fixed margins. For real coarse fields with* $\|\theta\|_\infty \le r \le \rho$ *and a radius Q for the variables q such that* $r + Q < r_J$*,* $1 - C_J(r+Q) > 0$*, all intermediate margins hold, and* $\mathfrak{M}_J(r,Q) < r/2$*, the image of the entire real product lies in* $B_{r/2}$*. These are statements about the whole product, not only about its center.*

4. *Suppose that two coarse fields related by a periodic gauge transformation have reconstructions* $C' = C^{\widetilde{k}}$*, related by the exact triangular transition of the fluctuation variables. Then*

$$(C')^{\Omega(\theta')} = \big(C^{\Omega(\theta)}\big)^{\Omega(\theta')\widetilde{k}\Omega(\theta)^{-1}}.$$

The gauge transformation changes only the representative at which the input effective interaction is evaluated; it does not change the fluctuation variables, the cutoff domain, the Haar disintegration densities, or the triangular determinant.

Proof. We first fix domains on which the maps of each averaging step have coefficient bounds, then construct the gauge transformation from the background field of Lemma 11.9, compose the steps, and finally choose the radii.

Step 1: the maps of one averaging step. At the intermediate scale i, $0 \le i < J$, the depth is $d_0 + i$ and the sides are $mM^{J-i} \to mM^{J-i-1}$, with output side at least four. Thus Theorem 10.10 applies at every scale with the same constants m_0, C_0, r_c, r_z. Statements about order, minima, and positive Hessians concern only real coarse fields and real free

logarithmic coordinates. For complex data, we use the holomorphic minimizer and the analytic continuation of the nested minimization identity, without any order statement. The free logarithmic coordinates are the logarithms in the block axial gauge, and

$$m_0 I \le K_i(I) \le C_0 I, \qquad \|K_i(I)\|_{\mathrm{row+col}} + \|K_i(I)^{-1}\|_{\mathrm{row+col}} \le C_0.$$

This concerns the free logarithmic coordinates only; no lower bound in the directions of coarse gauge transformations or of constant harmonic one-forms is used.

We choose smaller products of coarse fields and free logarithmic coordinates, with a common initial radius R_{prim} independent of d_0 and m, strictly inside the domains of Theorem 10.10 and the larger classical and Haar disintegration domains of Lemma 12.3. Part (3) of that lemma applies on these products without a cutoff or a coupling. It provides absolute coefficient bounds at every fixed index for the logarithmic reconstruction B_i, the objective F_i, the logarithmic Haar density, the minimizers z_i^*, and $K_i^{\pm 1/2}$. For every vector tensor these bounds include all its volume-normalized columns, and a coefficient of positive degree of $K_i^{\pm 1/2}$ may instead be bounded with a coarse-field index fixed and both matrix indices summed. The scalar tensors have one input fixed and exclude values. The actions in these objectives are the E_{d_0+i} of Theorem 10.11, which applies at depth $d_0 + i$ and side $mM^{J-i} \ge 4$; it provides factorial bounds for their derivatives at one rate, and $DE_{d_0+i}(I) = 0$. We take a positive rate below the rates of these results. This rate is valid at every scale, since each mesh is at most one in units of the coarse lattice spacing. All later reductions of these products are fixed reductions inside these domains.

Step 2: the zero-fluctuation reconstruction and the gauge. By Lemma 11.9, the background field $C(\theta) = C_{d_0,J}(\theta) = e^{\delta \overline{A}_{d_0,J}(\theta)}$ satisfies $T_M^J C(\theta) = e^{\theta}$, and the output rows of $(\overline{A}_{d_0,J}, \nabla_\delta \overline{A}_{d_0,J})$ have the majorant $Z(u) = Cu/(1 - Cu)$, uniformly before J. Each column at a coarse input, with output volume δ^3, is bounded by the corresponding derivative of Z. By the same lemma, for fixed J, there exists a block axial gauge $F(\theta) = F_J(\theta)$, fixed successively on the intermediate scales, such that

$$C(\theta)^{F(\theta)} = \mathscr{C}_{\mathrm{raw}\, d_0,J}(\theta, 0) \tag{13.4}$$

on a complex ball of fixed radius. The gauge transformation F takes values in $\mathrm{SU}(2)$ for real data, equals the identity at the vertices of the coarse lattice and at $\theta = 0$, and F and F^{-1} have factorial coefficient bounds at every fixed index. These bounds are uniform in d_0, m, L, and γ for fixed M and J, and they are not used to choose J.

We set $\Omega = F^{-1}$. Since Ω equals the identity at the vertices of the coarse lattice, it preserves the coarse field. By (13.4) and the rule $(U^k)^l = U^{lk}$, we have $\mathscr{C}_{\mathrm{raw}}(\theta, 0)^{\Omega} = C(\theta)$ and $\mathrm{Log}[\mathscr{C}_{\mathrm{raw}}(\theta, 0)^{\Omega}] = \delta \overline{A}_{d_0,J}(\theta)$. We reduce the radius so that the values of Ω lie in one identity chart. The absolutely convergent series $\mathrm{Log}(I + X) = \sum_{l \ge 1} (-1)^{l+1} X^l / l$ and Lemma 13.1 give the bounds for κ_Ω. Its constant coefficient vanishes, and its majorant is

$C_J u/(1 - C_J u)$ after increasing $C_J \geq 1$. At the vertices of the coarse lattice the matrix is I, and the logarithm vanishes there.

Step 3: composition of the steps. The recursion uses the independent variables $q_i = g_i w_i$ in

$$z_i = z_i^*(c_{i+1}) + K_i(c_{i+1})^{-1/2} q_i,$$

that is, the square root is not absorbed into q_i. We apply the bounds of Step 1 at every scale. If X_{i+1} is a majorant for the rows of $\operatorname{Log} c_{i+1}$, the majorants of the minimizer, of S_i, and of B_i give

$$X_i \preccurlyeq G(X_{i+1}, v), \qquad G(x, y) = \frac{A(x+y)}{1 - A(x+y)}, \qquad X_J = u,$$

after one enlargement of the constant A. All maps vanish at $(\theta, q) = (0, 0)$, except for the bounded constant matrix $S_i(I)$ multiplying q_i. There are only J compositions, and we choose $r_J > 0$ so that these scalar compositions converge and all intermediate values stay below the radii of Step 1. The networks are connected, since each composition joins the outputs of one step to the inputs of the next and the factor $S_i q_i$ contracts its index of z. The derivative of the same composition with respect to a fixed input controls each column at the mesh of that input. We obtain the joint absolute coefficient series of the reconstruction, independently of d_0 and m; the constants and the radius may depend on J.

To include the factors of the gauge transformation at the endpoints of each link, we transfer arrays indexed by vertices to the start or to the end of each link by the local incidence maps. These maps have one entry in each output row and a bounded number of entries in each input column. The corresponding segments have length at most δ, and these maps therefore have bounded series at the fixed rate. The three resulting factors indexed by links have a common output, and their connected pointwise product is the matrix

$$\Omega_x(\theta)\, \mathscr{C}_{\mathrm{raw}\, xy}(\theta, q)\, \Omega_y(\theta)^{-1}$$

on the link (x, y). Reducing r_J so that the logarithm of the identity chart applies, we obtain a joint absolute series for its logarithm at every fixed index. At $q = 0$ this series is exactly $\delta\overline{A}$. Subtracting this series coefficient by coefficient leaves only terms of positive degree in q. Any convergent nonnegative series in two variables with this property is bounded, on a smaller fixed product, by

$$\frac{C_J v}{1 - C_J(u + v)}.$$

Indeed, its coefficient of degree (r,s), $s \geq 1$, is at most AR^{-r-s} on a smaller disc of absolute convergence, and if $C_J R \geq \max(1, A)$, then

$$[u^r v^s] \frac{C_J v}{1 - C_J(u+v)} = C_J^{r+s} \binom{r+s-1}{r} \geq AR^{-r-s} \qquad (r \geq 0,\ s \geq 1),$$

including the coefficient of v itself. We reduce the final radius so that $C_J r_J < 1/2$. The part of degree zero in q has the separate majorant $\delta Z(u)$. This proves the majorant $\mathfrak{M}_J$ as a statement about coefficients on the larger product.

Step 4: columns and rates. Every input is kept as a fixed input in this composition, and its column has the volume normalization of its own lattice. Weighting each input, including the fixed one, by its radius turns the derivative of the composed majorant with respect to the variable of the fixed input into $u\,\partial_u$ or $v\,\partial_v$ of that majorant. This gives the column majorants c_θ and c_q of (1). Since every term of the part of positive degree in q contains a variable q_i and the part of degree zero does not depend on q, we have $c_q(u,0) = 0$. The sum over the output carries the factor δ^3; converting it to a sum with a coarse-field index fixed therefore introduces no factor of the total volume. Summing over the kinds of indices of q costs only D_J. The spatial decay rate in coarse units can be fixed before J. Indeed, a step of mesh $\eta \leq 1$ turns a rate b_0 in its own units into the rate $b_0/\eta \geq b_0$ in coarse units, and contractions use the union of networks at this one rate. The block forests of all scales together extend over a distance at most $C_M \sum_{l=1}^{J} M^{-l} < C_M/(M-1)$. A fixed part of the decay rate is used once for the conversion from rows to columns in Lemma 13.1, not at every scale. The constants for the first three derivatives at zero fluctuation, which are uniform before J, are those of Lemma 11.9.

Step 5: color equivariance. All operations in the construction of F commute with constant color conjugation: ordered transports, logarithms in the identity chart, the minimizers, and the positive square root. For the square root, conjugation carries the positive square root to the positive square root of the conjugated matrix, by uniqueness. Equivariance for real data extends to the holomorphic continuations by comparing Taylor coefficients. This proves (2).

Step 6: the choice of radii. We first take ρ_0 with $4K_* C\rho_0 < 1/2$ for the uniform majorant Z, so that $Z(4K_*\rho) \leq 8K_* C\rho$ for $\rho \leq \rho_0$. We choose J with $8K_* C\delta < 1/4$. After this choice we take $\rho < \min(\rho_0, r_J/(8K_*), (32K_* C_J)^{-1})$, and finally $0 < s_J < r_J/(8K_*)$ with $4K_* C_J s_J < \rho/16$, reduced further if needed for the fixed construction margins. Then the denominator in $\mathfrak{M}_J(4K_*\rho, 4K_* s_J)$ is larger than $1/2$, the first term is less than $\rho/4$, and the second term is less than $\rho/8$. Together, these bounds show that the majorant is less than $\rho/2$. The coefficient bound holds on the entire complex product, since also $4K_*(\rho + s_J) < r_J$. For real radii (r, Q) we require $r + Q < r_J$, $1 - C_J(r+Q) > 0$, and

the intermediate classical and Haar disintegration margins on this product; only then is $\mathfrak{M}_J(r, Q)$ a convergent majorant. If its value is less than $r/2$, domination of the coefficients places the image of the entire real product in $B_{r/2}$. This proves (3).

Step 7: overlaps. If $C' = C^{\widetilde{k}}$, then by the rule $(U^k)^l = U^{lk}$ we have

$$(C')^{\Omega(\theta')} = C^{\Omega(\theta')\widetilde{k}} = \bigl(C^{\Omega(\theta)}\bigr)^{\Omega(\theta')\widetilde{k}\Omega(\theta)^{-1}}.$$

No fluctuation variable changes in this calculation. The coordinate map, the cutoff domain, and the triangular determinant are therefore those of Theorem 12.13. This proves (4) and completes the proof. □

13.3 Cutoffs and gauge invariance on overlapping charts

We compute the integral over one renormalization group step in a chart, that is, for a chosen small representative of the coarse field. Different representatives are related by gauge transformations whose logarithms need not be small. The following definition states the invariance property used to glue the local formulas and the two hypotheses on the reconstruction.

Definition 13.3. Fix the larger construction domains and the coefficient bounds of Theorem 13.2.

1. A scalar function R on configurations of a periodic lattice is *gauge invariant on* B_ρ if it is real analytic on B_ρ and
$$R(U^k) = R(U)$$
for every periodic $\mathrm{SU}(2)$-valued gauge transformation k of that lattice with $U, U^k \in B_\rho$. Its gauge-invariant extension is $R_{\mathrm{sat}}(U) = R(U^k)$ whenever $U^k \in B_\rho$; it is defined on $D_\rho = \mathcal{G}B_\rho$.
2. The *enlarged-domain reconstruction hypothesis* consists of the coefficient inequality $\mathfrak{M}_J(4K_*\rho, 4K_* s_J) < \rho/2$, including the column bounds at every fixed input, together with fixed margins for every intermediate classical, constraint, and Haar disintegration map, and fixed margins for the classical comparison domains under the exact transitions between gauge-related charts. It does not depend on the support radius.
3. Let $0 < r \le \rho$. A fixed real product Ω_p satisfies the *support-inclusion hypothesis* if, for every $c = e^\theta \in B_r$ and every $w \in \Omega_p$, the variables $q_i = g_i w_i$ lie in the enlarged product of Theorem 13.2, all intermediate domain conditions hold, and $\mathscr{C}_{\mathrm{raw}\, d_{0,J}}(\theta, q) \in D_r$. The condition $\mathfrak{M}_J(r, tp) < r/2$, together with the margins of the enlarged product, is sufficient.

Both hypotheses are required at every depth that is used. Neither imposes a condition D_r at an intermediate scale of the renormalization group step.

The *restriction event* of a renormalization group step, at a given small representative of the coarse field, is the image of Ω_p under the sequential reconstruction of Theorem 12.13, together with the domain conditions of all intermediate classical, constraint, and Haar disintegration maps, the condition that the fine field lie in D_r, and the condition that the coarse field lie in D_r. We write $\mathbf{1}_{\mathrm{cut}}$ for its indicator.

Theorem 13.4. *Let $0 < r \le \rho$, and suppose that both hypotheses of Definition 13.3 hold for the renormalization group step under consideration. Let R be gauge invariant on B_ρ, with $DR(I) = 0$ and $\mathcal{B}_{\rho,a}(R) \le E_*$, and invariant under translations, the spatial inversion, and constant color conjugations. Then the following statements hold for every depth d_0.*

1. *The extension R_{sat} is well defined and real analytic on D_ρ, and*

$$|R_{\mathrm{sat}}(U) - R(I)| \le C|\mathcal{E}|E_*\rho^2,$$

   where $|\mathcal{E}|$ is the number of links. The input density

$$P_{\mathrm{in}}(U) = \mathbf{1}_{D_r}(U)\, e^{-E_{d_0,\mathrm{sat}}(U)/g_0^2 - R_{\mathrm{sat}}(U)}$$

   has a finite and strictly positive integral on every finite torus.
2. *At a chosen representative of the coarse field, the restriction event is exactly the image of the fluctuation product described above. Its union over the gauge transformations of the fine lattice that equal the identity at the vertices of the coarse lattice is a Borel event, and it does not depend on the representative.*
3. *Whenever two coarse fields related by a periodic gauge transformation lie, with margins, in the comparison domains, the exact transitions $w_i' = O_i(c_{i+1})w_i$ are triangular from coarser to finer scales, with orthogonal block permutations on the diagonal; they preserve every ball and the Gaussian term and have absolute Jacobian one. They identify the full integrals, including all Jacobians, Haar disintegration densities, and values of R. In particular the output density defined by this integral is a pointwise defined function, consistent on overlapping charts, and positive at every $c \in B_r$. Its effective interaction, obtained by subtracting E_{d_0+J}/g_J^2 from the negative logarithm of the density, is gauge invariant in the same sense, has the same symmetries, and has vanishing derivative at the identity. The auxiliary integral on B_ρ satisfies the same identities, but it is identified with the integral of the restricted input measure only on B_r.*
4. *Let $\mathsf{B}_{\mathrm{ref}}$ and $H_{d_0,J}$ be as in Theorem 12.13 with $s = J$, let $\varphi_\theta(w) = \Phi_{d_0,J}(\theta, (g_i w_i)_i)$ and $R_{\mathrm{ref}}(c) = R(e^{\varphi_\theta(0)})$, and set*

$$V_c(w) = \tfrac{1}{2}|w|^2 + H_{d_0,J}(\theta, w) + R(e^{\varphi_\theta(w)}) - R_{\mathrm{ref}}(c), \qquad A_{\mathrm{coord}} = \prod_i \mathcal{J}_i(I,0) g_i^{3f_i}.$$

With respect to the product Haar measure dH on the coarse configuration,

$$(T_M^J)_*(\mathbf{1}_{\mathrm{cut}} P_{\mathrm{in}}\, dH) = \mathbf{1}_{D_r}(c)\, A_{\mathrm{coord}}\, e^{-E_{d_0+J,\mathrm{sat}}(c)/g_J^2 - \mathsf{B}_{\mathrm{ref,sat}}(c) - R_{\mathrm{ref,sat}}(c)} \Big(\int_{\Omega_p} e^{-V_c(w)}\, dw \Big)\, dH(c). \tag{13.5}$$

The right side is defined by gluing the whole expression across charts. The terms $\mathsf{B}_{\mathrm{ref}}$ and R_{ref} need not be separately gauge invariant, and the subscript sat *on them is notation for the glued expression. Every indicator in $\mathbf{1}_{\mathrm{cut}}$ is kept in its definition; the support-inclusion hypothesis shows that the indicator of D_r for the fine field equals one on the domain of integration.*

5. *Start with $d_0 = 0$, $R_0 = 0$, and the measure $\mathbf{1}_{D_r} e^{-S_{\mathrm{W}}/g_N^2}\, dH_N$. Then any finite iteration of these positive operators gives the pushforward of the Wilson measure restricted to the initial condition D_r and to the intersection of the pulled-back restriction events of the steps. After normalization this is the Wilson measure conditioned on this event, pushed forward to the current scale.*

The constants depend only on M, J, ρ, a, E_*, and the fixed construction margins; they do not depend on the side, the depth, L, γ, or the number of steps.

Proof. We glue local formulas, using the gauge transformation and the coefficient bounds of Theorem 13.2 and the two hypotheses of Definition 13.3. The main point is that the transition between two charts is an exact, orthogonal, and triangular change of the fluctuation variables, so that the full integrals agree pointwise and not only almost everywhere.

Step 1: gluing and normalization. If $U^k, U^l \in B_\rho$, then $U^l = (U^k)^{lk^{-1}}$, and gauge invariance on B_ρ implies that $R(U^l) = R(U^k)$. Thus R_{sat} is well defined. The set D_ρ is open, as the union of the images of B_ρ under fixed gauge transformations. On the open set where $U^k \in B_\rho$ the function $U \mapsto R(U^k)$ is real analytic. These functions agree on intersections, and together they define a real analytic function on D_ρ. Translations and the spatial inversion preserve B_ρ and intertwine the gauge action, and the corresponding identities glue as well. For the effective classical action, the gluing is Theorem 11.6 on the classical domain.

We write $R(e^x) = R(I) + \sum_{k\geq 2} \sum_{|\alpha|=k} r_\alpha x^\alpha$ near zero, in scalar coordinates. The degree-k sum of $|r_\alpha|$ is at most $3|\mathcal{E}|$ times the corresponding sum with one index fixed, and the norm $\mathcal{B}_{\rho,a}(R)$ sums these at radius ρ. This implies that the Taylor series converges absolutely on the complex product $\|x\|_\infty < \rho$. It agrees with R on the real ball, since both are real analytic on this connected ball and agree near zero. This also specifies the complex continuation used below. By Euler's identity,

$$\sum_{|\alpha|=k} |r_\alpha| = \sum_i \sum_{|\alpha|=k} \frac{\alpha_i}{k} |r_\alpha|.$$

There are $3|\mathcal{E}|$ scalar indices i, and the inner sum is the sum of the ordered derivatives with i fixed, divided by $k!$, without its spatial weight, which is at least one. Summing over the degrees, we obtain

$$\sup_{B_\rho} |R - R(I)| \leq 3|\mathcal{E}|\rho^2 \mathcal{B}_{\rho,a}(R). \tag{13.6}$$

The same bound holds for R_{sat}, which takes the same values. The effective classical action is nonnegative, since it is a minimum of the Wilson action multiplied by a positive normalization. Hence $P_{\mathrm{in}} \leq \exp[-R(I) + 3|\mathcal{E}|E_*\rho^2]$, and since the Haar measure has mass one, the integral of P_{in} is finite. The classical action and the effective interaction are finite and continuous near the identity, and D_r contains an open neighborhood of the identity, of positive Haar measure. Integrating over a smaller closed neighborhood shows that the integral is strictly positive. This argument keeps the constant $R(I)$. This proves (1).

Step 2: the exact transition between charts. Fix real coarse fields c and $c' = c^k$ in the comparison domains, with margins. The overlap statement of Theorem 11.6 applies on every comparison domain required by the enlarged-domain reconstruction hypothesis. In a block forest, we transport each link variable to the root before taking its logarithm. Changing the frame at the root by k conjugates the transported variables by the value of k at the root, and the factors of the paths at intermediate vertices cancel in pairs. Thus a free logarithmic coordinate changes by the orthogonal adjoint action on its block. A translation or the spatial inversion in addition relabels the oriented blocks, and the reversal of an orientation acts by an orthogonal map on the color components. We denote by $O_i(c_{i+1})$ the resulting orthogonal map of the free logarithmic coordinates of scale i, which permutes the blocks. It depends on the coarser field and not on the free logarithmic coordinates of scale i. These are the transformations of Proposition 12.11 and Theorem 12.13.

By Theorem 11.6 the two classical objectives agree on these domains. Their minimizers are unique, and the transformation of the coordinates carries one to the other. Differentiating the objective in the orthogonal coordinates, we obtain

$$z_i^{*\prime} = O_i z_i^*, \qquad K_i' = O_i K_i O_i^{\mathsf{T}}, \qquad S_i' = O_i S_i O_i^{\mathsf{T}};$$

the last identity follows by taking the positive square root of real matrices, and it is continued analytically only on the fixed neighborhoods. Substituting in $z_i = z_i^* + g_i S_i w_i$ gives $w_i' = O_i(c_{i+1}) w_i$. We proceed from scale $J-1$ to finer scales; when O_i is evaluated, every coarser field has already been transformed. This proves $C' = C^{\widetilde{k}}$ for the reconstructions, with an $\mathrm{SU}(2)$-valued gauge transformation $\widetilde{k}$ of the fine lattice, as well as the triangular transition of the fluctuation variables.

In this order the derivative matrix of the transition is triangular. Its diagonal blocks are the O_i, and its off-diagonal blocks contain all derivatives of the O_i with respect to the coarser fluctuations. Therefore

$$|\det D_w w'| = \prod_i |\det O_i| = 1, \qquad \sum_i |w_i'|^2 = \sum_i |w_i|^2,$$

and each ball is carried onto the corresponding ball. The identity for block forests in Lemma 5.1 preserves the product Haar measure, gives mass one to the forest variables, and keeps every vertex of the coarse lattice fixed. The changes of the free logarithmic coordinates and of the determinants of the constraints are exactly the changes in the Haar disintegration formula of Lemma 6.3; since that formula is the disintegration of the Haar measure, the product of these factors is preserved. Equivalently, we may substitute $z_i' = O_i z_i$ in each integral over the free logarithmic coordinates and use the conjugation identity for S_i; the diagonal determinants and all Haar disintegration factors agree. No off-diagonal derivative is dropped in either computation.

Step 3: values of the input effective interaction. The two gauge-transformed reconstructions lie in $B_{\rho/2}$, and they are related by the gauge transformation $\Omega(\theta')\widetilde{k}\Omega(\theta)^{-1}$ of Theorem 13.2(4). The values of R agree by gauge invariance on B_ρ, not by smallness of the logarithm of this gauge transformation. In particular,

$$R_{\mathrm{sat}}\big(\mathscr{C}_{\mathrm{raw}}(\theta, (g_i w_i)_i)\big) = R\big(e^{\varphi_\theta(w)}\big). \tag{13.7}$$

For the auxiliary coarse fields in B_ρ this identity uses D_ρ only. For coarse fields in B_r, the support-inclusion hypothesis also places the reconstructed fine field in D_r. This removes the indicator of D_r for the fine field from the integral over the fluctuation product.

Step 4: the restriction event. On a chart of the coarse field, we take the image of the fluctuation product under the triangular reconstruction, with its classical, constraint, and Haar disintegration domain conditions. We keep the conditions D_r for the fine field and for the coarse field. We take its orbit under the gauge transformations of the fine lattice that equal the identity at the vertices of the coarse lattice. Changing the small representative of the coarse field changes this local set by the bijective triangular transition of Step 2. Extending also by the gauge transformations of the coarse lattice defines one event, independent of the chart; representatives are not counted.

This event is Borel. To see this, we exhaust the open ball of logarithms of the coarse field by smaller closed balls, and each construction margin by closed positive margins. On each such compact set the finite reconstruction and its domain data are continuous. The product of such a set with the closed balls of fluctuations and the compact group of gauge transformations therefore has a compact image in the finite-dimensional configuration manifold. By Step 2, the union of the local events over all charts coincides with the

local event on every chart; as the countable union of these compact images, it is Borel. Intersecting with the Borel conditions on the fine and the coarse field yields a Borel event. No measurable global choice of gauge is used. This proves (2).

Step 5: the density. We use the action identity and the triangular determinant of Theorem 12.13, and we insert (13.7). The normalization of the Haar disintegration is $A_{\mathrm{coord}} = \prod_i \mathcal{J}_i(I,0) g_i^{3f_i}$. The exponent depending on w is

$$\tfrac{1}{2}|w|^2 + H_{d_0,J}(\theta, w) + R(e^{\varphi_\theta(w)}) - R(e^{\varphi_\theta(0)}),$$

and the terms removed from it are exactly $E_{d_0+J}/g_J^2 + \mathsf{B}_{\mathrm{ref}} + R_{\mathrm{ref}}$. Including them, we obtain (13.5) with respect to the product Haar measure on the coarse configuration. There is no additional Haar density of the coarse field and no additional factor for the volume of gauge orbits.

The integral is finite and strictly positive at every coarse field satisfying the hypotheses, since the integrand is positive and continuous on the compact product of balls, which has positive Lebesgue measure. By Step 2, the entire integral, including the terms evaluated at the zero-fluctuation reconstruction and the constant A_{coord}, takes the same value in overlapping charts. It is therefore a pointwise defined version of the density, which is stronger than an identity almost everywhere. Taking the real logarithm and subtracting the gauge-invariant classical term proves the gauge invariance of the effective interaction on overlapping charts. The same argument for translations, the spatial inversion, and constant color conjugations proves its other symmetries. If ℓ is its derivative at the identity, color symmetry shows that ℓ is a linear functional on each link variable that is invariant under all rotations of the color components. Rotations by π about two coordinate axes force all three components to vanish. Hence $DR_+(I) = 0$, where R_+ denotes the output effective interaction.

On B_ρ the formula over the fixed product is the auxiliary integral. All comparisons of charts used above stay inside the enlarged construction domains, so the same identities hold for it. The condition D_r for the fine field was used only on B_r; outside B_r the auxiliary integral is not identified with the integral of the restricted input measure. The subscript sat on the terms evaluated at the zero-fluctuation reconstruction is only notation for the glued expression, and the argument does not require their separate invariance. This proves (3) and (4).

Step 6: iteration. Let A_j be the restriction event of the step applied to the configuration obtained after j completed steps, and let η_j be the unnormalized measure after j steps. For every nonnegative Borel function F, by the definition of the pushforward, we have

$$\int F \, d\eta_{j+1} = \int \mathbf{1}_{A_j}(U) F(T_M^J U) \, d\eta_j(U).$$

Starting from the restricted Wilson density and substituting this identity repeatedly, we obtain, since all integrands are nonnegative,

$$\int F\, d\eta_k = \int \mathbf{1}_{D_r}(U) \prod_{j=0}^{k-1} \mathbf{1}_{A_j}(T_M^{jJ}U)\, F(T_M^{kJ}U)\, e^{-S_W(U)/g_N^2}\, dH_N(U).$$

Every normalization is positive by Step 5. Dividing this identity by its value at $F = 1$, we obtain exactly the Wilson measure conditioned on the stated intersection of events. The constants used above depend only on the data stated in the theorem, and the extensive factor in (13.6) is explicit. This proves (5). □

13.4 Preservation of analytic bounds under iteration

We now show that one renormalization group step maps an effective interaction with $\mathcal{B}_{\rho,a}(R) \le E_*$ to one with the same bound, at the same radius ρ and rate a. The new effective interaction has three parts: the newly generated effective interaction $Q^{\mathrm{w}}_{d_0,J}$, which is bounded by Theorem 12.13; the pullback $\mathcal{P}_\delta R$ of R at zero fluctuation, which contracts by Theorem 11.10; and the fluctuation correction $\mathcal{D}_J R$ to the pullback, which is of second order in t by the argument of Lemma 12.16. Two points require care. First, the supported estimates must be converted back to the norm $\mathcal{B}_{\rho,a}$ without reducing ρ, since otherwise the radius would shrink at every step; this uses the translation invariance of the total effective interaction. Second, the composition of R with the reconstruction must be estimated at the level of coefficients, on the whole range of the reconstruction.

Theorem 13.5. *Fix an odd integer $M \ge 3$ and the bounds for the classical coefficients and for the reconstruction. Then the following statements hold.*

1. *There exist a spatial decay rate $a > 0$, a larger rate $b > a$, a box scale $\mathscr{L}$, a factor $K_* \ge 2$, and $\rho_0 > 0$, all chosen before J; the density of the coefficient indices affects only constants that depend on J. Let $C_{\mathrm{geom}} \ge 1$ be a constant, depending only on the metric conventions, that bounds the lengths of the rectilinear networks used to construct supports by the lengths of shortest connecting networks. The rate a is chosen below $a_{\mathrm{cen}}/8$, where a_{cen} is the rate of the bounds of Lemma 11.9. Choose J such that*

$$q_P = C_P(a) M^{-J} < \tfrac{1}{4}, \qquad M^{-J} Z(4K_*\rho) \le \rho/4 \quad (0 < \rho \le \rho_0), \qquad C_{\mathrm{geom}} b M^{-J} \le a,$$

where $C_P(a)$ is the constant of Theorem 11.10 and Z is the majorant of Theorem 13.2. Then choose $0 < \rho \le \min(\rho_0, r_J/(8K_*))$, with $\rho C_B \le 1/2$ for a constant C_B depending only on M, J, and the larger domains (defined in the proof), and $s_J > 0$ such that the enlarged-domain reconstruction hypothesis of Definition 13.3 holds strictly. These choices use only the fixed larger domains, not the support radius r.

2. *Let $\{\Psi_Y\}$ be a family of functions of the coarse field indexed by supports, with coefficient norms at radius ρ, whose sum $f = \sum_Y \Psi_Y$ is invariant under the translations of the coarse lattice. Suppose that $a\mathfrak{t} \le 2|Y|$ for the coarse-field labels of each coefficient of Ψ_Y. Then*

$$\mathcal{B}_{\rho,a}(f) \le 9\rho^{-2} \sup_x \sum_{Y \ni x} e^{2|Y|} \|\Psi_Y\|_{\rho,\mathrm{coeff}}$$

in scalar orientation and color coordinates. The individual Ψ_Y need not be translation invariant. Without translation invariance of f, a bound of this kind requires a strictly larger coefficient radius.

3. *There exist $C_G, C_T, c_* > 0$, depending on M, J, ρ, a, b, K_*, s_J, and the larger domains, and independent of the side and of d_0, such that the following holds. Let R be gauge invariant on B_ρ, invariant under translations, the spatial inversion, and constant color conjugations, with $DR(I) = 0$ and $\mathcal{B}_{\rho,a}(R) \le \epsilon$. Then the pullback $R(e^{\Phi_{d_0,J}(\theta,q)})$ has the joint coefficient bound $C_{J,\rho,a}\epsilon$ at every fixed index on the enlarged product of coarse fields and variables q. Define the auxiliary recursion by the integral over the fixed product of fluctuation variables and the formula* (13.5)*, using this pullback on the gauge-transformed image in $B_{\rho/2}$, and without any indicator of D_r at coarse fields outside B_r. Let $p \ge p_0$, and assume*

$$0 < t \le \frac{c_*}{2(p^3 + \epsilon p)}. \tag{13.8}$$

Then, with $R_{\mathrm{aux}} = c_*/(p^3 + \epsilon p)$, for every complex ζ with $|\zeta| \le R_{\mathrm{aux}}$ and every $w \in \Omega_p$ the variables $\zeta\lambda_i w_i$ lie in the enlarged product of Theorem 13.2, the conditions (12.23) *hold at (t, p), and the supported families of the auxiliary interaction and of the inserted interaction constructed in the proof lie in the ball of radius $\eta_0/2$ of Theorem 12.7. Under these conditions, apart from the field-independent factor A_{coord}, the output effective interaction is*

$$R_+ = Q^{\mathrm{w}}_{d_0,J} + \mathcal{P}_\delta R + \mathcal{D}_J R, \qquad \mathcal{B}_{\rho,a}(R_+) \le C_G + q_P\epsilon + C_T t^2 \epsilon(p^4 + \epsilon p^2). \tag{13.9}$$

Here $\mathcal{P}_\delta R(\theta) = R(e^{\varphi_\theta(0)}) = R(e^{\delta\overline{A}_{d_0,J}(\theta)})$ is the pullback at the zero-fluctuation reconstruction, $\mathcal{D}_J R$ is the difference of the logarithms of the fluctuation partition functions without and with the inserted interaction, as in Lemma 12.16 at the parameter t, and $Q^{\mathrm{w}}_{d_0,J}$ is the effective interaction of Theorem 12.13. The output R_+ is gauge invariant on B_ρ, invariant under translations, the spatial inversion, and constant color conjugations, and $DR_+(I) = 0$. Coupling parameters internal to R are held fixed when the auxiliary parameter varies.

4. *Fix $E_* \ge 2C_G/(1 - q_P)$ and $p(t) = A_{\mathrm{w}} \log(1/t)$ with $A_{\mathrm{w}} \ge 1$. There exists $t_* > 0$, depending only on the fixed data, such that for every $0 < t \le t_*$ we have $p(t) \ge p_0$, $tp(t) < s_J$, the enlarged-domain hypotheses, and*

$$t \le \frac{c_*}{2(p(t)^3 + E_* p(t))}, \qquad C_T t^2 \big(p(t)^4 + E_* p(t)^2\big) \le \frac{1 - q_P}{2}.$$

Consequently $\mathcal{B}_{\rho,a}(R) \le E_*$ implies $\mathcal{B}_{\rho,a}(R_+) \le E_*$.

5. *The auxiliary recursion starting at $R_0 = 0$ exists, with the same ρ, a, and E_*, for any finite number of renormalization group steps. For any $r \le \rho$ for which the support-inclusion hypothesis holds at every step, the restricted densities after k steps are exactly*

$$Z_k^{-1} \mathbf{1}_{D_r} e^{-E_{kJ,\mathrm{sat}}/g_{kJ}^2 - R_{k,\mathrm{sat}}}, \qquad \mathcal{B}_{\rho,a}(R_k) \le E_*,$$

for every k for which the output sides are at least four and the couplings of the integrated scales are at most t_*. Nothing is asserted about the integral of the restricted input measure at coarse fields outside B_r.

Proof. We use the coefficient bounds of Theorem 13.2. We first fix the rates and the supports, then prove (2), then estimate the three parts of R_+, and finally choose the coupling threshold.

Step 1: rates, supports, and the order of choices. At an intermediate scale of mesh $\eta_i \le 1$, a weight $e^{A\mathrm{t}}$ with t measured in the units of that scale equals $e^{(A/\eta_i)\mathrm{t}}$ with t measured in coarse units. In particular, it gives any fixed rate below A in coarse units. The union of networks in Lemma 13.1 keeps one rate under finite composition and does not divide it by the number of scales. Sums over the kinds of coordinates change constants by D_J.

We separate these two effects with the following geometric bounds. For a monomial with n coordinate locations, we choose a rectilinear network of length at most $C_{\mathrm{geom}}\mathrm{t}$. To that end, we first replace a shortest connected network by a tree on the locations, of at most twice its length, by traversing its edges and shortcutting the walk. Then we replace each edge of the tree by its three coordinate segments. This also shows that the number of segments is at most a fixed multiple of $n+1$. We partition the torus into boxes with integer side lengths between $\mathscr{L}$ and $2\mathscr{L}$, a shorter direction forming one interval. Since a coordinate segment of length l meets at most $2 + l/\mathscr{L}$ intervals in its direction, the connected set X of boxes met by the network satisfies

$$|X| \le c_0\big(n + 1 + C_{\mathrm{geom}}\mathrm{t}/\mathscr{L}\big). \tag{13.10}$$

All constructions are periodic and include sets winding around the torus, and c_0 depends only on the dimension, not on the density of labels.

We choose $\mathscr{L}$ so large that $8c_0C_{\mathrm{geom}}/\mathscr{L}$ is at most one quarter of the available rate. The factor $e^{8c_0(n+1)}$ in $e^{8|X|}$ is absorbed by enlarging $K_* \ge 2$ once, since the radii carry the factor K_*^n. A second quarter of the available rate is used for the sums over the location of the fixed index. If $x \in X$ and u is any location of the monomial, the network from u to x has length at most $C_{\mathrm{geom}}\mathrm{t} + C_{\mathscr{L}}$, which leaves a factor that decays exponentially in $\mathrm{dist}(x,u)$. Summing over u then costs only D_J. These choices give the support weights used in Theorem 12.6 without a factor depending on J in the degree.

Each box contains at most $C\mathscr{L}^3$ coarse-field labels. Joining them inside each box and then joining adjacent boxes of a connected set Y, we obtain

$$\mathsf{t}(\text{coarse-field labels in } Y) \le C_{\mathscr{L}}|Y|,$$

and repeated labels do not increase this length. The bounds of Lemma 11.9 for the background field $e^{\delta\overline{A}_{d_0,J}}$ hold at a rate a_{cen}, and for this representative Theorem 11.10 provides the contraction at every output rate $0 < a < a_{\mathrm{cen}}/8$, and at no larger rate. We therefore choose a with $0 < a < a_{\mathrm{cen}}/8$ and $aC_{\mathscr{L}} \le 2$; such an a also satisfies $a < a_*/8$, where a_* is the rate of Theorem 10.11. We choose $b > a$ below the rate b_* of Theorem 13.2, with enough room for the support and location estimates above. This is possible since b_* is a fixed positive rate chosen before J, and a may be taken as small as needed. The condition $C_{\mathrm{geom}}bM^{-J} \le a$ is then imposed when J is chosen, after a and b are fixed. All these choices precede J, and the metric conventions are included once in C_{geom}.

The coefficient bounds for the reconstruction $\Phi_{d_0,J}$, for the auxiliary interaction H, and for $\mathsf{B}_{\mathrm{ref}}$ hold at a common rate $b_* > 0$ in coarse units, chosen before J. Indeed, the bounds of one averaging step in Lemma 12.3 hold at a rate chosen before J. This rate does not decrease when lengths are measured in coarse units, since every mesh is at most one, and composition through connected networks keeps one rate, by Lemma 13.1. The rate b_* of Theorem 13.2 is chosen below these rates. The inserted interaction is treated separately in Step 3: the network of R has the rate a/δ in coarse units, the condition $C_{\mathrm{geom}}b\delta \le a$ supplies the rate b needed for the support estimates, and the attached networks of the reconstruction have rate at least $b_* > b$. Since

$$0 < a < b < b_*,$$

all four families of bounds hold at the rate a of the norm $\mathcal{B}_{\rho,a}$ and at the rate b used for the supports. The rate b_J of Theorem 12.13(5), which may depend on J, is not used; this is why the bound on $Q^{\mathrm{w}}_{d_0,J}$ in Step 5 is proved directly.

The constant $C_P(a)$ of Theorem 11.10 does not change under later reductions of the radius. We choose ρ_0 in the range allowed by that theorem and in the range of convergence of Z, so that $Z(4K_*\rho) \le C_1\rho$ for $\rho \le \rho_0$. We then take J so large that $q_P < 1/4$, that $M^{-J}Z(4K_*\rho) \le \rho/4$, that $C_{\mathrm{geom}}bM^{-J} \le a$, and that M^{-J} is below the threshold $\delta_0(a)$ of Theorem 11.10. This is the only choice of J. Next we choose ρ and s_J as in Theorem 13.2(3), with strict inequalities and with $\rho C_B \le 1/2$. Here C_B is the constant in the coefficient bound for $\mathsf{B}_{\mathrm{ref}}$ of Step 5, which depends only on M, J, and the larger domains. Reducing these radii does not change q_P, and none of these choices uses r. This proves (1).

Step 2: conversion at the same radius. For a monomial $c_\alpha \theta^\alpha$ of degree k, the ordered derivatives with a scalar input i fixed satisfy

$$\frac{1}{k!} \sum_{i_2,\dots,i_k} |D_i D_{i_2} \cdots D_{i_k} (c_\alpha \theta^\alpha)(0)| = \frac{\alpha_i}{k} |c_\alpha|. \tag{13.11}$$

Indeed, the remaining indices can be ordered in $(k-1)!/((\alpha_i - 1)! \prod_{j \neq i} \alpha_j!)$ ways, and each derivative equals $c_\alpha \prod_j \alpha_j!$. For sums of supported terms the triangle inequality gives the corresponding upper bound. A term differentiated at i has $i \in Y$, and $e^{a\mathfrak{t}} \leq e^{2|Y|}$ by hypothesis.

At each degree the translation-invariant function f has the same norm with a fixed index at all translates of a given scalar orientation and color type. We choose one reference index for each of the $3 \cdot 3 = 9$ types, replace the maximum of the nine nonnegative degree sums by their sum, and only then sum over the degrees. Applying (13.11) at these fixed indices, we obtain

$$\mathcal{B}_{\rho,a}(f) \leq 9\rho^{-2} \sup_x \sum_{Y \ni x} e^{2|Y|} \|\Psi_Y\|_{\rho,\mathrm{coeff}}.$$

The individual Ψ_Y need not be translation invariant. Without translation invariance of f, a coefficient norm at a radius $u > \rho$ bounds the degree-k norm with a fixed index by u^{-k} times the norm at u, and summing $\rho^{k-2}u^{-k}$ over $k \geq 2$ gives $u^{-2}(1-\rho/u)^{-1}$. This explains the need for a strictly larger radius in that case. A supremum over the fixed index cannot be interchanged with the infinite sum over degrees at the same radius. This proves (2).

Step 3: the coefficients of the composed input interaction. Let $\epsilon = \mathcal{B}_{\rho,a}(R)$. We write the logarithms of the fine field as $A = (A_j)$, where the labels j of the fine lattice have volume $v_{\mathrm{old}} = \delta^3$, and we expand

$$\begin{aligned} R(e^A) &= R(I) + \sum_{n \geq 2} \frac{1}{n!} \sum_{j_1,\dots,j_n} R_n(j_1,\dots,j_n) \prod_{r=1}^n A_{j_r}, \\ P_j(\theta, q) &= \Phi_{d_0,J}(\theta, q)_j = \sum_{|\xi|+|\eta| \geq 1} p_{j;\xi\eta} \theta^\xi q^\eta; \end{aligned} \tag{13.12}$$

there is no term with $n = 1$ since $DR(I) = 0$. For a multiindex (ν, η) of positive total degree $N = |\nu| + |\eta| \geq 1$, the coefficient of $\theta^\nu q^\eta$ in $R(e^P)$ is

$$[\theta^\nu q^\eta] R(e^P) = \sum_{n=2}^N \frac{1}{n!} \sum_{j_1,\dots,j_n} \sum_{\substack{\sum_r \xi_r = \nu,\ \sum_r \eta_r = \eta \\ |\xi_r|+|\eta_r| \geq 1}} R_n(j_1,\dots,j_n) \prod_{r=1}^n p_{j_r;\xi_r\eta_r}, \tag{13.13}$$

where the inner sum is over ordered allocations. No further multinomial factor occurs, since each $p_{j;\xi\eta}$ is already the coefficient of a monomial. For example, the allocation

$(\xi_1, \eta_1) = (\mathbf{e}_i, 0)$, $(\xi_2, \eta_2) = (0, \mathbf{e}_l)$ with $n = 2$ contributes $(1/2) \sum_{j_1, j_2} R_2(j_1, j_2) p_{j_1;\mathbf{e}_i,0}\, p_{j_2;0,\mathbf{e}_l}$, and the exchanged allocation contributes the other half. We keep each summand of (13.13) with the union of the network of R_n and the networks of the attached coefficients of the reconstruction. These are connected through the indices j_r, and Lemma 13.1 applies; no product of independent extensive scalars occurs.

Let $r_n = |R_n|_a / n!$, where $|R_n|_a$ is the norm with one index fixed, and $F(s) = \sum_{n \geq 2} r_n s^n$. Then $\sum_n r_n \rho^{n-2} = \epsilon$, so each $r_n \rho^{n-2} \leq \epsilon$, and for $0 \leq m \leq \rho/2$,

$$F'(m) \leq \epsilon\rho \sum_{n \geq 2} n 2^{-(n-1)} = 3\epsilon\rho. \tag{13.14}$$

At the radii $U_0 = 4K_*\rho$ and $V_0 = 4K_* s_J$ the majorant for the output-fixed rows satisfies $\mathfrak{M}_J(U_0, V_0) < \rho/2$; that is, every attached factor has majorant less than $\rho/2$. Fix an external input i. We choose the factor containing it and its position there, and we use the column of that factor and rows for all other factors. The column carries the factor v_{old}/v_i, while the norm of R_n with a fixed index has no volume factor, and the bound for the composed scalar with i fixed therefore contains $v_i/v_{\text{old}} \leq \Gamma_J$, where

$$\Gamma_J = \max_i \frac{v_i}{v_{\text{old}}} \leq M^{3J},$$

the maximum being over indices of θ and of q. Let $c_\theta(U, V)$ and $c_q(U, V)$ be the majorant series of Theorem 13.2(1) for the columns at a fixed coarse-field input and at a fixed input of q, in which the fixed input carries its radius U or V. In particular, $c_q(U, 0) = 0$. Then the series with the input i fixed is bounded by

$$\Gamma_J\, F'\big(\mathfrak{M}_J(U, V)\big)\big(c_\theta(U, V) + c_q(U, V)\big), \tag{13.15}$$

and by (13.11) the series without a distinguished input is no larger. The column majorants are finite at (U_0, V_0). Combining (13.14) and (13.15), we obtain the joint coefficient bound $C_{J,\rho,a}\epsilon$ on the enlarged product. It controls coefficients with a coarse-field index fixed, with an index of q fixed, and mixed ones, before any evaluation, and the constant $R(I)$ never enters.

A network of locations of the fine lattice has length δ^{-1} times its length in coarse units. Its weight at the rate a therefore gives the rate a/δ in coarse units, and the condition $C_{\text{geom}} b\delta \leq a$ provides the rate b on this part of the composed network. Each attached network of the reconstruction has its own rate, which is at least b. Their union provides the rates used for the supports and for the location sums in Step 1, while the output norm still has the rate a. Conversions between the fixed meshes cost factors depending only on J, not volume factors.

For real coarse fields and fluctuations, the value of this pullback is $R_{\text{sat}}(\mathscr{C}_{\text{raw}})$, by (13.7). Thus $R(e^{\Phi_{d_0,J}(\theta,q)})$ is the holomorphic pullback required in Lemma 12.16, and its hypothesis is verified on the whole range of the reconstruction, not only at its center. This proves the first assertion of (3).

Step 4: the inserted interaction at the radius ρ. We now show that the estimate of Lemma 12.16 holds at the radius ρ itself, rather than at a smaller radius. We fix p, every parameter internal to R, the balls, and the classical functions, and we substitute $q_i = \zeta\lambda_i w_i$. For each summand o of (13.13) with $|\eta| \geq 1$, where o specifies n, the indices j_r, the allocation, and the refinements of the networks, we set

$$a_o(\zeta) = \frac{\zeta^{|\eta|}}{n!} R_n(j_1, \dots, j_n) \prod_{r=1}^{n} p_{j_r;\xi_r\eta_r} \prod_l \lambda_{s(l)}^{\eta_l},$$

where $s(l)$ is the scale of the index l of q. Let Y_o be the set of boxes assigned to the external locations of o by the construction of Lemma 12.9, and set $(A_R)_Y(\theta, w; \zeta) = \sum_{o:\, Y_o = Y} a_o(\zeta)\theta^\nu w^\eta$. Then, exactly,

$$\sum_Y (A_R)_Y = R\big(e^{\Phi(\theta,(\zeta\lambda_i w_i)_i)}\big) - R\big(e^{\Phi(\theta,0)}\big),$$

supports winding around the torus being included; the construction is linear in R. We replace the supremum over w in the norm $\mathscr{S}_8$ of Theorem 12.7, at the coefficient radius ρ, by the sum of absolute coefficients at $|w_l| \leq p$. We then bound each monomial by the sum over its variables w_l of the corresponding terms with that variable fixed. The support-weight estimate (12.20) costs a fixed constant and a factor K^N for a monomial with N locations, which we absorb by multiplying all radii by K. This enlargement is included in K_*, so that $K\rho \leq U_0$ and $K|\zeta|p \leq V_0$ in the range used below. The sum over the location of the fixed index of w costs a constant depending on the density. By (13.14), (13.15), and the bound $c_q(U, V) \leq L_q V$ for $U \leq U_0$, with $L_q = \sup_{0<V\leq V_0} c_q(U_0, V)/V < \infty$, we obtain, after enlarging C_J,

$$\|\boldsymbol{A}_R(\zeta)\|_{\mathscr{S}_8} \leq \frac{C_J|\zeta|\epsilon p}{1 - C_J|\zeta|p} \qquad (C_J|\zeta|p < 1). \tag{13.16}$$

The bound is linear in ϵ, since it comes from the single tensor family (R_n). In the same way, repeating Step 6 of the proof of Theorem 12.13 at the coefficient radius ρ and with the boxes of Step 1, we obtain for the auxiliary interaction of Definition 12.15

$$\|\boldsymbol{H}(\zeta)\|_{\mathscr{S}_8} \leq \frac{C_J|\zeta|(p^3 + p)}{1 - C_J|\zeta|p},$$

since its classical terms contain at least three fluctuation variables of their own scale and its Haar density and determinant terms at least one.

Let $s_{\mathrm{aux}} > 0$ be such that $Ks_{\mathrm{aux}} \leq V_0$, and choose

$$0 < c_* < \min\Big\{s_{\mathrm{aux}}, \frac{1}{2C_J}, \frac{\eta_0}{12C_J}, \frac{\sigma_0}{2C_J}\Big\}, \qquad R_{\mathrm{aux}} = \frac{c_*}{p^3 + \epsilon p}, \tag{13.17}$$

where η_0 is the constant of Theorem 12.7, σ_0 is the constant of Theorem 12.13, and C_J is enlarged to dominate the constant of that theorem. Since $p \geq 1$, we have $R_{\mathrm{aux}} p \leq c_*$, so for $|\zeta| \leq R_{\mathrm{aux}}$ the substituted variables satisfy $|\zeta \lambda_i w_i| \leq c_* \leq s_{\mathrm{aux}}$, the denominators above are at least $1/2$, and, since $p^3 + p + \epsilon p \leq 2(p^3 + \epsilon p)$,

$$\|\boldsymbol{H}(\zeta) + s\boldsymbol{A}_R(\zeta)\|_{\mathscr{S}_8} \leq 2C_J R_{\mathrm{aux}}(p^3 + p + \epsilon p) \leq 4C_J c_* < \eta_0/2 \qquad (0 \leq s \leq 1).$$

Under (13.8) we have $tp \leq tp^3 \leq c_*/2$, which implies $C_J tp < 1/2$ and $C_J(tp^3 + tp)/(1 - C_J tp) \leq 2C_J c_* \leq \sigma_0$; these are the conditions (12.23). This proves the statements about the domain in (3).

By Theorem 12.7 and (13.16), the family $\boldsymbol{F}_s(\zeta) = D\boldsymbol{\mathcal{L}}(\boldsymbol{H}(\zeta) + s\boldsymbol{A}_R(\zeta))[\boldsymbol{A}_R(\zeta)]$ satisfies $\|\boldsymbol{F}_s(\zeta)\|_{\mathscr{S}_2} \leq C|\zeta|\epsilon p$ on the disc. Every term of H and of A_R vanishes at $\zeta = 0$. Their coefficients of order one in ζ are cubic polynomials in the fluctuation variables for the classical terms, and linear polynomials for the Haar density and determinant terms and for the terms from R. Since each of them changes sign under $w \mapsto -w$, while the reference product π_p^{all} is invariant under this reflection, each supported integral of first order vanishes. Terms with two interaction factors are of order at least two. Thus $\boldsymbol{F}_s(0) = \boldsymbol{F}_s'(0) = 0$ on every support. The family $\boldsymbol{F}_s(\zeta)/\zeta$ is holomorphic, vanishes at zero, and is bounded by $C\epsilon p$. Cauchy's formula then gives, for $0 < t \leq R_{\mathrm{aux}}/2$,

$$\|\boldsymbol{F}_s(t)\|_{\mathscr{S}_2} \leq C\epsilon p \, \frac{t^2}{R_{\mathrm{aux}}(1 - t/R_{\mathrm{aux}})} \leq \frac{2C}{c_*} t^2 \epsilon(p^4 + \epsilon p^2).$$

Integrating over $s \in [0,1]$, we find that the difference $\boldsymbol{\mathcal{D}}(t) = \boldsymbol{\mathcal{L}}(\boldsymbol{H}(t) + \boldsymbol{A}_R(t)) - \boldsymbol{\mathcal{L}}(\boldsymbol{H}(t))$ satisfies

$$\|\boldsymbol{\mathcal{D}}(t)\|_{\mathscr{S}_2} \leq C\epsilon p \frac{t^2}{R_{\mathrm{aux}}} \leq Ct^2 \epsilon(p^4 + \epsilon p^2), \tag{13.18}$$

at the coefficient radius ρ, without differentiation in the coarse field and without reduction of the radius. The dependence on ϵ^2 comes from the radius of the disc.

The auxiliary integral with the inserted interaction, the one without it, and the pullback at the zero-fluctuation reconstruction have the identities of Theorem 13.4 under gauge transformations, translations, the spatial inversion, and color conjugations. Subtracting, we find that the total difference of logarithms $\mathcal{D}_J R$ is translation invariant. Applying part (2) to (13.18), we obtain

$$\mathcal{B}_{\rho,a}(\mathcal{D}_J R) \leq C_T t^2 \epsilon(p^4 + \epsilon p^2).$$

The constant term of $\mathcal{D}_J R$ is not controlled by this norm; it is transferred to the normalization constant Λ, with densities written as $\exp(\Lambda - E/g^2 - R)$.

Step 5: the pullback at zero fluctuation and the newly generated effective interaction. Gauge invariance on B_ρ implies the local gauge-invariance identities required in

Theorem 11.10. Indeed, for a fixed real small field, we take a small gauge variation at one vertex whose endpoints remain in the chart and differentiate the exact invariance identity. The other symmetries and $DR(I) = 0$ are hypotheses. The background field $e^{\delta\overline{A}_{d_0,J}(\theta)}$ has the first-derivative bounds of Lemma 11.9, and by the choice of J its image under the reconstruction majorant on $\|\theta\|_\infty \le 2\rho$ lies in the ball of radius $\rho/2$, since $\delta Z(2\rho) \le \delta Z(4K_*\rho) \le \rho/4$. Theorem 11.10, applied to this representative at the rate $a < a_{\mathrm{cen}}/8$ chosen in Step 1, with $2\rho_0$ below the radius of Lemma 11.9, implies that

$$\mathcal{B}_{\rho,a}(\mathcal{P}_\delta R) \le q_P \epsilon.$$

Its value is the value of R at the zero-fluctuation reconstruction that appears in the integral. By gauge invariance on B_ρ, this identification holds even if the representative in the block axial gauge is not in B_ρ.

The newly generated effective interaction, from Theorem 12.13, is

$$Q^{\mathrm{w}}_{d_0,J} = \mathsf{B}_{\mathrm{ref}} - \Big(\sum_i f_i\Big) \log z_p - \log \Xi_{d_0,J}.$$

We bound its three terms in the norm $\mathcal{B}_{\rho,a}$ directly, using only rates at least b_*; the rate b_J of Theorem 12.13(5), which may depend on J, is not used.

The function $\mathsf{B}_{\mathrm{ref}}(c) = \sum_i \mathsf{B}_i(\widehat{c}_{i+1})$ depends on the coarse field; it is not a constant. Its coefficients of positive degree are obtained by composing the coefficient series of the terms B_i with the zero-fluctuation reconstruction $\theta \mapsto \widehat{c}_{i+1}$, that is, with the reconstruction of Step 3 of the proof of Theorem 13.2 at $q = 0$. The coefficients of positive degree of B_i, with one index fixed, are bounded by the logarithmic determinant series of the proof of Proposition 12.10 and by the bounds for the logarithmic Haar density and the minimizer of Lemma 12.3(3), at the rate of one averaging step. The reconstruction has coefficient bounds at the rate b_*, with its columns. The networks of the composed coefficients are connected through the indices of the fields $\widehat{c}_{i+1}$, and Lemma 13.1 applies. The conversion from the column normalization of these indices to the counting normalization of the scalar norm costs at most the factor $\Gamma_J \le M^{3J}$, as in Step 3. We conclude that there exists C_B, depending only on M, J, and the larger domains, such that

$$\frac{1}{k!}\|D^k_\theta \mathsf{B}_{\mathrm{ref}}(0)\|_{b_*,\mathrm{root}} \le C_B^{k+1} \qquad (k \ge 1),$$

uniformly in d_0 and m. Since $a < b_*$ and $\rho C_B \le 1/2$ by the choice of ρ in Step 1,

$$\mathcal{B}_{\rho,a}(\mathsf{B}_{\mathrm{ref}}) \le \sum_{k\ge 2} \rho^{k-2} C_B^{k+1} \le 2C_B^3.$$

For the logarithm of the fluctuation partition function, Step 4 gives an exact supported decomposition $\boldsymbol{H}(t)$ of $H_{d_0,J}$, at the coefficient radius ρ and with the boxes of Step 1,

with $\|\boldsymbol{H}(t)\|_{\mathscr{S}_8} \le \eta_0/2$ under (13.8). By Theorem 12.7, $-\log \Xi_{d_0,J} = \sum_Y \mathcal{L}_Y(\boldsymbol{H}(t))$ with $\|\boldsymbol{\mathcal{L}}(\boldsymbol{H}(t))\|_{\mathscr{S}_2} \le C\eta_0$, and each $\mathcal{L}_Y$ depends only on the coarse-field coordinates in Y. The integral (12.25), the action E_{d_0+J}, and the function $\mathsf{B}_{\mathrm{ref}}$ are invariant under the translations of the coarse lattice, by Theorem 12.13(6) and its proof, so $\log \Xi_{d_0,J}$ is translation invariant. Since $aC_{\mathscr{L}} \le 2$, the support condition of part (2) holds, and by part (2) we have

$$\mathcal{B}_{\rho,a}(\log \Xi_{d_0,J}) \le 9C\eta_0\rho^{-2}.$$

The Gaussian normalization $(\sum_i f_i)\log z_p$ is a constant; it has zero norm but remains in the density. Altogether $\mathcal{B}_{\rho,a}(Q^{\mathrm{w}}_{d_0,J}) \le C_G$ with $C_G = 2C_B^3 + 9C\eta_0\rho^{-2}$, uniformly in the side, in d_0, and in t, p satisfying (13.8). Taking the negative logarithm of the integral formula (13.5) at the parameter t, and separating $-\log A_{\mathrm{coord}}$, we obtain

$$R_+ = Q^{\mathrm{w}}_{d_0,J} + \mathcal{P}_\delta R + \mathcal{D}_J R.$$

Adding the three bounds proves (13.9). The symmetries of the integral give the stated symmetries of R_+, and the color argument of Step 5 of the proof of Theorem 13.4 shows that $DR_+(I) = 0$. This proves (3).

Step 6: one coupling threshold and the induction. Let E_* and $p(t) = A_{\mathrm{w}}\log(1/t)$ be as in (4). For $k > 0$ and $l \ge 0$ we have $t^k \log(1/t)^l \to 0$ as $t \downarrow 0$. There are finitely many strict requirements: the image conditions, the cluster conditions, the condition $t \le c_*/(2(p(t)^3 + E_* p(t)))$, the condition on $C_T t^2(p(t)^4 + E_* p(t)^2)$, the bound $tp(t) < s_J$, and $p(t) \ge p_0$. For $r \le \rho$, the bound $tp(t) < s_J$ implies $r + tp(t) < r_J$ and a positive denominator in $\mathfrak{M}_J(r, tp(t))$, by the inequalities for the enlarged product, and the intermediate maps have the margins already fixed. The additional inequality $\mathfrak{M}_J(r, tp(t)) < r/2$ is still required whenever the support-inclusion hypothesis is invoked; it is not implied by a coupling threshold independent of r. We choose $t_* > 0$ below the thresholds of all these requirements. For $\epsilon \le E_*$, condition (13.8) holds, and by the recursion we have

$$C_G + q_P\epsilon + C_T t^2 \epsilon(p^4 + \epsilon p^2) \le \frac{1-q_P}{2}E_* + q_P E_* + \frac{1-q_P}{2}E_* = E_*.$$

This proves (4). Starting with $R_0 = 0$, we construct the next effective interaction at the same ρ, a, and E_* from the auxiliary integral, the nonvanishing of its continuation, and this bound, and we repeat this for any finite number of steps. Where the support-inclusion hypothesis holds, Theorem 13.4 identifies each restricted density with the displayed expression, and the induction keeps every initial and pulled-back indicator. This proves (5). □

13.5 The conditional fluctuation potential

Dividing (13.5) by the integral over the fluctuations gives the conditional law of the normalized fluctuation variables given the coarse field. We show that its potential is

uniformly convex, which implies dimension-free concentration and covariance estimates. The heuristic reason is the following count of powers of the coupling. By stationarity and the normalization by the constrained Hessian,

$$\frac{F(z^* + gK^{-1/2}w) - F(z^*)}{g^2} = \frac{1}{2}|w|^2 + O(g|w|^3),$$

while the Haar density terms, the determinant terms, and the input effective interaction contribute $O(g|w|) + O(g^2|w|^2) + \cdots$. Substituting the fluctuations of coarser scales into the backgrounds of finer scales adds one factor $g_l w_l$ for each such variable and preserves these powers. Thus the Hessian of the interaction is small when tp is small, while the complex polymer expansion of Section 13.4 needs tp^3 small. On a larger product with radius $P = q_*/t$, in which only $tP = q_*$ is small, real convexity still holds although the polymer expansion is not available.

We first record some facts about probability measures on a fixed product of balls. Here the product does not move when parameters vary. Differentiation of a family of observables means differentiation of continuous functions with continuous derivatives on a neighborhood of the product, and the same formulas hold for families with dominated difference quotients and integrable derivatives.

Lemma 13.6. *Let Ω be a fixed product of closed balls, let $I \subset \mathbb{R}$ be an interval, and let $(V_u)_{u\in I}$ be real functions such that $V_u(w)$ and $\partial_u V_u(w)$ are continuous on $I \times N$ for a neighborhood N of Ω. Let $\mathbb{E}_u$, Cov_u refer to the probability measure on Ω with density proportional to e^{-V_u}, and let F_u be a family of observables as above.*

1. *We have*

$$\partial_u \mathbb{E}_u F_u = \mathbb{E}_u \partial_u F_u - \mathbb{E}_u(F_u \partial_u V_u) + \mathbb{E}_u F_u \, \mathbb{E}_u \partial_u V_u = \mathbb{E}_u \partial_u F_u - \mathrm{Cov}_u(F_u, \partial_u V_u), \tag{13.19}$$

   and $\partial_u \log \int_\Omega e^{-V_u}\, dw = -\mathbb{E}_u \partial_u V_u$.

2. *Let $m_u = \mathbb{E}_u w$, $\xi = w - m_u$, $\Sigma_u = \mathbb{E}_u \xi\xi^{\mathsf{T}}$, and $Q_u = \partial_u V_u - \mathbb{E}_u \partial_u V_u$. Then*

$$\partial_u \Sigma_u(i,j) = -\mathbb{E}_u \xi_i \xi_j Q_u, \tag{13.20}$$

   and

$$\mathbb{E}\xi_i\xi_j Q_u = \mathrm{Cov}(\xi_i\xi_j, Q_u) = \mathrm{Cov}(\xi_i, \xi_j Q_u) = \mathrm{Cov}(\xi_j, \xi_i Q_u), \tag{13.21}$$

   including the case $i = j$.

3. *For a matrix A, $\|A\|_{\mathrm{op}} \le (\|A\|_{\mathrm{row}}\|A\|_{\mathrm{col}})^{1/2}$, where $\|A\|_{\mathrm{row}} = \sup_i \sum_j |A_{ij}|$ and $\|A\|_{\mathrm{col}} = \sup_j \sum_i |A_{ij}|$. If an array (b_{eij}) satisfies $\sup_e \sum_{i,j} |b_{eij}| \le C$ and $\sup_{i,j} \sum_e |b_{eij}| \le C$, then $\|\sum_e a_e b_{e\cdot\cdot}\|_{\mathrm{HS}} \le C\|a\|_2$ for every array (a_e).*

Proof. On a compact interval of u, the functions e^{-V_u}, F_u, and their u-derivatives are bounded on Ω. The fundamental theorem of calculus applied to difference quotients,

followed by integration over the fixed set Ω, differentiates the integrals without a boundary term, and the quotient rule gives (13.19). Taking $F = 1$ before normalizing gives the formula for the logarithm. No integration by parts in w is used. For families with dominated difference quotients, the same argument applies with the integrable dominating function.

For (2), the explicit u-derivative of the observable $\xi_i\xi_j$ has expectation $-(\partial_u m_i)\mathbb{E}\xi_j - (\partial_u m_j)\mathbb{E}\xi_i = 0$. Then (13.19) implies (13.20). Since ξ_i, ξ_j, and Q_u are centered, expanding the definition of the covariance gives (13.21).

For (3), by the Cauchy–Schwarz inequality, we have

$$\sum_i \Big|\sum_j A_{ij}v_j\Big|^2 \le \Big(\sup_i \sum_j |A_{ij}|\Big) \sum_{i,j} |A_{ij}||v_j|^2 \le \|A\|_{\mathrm{row}}\|A\|_{\mathrm{col}} \sum_j |v_j|^2.$$

Regard (b_{eij}) as a matrix T with rows indexed by e and columns by pairs (i,j). Since its row sums and column sums are at most C, we have $\|T\|_{\mathrm{op}} \le C$, and the same holds for its transpose. The array $\sum_e a_e b_{e\cdot\cdot}$ is $T^{\mathsf{T}}a$, and its Hilbert–Schmidt norm is $\|T^{\mathsf{T}}a\|_2 \le C\|a\|_2$. This uses the column sums; a bound for each output e separately would not suffice. □

The next lemma bounds conditional means along an interpolation that starts from a measure with zero means. We use it twice below.

Lemma 13.7. *Let Ω be a fixed product of balls in the scalar coordinates w_i, and for $s \in [0,1]$ let π_s be the probability measure on Ω with density proportional to e^{-V_s}, where V_s satisfies the hypotheses of Lemma 13.6 in s, with continuous derivatives $\partial_{w_j}\partial_s V_s$. Let $m(s) = \max_i |\mathbb{E}_{\pi_s} w_i|$. Assume that*

1. *$m(0) = 0$;*
2. *there is a matrix $L = (L_{ij})$ with nonnegative entries such that, for every s and i, $|\mathrm{Cov}_{\pi_s}(w_i, \partial_s V_s)| \le \sum_j L_{ij}\|\partial_{w_j}\partial_s V_s\|_{L^2(\pi_s)}$, with $\sup_i \sum_j L_{ij} \le \Lambda_0$;*
3. *for every s, $\sup_j \|\partial_{w_j}\partial_s V_s\|_{L^2(\pi_s)} \le \beta(1 + m(s)^2)$.*

If $2\Lambda_0\beta < 1$, then $m(s) < 1$ and $m(s) \le 2\Lambda_0\beta s$ for every $s \in [0,1]$.

Proof. By (13.19) with $F = w_i$, we have $d\mathbb{E}_{\pi_s} w_i/ds = -\mathrm{Cov}_{\pi_s}(w_i, \partial_s V_s)$. Since the entries of L are nonnegative, (2) and (3) give $|d\mathbb{E}_{\pi_s} w_i/ds| \le \Lambda_0\beta(1 + m(s)^2)$. Integrating from 0 and using (1), we obtain $m(s) \le \Lambda_0\beta \int_0^s (1 + m(v)^2)\, dv$. The function m is continuous. If m reached the value one, then at the first such time $s_1 \le 1$ we would have $1 = m(s_1) \le 2\Lambda_0\beta s_1 < 1$, which is impossible. Thus $m < 1$ on $[0,1]$, and inserting this in the integral, we obtain $m(s) \le 2\Lambda_0\beta s$. □

Theorem 13.8. *Fix the parameters and the coupling threshold of Theorem 13.5, and an effective interaction R as in part (4) of that theorem, with $\mathcal{B}_{\rho,a}(R) \le E_*$. Consider a renormalization group step whose restriction event satisfies both hypotheses of Definition 13.3. Then the following statements hold for every $c = e^{\theta} \in B_r$, every depth, and every side $m \ge 4$.*

1. *The conditional law of the normalized fluctuation variables given the coarse field is the conditional fluctuation kernel*

$$k(c, dw) = \frac{\mathbf{1}_{\Omega_p}(w) e^{-V_c(w)}\, dw}{\int_{\Omega_p} e^{-V_c(w)}\, dw}, \qquad V_c = \tfrac{1}{2}|w|^2 + H_{d_0,J} + R(e^{\varphi_\theta(w)}) - R(e^{\varphi_\theta(0)}).$$

   The domain is the fixed product of three-dimensional balls, independent of c. The conditional fluctuation potential V_c contains all classical terms, the differences of Haar densities, the dependence of the determinants of finer scales on coarser fluctuations, and the full chain rule for the input effective interaction. If the whole hierarchy of restrictions is conditioned on this coarse field, the conditional law of the fluctuations of this step is the same kernel: the restrictions at coarser scales depend only on c and cancel in the normalization.

2. *There exist $b, C > 0$, depending only on M, J, ρ, a, E_*, and the larger domains, such that the entrywise envelope $\mathcal{H}_{ij} = \sup_{w\in\Omega_p} |\partial_{w_i}\partial_{w_j}(V_c - |w|^2/2)|$ satisfies*

$$\|\mathcal{H}\|_{b,\mathrm{row+col}} \le \frac{C[tp + t^2(1+E_*)]}{(1-Ctp)^3} \le \frac{1}{2}.$$

   In particular $D_w^2 V_c \ge I/2$ on the closed product, and V_c is smooth on a neighborhood of it. For the Neumann realization on the convex product Ω_p, every real $F \in H^1(k)$ satisfies

$$\mathrm{Var}_k F \le 2\mathbb{E}_k|\nabla F|^2, \qquad \mathrm{Ent}_k(F^2) \le 4\mathbb{E}_k|\nabla F|^2,$$

   and for real or complex F, G, with the covariance taken bilinear,

$$|\mathrm{Cov}_k(F,G)| \le C\sum_{i,j} e^{-b'\,\mathrm{dist}(i,j)} \|\partial_i F\|_2 \|\partial_j G\|_2$$

   for a fixed $b' > 0$. The constants do not depend on the dimension, on the radii of the balls, on the side, on the depth, or on the coupling satisfying the conditions of Theorem 13.5.

3. *Choose $q_* > 0$ inside the larger domain of the variables q and put $P(t) = q_*/t$. On $\Omega_{P(t)}$ define the same smooth potential, whether or not this larger product satisfies the support-inclusion hypothesis. If*

$$\frac{C[q_* + t^2(1+E_*)]}{(1-Cq_*)^3} \le \frac{1}{2},$$

   then for each $s \in [0,1]$ the potential $V^P_{s,c} = |w|^2/2 + s(V_c - |w|^2/2)$ has Hessian at least $I/2$ on $\Omega_{P(t)}$ and satisfies the inequalities of (2). If $\pi^P_{s,c}$ denotes the normalized measure, then, for a sufficiently small fixed t_*,

$$\sup_{s,c,i} |\mathbb{E}_{\pi^P_{s,c}} w_i| \le Ct(E_* + 2), \qquad \|w_i\|_{L^4(\pi^P_{s,c})} \le C\big(1 + \sup_j |\mathbb{E}_{\pi^P_{s,c}} w_j|\big).$$

Proof. We use the coefficient bounds of Theorem 13.2 and estimate the potential directly, before taking any logarithm of a partition function.

Step 1: the conditional kernel. In the density of Theorem 13.4, the factors A_{coord} and $\exp[-E_{d_0+J}/g_J^2 - \mathsf{B}_{\mathrm{ref}} - R_{\mathrm{ref}}]$ do not depend on w. Dividing the joint density by its positive integral over w cancels exactly these factors, and we obtain $k(c, dw)$. The domain is the product of balls of the normalized fluctuation variables, which does not depend on c. The terms $\mathsf{B}_i(c_{i+1}) - \mathsf{B}_i(\widehat{c}_{i+1})$ in $H_{d_0,J}$ keep the dependence of the determinants and of the Haar densities at the minimizers on the coarser fluctuations, and its other terms are the differences of the Haar densities. Thus $k(c, dw)$ is the full conditional law, not a perturbation of a Gaussian reference measure.

The same calculation can be expressed without choosing a version of the conditional law. To see this, we multiply the joint density by a bounded Borel function of c and a bounded Borel function of w and integrate first in w and then in c. The result is the joint integral of Theorem 13.4. This verifies the identity for the conditional kernel, and its pointwise version is the positive continuous integral. In a complete hierarchy, every restriction coarser than this step is a function of c and of its further averages. Such factors multiply both the numerator and the normalization of the conditional law by the same function of c and cancel. They do not cancel from the unnormalized law of the coarse field. This proves (1).

Step 2: powers of the coupling. Let $U = V_c - |w|^2/2$. We fix the coarse field in its larger ball but do not freeze the coarser fluctuations. At scale i the classical Taylor remainder has degree $s \geq 3$ in the variables of its own scale, and the normalization of the action gives the factor g_i^{s-2}. Substituting the coarser fluctuations into the background adds r_l fluctuation variables from each coarser scale $l > i$. With total degree $n = s + \sum_{l>i} r_l$ in w, the coupling factor is exactly

$$g_i^{s-2} \prod_{l>i} g_l^{r_l} = t^{n-2} \lambda_i^{s-2} \prod_{l>i} \lambda_l^{r_l}, \qquad n \geq 3. \tag{13.22}$$

No negative power of a ratio $\lambda_i \leq 1$ occurs, since $s \geq 3$. Centering at the minimizer removes the term of degree one in the variables of its own scale. The normalization by the positive square root of the Hessian removes the quadratic term, at every value of the coarser fluctuations. Thus no classical term of total degree one or two in w survives the substitution.

Each difference of Haar densities and each difference of determinant terms has positive total degree n in w and the coupling factor t^n. The composed difference of the input effective interaction obeys the same rule, with amplitude bounded by $C\epsilon \leq CE_*$. The joint coefficient bounds, evaluated on a slightly larger coarse-field radius and a slightly larger product of the variables q, therefore give the following bounds for the absolute

coefficients with one index fixed:

contribution	degree in w	coefficient bound
classical remainder	$n \geq 3$	$C^n t^{n-2}$
Haar density and determinant differences	$n \geq 1$	$C^n t^n$
difference of $R \circ e^{\varphi}$	$n \geq 1$	$C^n E_* t^n$.

(13.23)

These bounds include every substitution of a background and every derivative of the matrices S_i. The fixed ratios λ_i and the fixed radii are included in C.

Step 3: the Hessian. We take two derivatives in w and sum their weighted rows. The multiplicities of the two derivatives are at most $n(n-1)$, and the other coordinates have absolute value at most p. With $x = Ctp < 1$, the classical sum is

$$\sum_{n \geq 3} n(n-1) C^n t^{n-2} p^{n-2} = 2C^2 \big\{ (1-x)^{-3} - 1 \big\} \leq \frac{6C^3 tp}{(1-Ctp)^3},$$

where we used $1 - (1-x)^3 \leq 3x$. The sums for the Haar density and determinant terms and for the terms from R are bounded by

$$(1 + E_*) \sum_{n \geq 2} n(n-1) C^n t^n p^{n-2} = \frac{2C^2 t^2 (1 + E_*)}{(1-Ctp)^3},$$

and the terms of degree one contribute nothing. The network weights give the decay in the distance between the two remaining indices, and by symmetry the column sums have the same bound. These sums of absolute coefficients, evaluated at the radius p, are uniform in $w \in \Omega_p$, so they bound the entrywise envelope $\mathcal{H}_{ij}$; this is the bound (13.3) of Lemma 13.1 applied to the first derivatives of U. Increasing C, we obtain the stated bound for $\|\mathcal{H}\|_{b,\mathrm{row+col}}$. For the part coming from R, both terms of

$$D^2(R \circ e^{\varphi}) = D^2(R \circ \exp)(\varphi)[D\varphi, D\varphi] + D(R \circ \exp)(\varphi)[D^2\varphi]$$

are included in its series of degree n. In particular, the first derivative of R multiplying the second derivative of the reconstruction is kept.

We reduce the coupling threshold of Theorem 13.5 so that this bound is at most $1/2$. By Lemma 13.6(3), the operator norm is bounded by the row and column sums, and we obtain $D_w^2 V_c \geq I/2$. The margin in the coefficient bounds provides a smooth extension of the potential to an open neighborhood of the closed product.

Step 4: the inequalities of the Neumann realization. The balls are convex, have dimension three, and have radii independent of c, and the potential has the smoothness and the lower bound on the Hessian just proved. By Theorem 5.4 with $m = 1/2$, we have the variance constant 2 and the entropy constant 4, including the corners of the product. To

check its spatial hypothesis, recall that the weighted row-plus-column norm of $\mathcal{H}$ at the rate b is at most $1/2$. The hypothesis concerns the operator norms of the mixed blocks of the three-dimensional balls, so we group the scalar indices into their three-component blocks. The operator norm of a block is at most the sum of the absolute values of its scalar entries. Hence the weighted row and column sums of the operator norms of the mixed blocks are at most three times the scalar sums, that is, at most $3/2$. We set $b' = b/8$. For $z \geq 0$, convexity gives

$$e^{z/8} - 1 \leq \tfrac{1}{8}(e^z - 1) \leq \tfrac{1}{8} e^z.$$

Both block sums with the weight $e^{b' \operatorname{dist}(x,y)} - 1$ are therefore at most $3/16$, which is below $m/2 = 1/4$; the diagonal Gaussian blocks have no mixed contribution. Thus the spatial hypothesis of Theorem 5.4, which involves the suprema over Ω_p of the mixed blocks, holds at the rate b'. Expanding the block gradient norms into their scalar components, we obtain the stated scalar covariance inequality, with a fixed change of its constant. Distinct blocks with the same location can be treated by separating them by an arbitrarily small distance, applying the inequality at a slightly smaller rate, and passing to the limit; the strict inequality $3/16 < 1/4$ leaves room for this perturbation. All sums are finite at this stage, and the weighted bounds remain uniform in the limit. This proves (2).

Step 5: the larger product. The proof of the Hessian bound evaluated the majorant series at the radius tp of the variables q; it did not use smallness of tp^3. Let $0 < q_* < s_J$ lie in the same domain of the variables q, and set $P = q_*/t$. Then $\rho + q_* < r_J$, the denominator of the reconstruction majorant is positive, and all intermediate margins follow from the enlarged product. The gauge-transformed reconstruction lies in $B_{\rho/2}$, where the input effective interaction is defined, and no inclusion in D_r is needed. If desired, we reduce the coupling threshold so that $tp(t) < q_*$; then this product contains Ω_p. Repeating the two sums with p replaced by P, we obtain

$$\|\mathcal{H}^P\|_{b,\mathrm{row+col}} \leq \frac{C[q_* + t^2(1 + E_*)]}{(1 - Cq_*)^3},$$

for the entrywise envelope $\mathcal{H}^P$ of $D_w^2 U$ on Ω_P. The potential on this product is the smooth potential of the auxiliary integral, and no indicator of D_r is inserted. Under the displayed condition, $|w|^2/2 + sU$ has Hessian at least $I/2$ for every $s \in [0,1]$, its mixed blocks satisfy the same bound, and Step 4 applies on this product. No complex expansion at the radius P is used.

Step 6: the means on the larger product. It remains to bound the means without a loss of a factor P^2. By the concentration statement of Theorem 5.4, we have for each scalar coordinate $\mathbb{P}(|w_i - \mathbb{E}w_i| > u) \leq 2e^{-u^2/4}$, hence $\mathbb{E}|w_i - \mathbb{E}w_i|^4 \leq \int_0^\infty 8u^3 e^{-u^2/4}\,du \leq C$. Thus, with $m(s) = \max_i |\mathbb{E}_{\pi_{s,c}^P} w_i|$,

$$\|w_i\|_{L^4(\pi_{s,c}^P)} \leq C(1 + m(s)), \tag{13.24}$$

and the bound for three-component blocks changes only C.

If we differentiate a classical monomial of degree n in U with respect to one fluctuation variable, there remain $n-1 \geq 2$ fluctuation factors. We place two of them in L^4 and the others in L^∞, and Hölder's inequality bounds their product in L^2 by $C(1+m(s)^2)P^{n-3}$. The coupling factor becomes

$$t^{n-2}P^{n-3} = tq_*^{n-3}. \tag{13.25}$$

The absolute coefficient series converges at q_*, and the margin in the radius absorbs the multiplicities of the derivative and the choice of the two factors placed in L^4. The derivatives of the Haar density and determinant terms and of the terms from R of degree n give $t^n P^{n-1} = tq_*^{n-1}$, hence the bound $Ct(1+E_*)$. It follows that

$$\sup_j \|\partial_{w_j} U\|_{L^2(\pi^P_{s,c})} \leq Ct(1+E_*+m(s)^2) \leq Ct(1+E_*)(1+m(s)^2). \tag{13.26}$$

These bounds hold with one index of w fixed, with a profile that decays exponentially in the distance to that index. Summing the covariance kernel of Step 4 over its second index costs only a constant depending on the density. We apply Lemma 13.7 to $V_s = |w|^2/2 + sU$, for which $\partial_s V_s = U$. At $s=0$ the measure is the even product of truncated Gaussian measures, and $m(0)=0$. Hypothesis (2) of the lemma holds with the nonnegative kernel $L_{ij} = Ce^{-b'\operatorname{dist}(i,j)}$ of the covariance bound of Step 4, whose row sums are at most a constant Λ_0 depending only on the fixed data, and hypothesis (3) holds with $\beta = Ct(1+E_*)$ by (13.26). After one fixed reduction of the coupling threshold, $2\Lambda_0\beta < 1$, and the lemma implies that $m(s) \leq Ct(1+E_*) \leq Ct(E_*+2)$, uniformly in s, c, and the volume. Together with (13.24) this proves (3). All bounds are bounds at a fixed coordinate, and the total dimension does not appear. □

13.6 Conditional means and coarse-field derivatives

We now study how the conditional fluctuation kernel depends on the coarse field. The main point is that its means are small, of order $t\|\theta\|_\infty$, even though the kernel is interacting. At the identity coarse field they vanish by the global color symmetry. We also control the derivative of the conditional fluctuation covariance, by a three-point decay estimate, and the first two Taylor coefficients of the reconstruction at the conditional mean, which are used in the later reconstruction estimates. We first prove the three-point estimate under abstract hypotheses.

Lemma 13.9. *Let Ω be a fixed product of balls of radii at most p, $p \geq 1$, in scalar coordinates w_i, and let V_θ be potentials depending on parameters θ_u, with the probability measures of density proportional to e^{-V_θ} on Ω, along the segment $\{s\theta : 0 \leq s \leq 1\}$. Let Σ_θ be the covariance matrix*

of w. Suppose that $D_0 \ge 2$, $A_{\mathrm{sc}} \ge 0$, and that along the segment, for every location x and every $R \ge 0$,

$$\#\{i : \operatorname{dist}(i,x) \le R\} + \#\{u : \operatorname{dist}(u,x) \le R\} \le D_0(1+R)^3,$$
$$|\operatorname{Cov}(F,G)| \le \sum_{i,j} L_{ij}\|\partial_i F\|_2 \|\partial_j G\|_2, \qquad L_{ij} \le D_0 e^{-\operatorname{dist}(i,j)/D_0},$$
$$\sup_{\Omega} |\partial_{w_i}\partial_{\theta_u} V| \le A_{\mathrm{sc}} D_0 e^{-\operatorname{dist}(i,u)/D_0}.$$

Let $\tau_3(i,j,u)$ be the sum of the two smallest of the distances $\operatorname{dist}(i,j)$, $\operatorname{dist}(i,u)$, and $\operatorname{dist}(j,u)$. Then, for an absolute constant C,

$$|\partial_{\theta_u}\Sigma_\theta(i,j)| \le C p A_{\mathrm{sc}} D_0^6 e^{-\tau_3(i,j,u)/(4D_0)}, \qquad \|\Sigma_\theta - \Sigma_0\|_{\mathrm{op}} \le C p A_{\mathrm{sc}} D_0^{14} \|\theta\|_\infty.$$

Proof. We write $D = D_0$ and $A = A_{\mathrm{sc}}$. The counting hypothesis implies, for each fixed $c > 0$,

$$\sup_x \sum_i e^{-\operatorname{dist}(i,x)/(cD)} + \sup_x \sum_u e^{-\operatorname{dist}(u,x)/(cD)} \le C_c D^4. \tag{13.27}$$

To prove it, let $N_x(R) = \#\{i : \operatorname{dist}(i,x) \le R\}$ and use $e^{-r/(cD)} = (cD)^{-1}\int_r^\infty e^{-R/(cD)}\,dR$; summing this identity over i bounds the first sum by

$$\frac{1}{cD}\int_0^\infty e^{-R/(cD)} D(1+R)^3\,dR \le C_c D^4,$$

and the sum over u is bounded in the same way. The argument also works on small periodic tori. By the triangle inequality,

$$\sum_l e^{-\operatorname{dist}(i,l)/D - \operatorname{dist}(l,u)/D} \le C D^4 e^{-\operatorname{dist}(i,u)/(2D)}; \tag{13.28}$$

indeed, we extract the exponential on the right using half of the two distances and sum the remaining factor $e^{-\operatorname{dist}(i,l)/(2D)}$ by (13.27).

Since each coordinate and its mean have absolute value at most p, we have $|\xi_i| \le 2p$, where $\xi = w - \mathbb{E}w$. Moving between two points of the convex product along a segment and using the bound on the mixed derivatives, we find that the oscillation of $\partial_{\theta_u} V$ is at most $2pAD\sum_l e^{-\operatorname{dist}(l,u)/D}$. Subtracting the expectation does not increase this bound, and the centered potential derivative $Q_u = \partial_{\theta_u} V - \mathbb{E}\partial_{\theta_u} V$ satisfies

$$\|Q_u\|_\infty \le C p A D^5, \qquad |\partial_l Q_u| \le A D e^{-\operatorname{dist}(l,u)/D}. \tag{13.29}$$

By (13.20), $\partial_{\theta_u}\Sigma(i,j) = -\mathbb{E}\xi_i\xi_j Q_u$, and we bound this by each of the three covariances in (13.21). For the first, the gradient of $\xi_i\xi_j$ is $\partial_l(\xi_i\xi_j) = \delta_{li}\xi_j + \delta_{lj}\xi_i$. Using $\|\xi_i\|_2 \le 2p$, the amplitudes D and AD of the two kernels, and (13.28), we obtain

$$|\mathbb{E}\xi_i\xi_j Q_u| \le C p A D^6 \big\{ e^{-\operatorname{dist}(i,u)/(2D)} + e^{-\operatorname{dist}(j,u)/(2D)} \big\}.$$

For the second, the gradient of ξ_i is the coordinate vector at i, and $\partial_l(\xi_j Q_u) = \delta_{lj} Q_u + \xi_j \partial_l Q_u$. The first term costs $L_{ij}\|Q_u\|_2 \le CpAD^6 e^{-\operatorname{dist}(i,j)/D}$, and the second costs the convolution (13.28) times $2pAD^2$. We obtain

$$|\mathbb{E}\xi_i\xi_j Q_u| \le CpAD^6\big\{e^{-\operatorname{dist}(i,j)/(2D)} + e^{-\operatorname{dist}(i,u)/(2D)}\big\}.$$

For the third, the coordinate vector is at j, the gradient of the product is $\delta_{li} Q_u + \xi_i \partial_l Q_u$, and the two resulting terms are bounded by

$$CpAD^6\big\{e^{-\operatorname{dist}(i,j)/(2D)} + e^{-\operatorname{dist}(j,u)/(2D)}\big\}.$$

Using only the first of these three bounds would not control the separation of i from j.

We order the three distances as $x \le y \le z$. The smallest of the three braces is at most $e^{-y/(2D)} + e^{-z/(2D)} \le 2e^{-y/(2D)}$, and since $\tau_3 = x + y \le 2y$, this is at most $2e^{-\tau_3/(4D)}$. This proves the bound on $\partial_{\theta_u}\Sigma(i,j)$.

Since τ_3 is the smallest length of the three trees with two edges on the points i, j, u, the factor $e^{-\tau_3/(4D)}$ is at most the sum of the three corresponding products of exponentials. For fixed i, summing one such tree over (j,u) removes its two leaves successively, and (13.27) gives a factor at most CD^8. Hence

$$\sup_i \sum_{j,u} |\partial_{\theta_u}\Sigma(i,j)| \le CpAD^{14}.$$

Integrating along the segment $s\theta$, $0 \le s \le 1$, and using $|\theta_u| \le \|\theta\|_\infty$, we bound the row sums of $\Sigma_\theta - \Sigma_0$. By symmetry in i, j, the column sums have the same bound, and Lemma 13.6(3) implies the operator bound. □

In the following theorem the conditional law is the kernel $k(c, dw)$ of Theorem 13.8 on the product Ω_p, and the derivatives are taken with the couplings, and hence the radii of the balls, held fixed. We write $\mathbb{E}_\theta$, $\operatorname{Cov}_\theta$ for this kernel at $c = e^\theta$.

Theorem 13.10. *Use the conditional fluctuation kernel of Theorem 13.8 with $p = A_{\mathrm{w}} \log(1/t)$, and reduce the coupling threshold once so that tp^3 is small. Let $m_\theta = \mathbb{E}_\theta w$, $\xi = w - m_\theta$, $\Sigma_\theta = \mathbb{E}_\theta \xi\xi^{\mathsf{T}}$, and $\varphi_\theta(w) = \Phi_{d_0,J}(\theta, (g_i w_i)_i)$. There exist $C, b > 0$ such that the following statements hold uniformly for all $\|\theta\|_\infty < r \le \rho$ for which the support-inclusion hypothesis holds, all depths, and all sides.*

1. *The conditional means satisfy*

$$\|m_\theta\|_\infty \le Ct\|\theta\|_\infty, \qquad \sup_e |\mathbb{E}_\theta \varphi_{\theta,e}(w) - \varphi_{\theta,e}(0)| \le Ct^2\|\theta\|_\infty,$$

and both vanish at $\theta = 0$ by the global color symmetry.

2. *For $0 \le s \le 1$ let $\dot V_s = dV_{s\theta}/ds$ on the same product. Then, uniformly in s,*

$$\sup_l \|\partial_{w_l} \dot V_s\|_{L^2(k(e^{s\theta},\cdot))} \le Ct\|\theta\|_\infty.$$

This bound holds at each fixed index of w, with the exponentially summable profile of the joint coefficient bounds; it is not a bound on a norm of the extensive function $\dot V_s$. It includes the classical, Haar density, and determinant terms of the potential, and the terms from R.

3. *For every family F_θ of observables on this fixed product satisfying the differentiability conditions stated before Lemma 13.6 (continuity with continuous derivatives on a neighborhood of the product, or dominated difference quotients with integrable derivatives), and every coordinate θ_u, the identities* (13.19), (13.20), *and* (13.21) *hold; in particular*

$$\partial_u \mathbb{E}_\theta F_\theta = \mathbb{E}_\theta \partial_u F_\theta - \mathrm{Cov}_\theta(F_\theta, \partial_u V_\theta), \qquad \partial_u \log \int_{\Omega_p} e^{-V_\theta}\, dw = -\mathbb{E}_\theta \partial_u V_\theta,$$

and $\partial_u \Sigma_\theta(i,j) = -\mathbb{E}_\theta \xi_i \xi_j Q_u$ with $Q_u = \partial_u V_\theta - \mathbb{E}_\theta \partial_u V_\theta$. The domain does not move, so there is no boundary term.

4. *The hypotheses of Lemma 13.9 hold with a fixed D_0 and with $A_{\mathrm{sc}} = Ctp^2$; more precisely,*

$$\sup_{\Omega_p} |\partial_{w_i} \partial_{\theta_u} V_\theta| \le Ctp^2 e^{-b\,\mathrm{dist}(i,u)},$$
$$\|\Sigma_\theta - \Sigma_0\|_{b',\mathrm{row+col}} \le Ctp^3\|\theta\|_\infty, \qquad \|\Sigma_\theta\|_{\mathrm{op}} \le 2,$$

for a fixed $b' > 0$. Here $\Sigma_0 = \Sigma_{\mathrm{sp}} \otimes I_3$ is the covariance of the conditional fluctuation kernel at the identity coarse field; this kernel is interacting and truncated, and Σ_{sp} includes all its spatial covariances.

5. *Put $g = g_0$, $\mathsf{E}_\theta = g^{-1} D_w \varphi_\theta(m_\theta)$, and $\mathsf{B}_\theta = (2g^2)^{-1} D_w^2 \varphi_\theta(m_\theta)$. For every $w = m_\theta + \xi \in \Omega_p$,*

$$\varphi_\theta(m_\theta + \xi) = \varphi_\theta(m_\theta) + g\mathsf{E}_\theta \xi + g^2 \mathsf{B}_\theta(\xi,\xi) + \mathcal{R}_\theta(\xi), \qquad \|\mathcal{R}_\theta\|_\infty \le Cg^3 p^3.$$

Moreover $\|\mathsf{E}_\theta\|_{\mathrm{op}} \le C$, the scalar coefficients b_{eij} of B_θ satisfy

$$\sup_e \sum_{i,j} |b_{eij}| + \sup_i \sum_{e,j} |b_{eij}| \le C, \qquad \Big\| \sum_e a_e b_{e\cdot\cdot} \Big\|_{\mathrm{HS}} \le C\|a\|_2$$

for every array (a_e), and

$$\|\mathsf{E}_\theta - \mathsf{E}_0\|_{\mathrm{op}} + \|\mathsf{B}_\theta - \mathsf{B}_0\|_{\mathrm{abs,root}} \le C\|\theta\|_\infty,$$
$$\|\mathsf{E}_\theta \Sigma_\theta \mathsf{E}_\theta^{\mathsf{T}} - \mathsf{E}_0 \Sigma_0 \mathsf{E}_0^{\mathsf{T}}\|_{\mathrm{op}} \le C\|\theta\|_\infty (1 + tp^3), \qquad \sup_e |\mathbb{E}_\theta \mathsf{B}_{\theta,e}(\xi,\xi)| \le C\|\theta\|_\infty,$$

where $\|\cdot\|_{\mathrm{abs,root}}$ is the sum of absolute coefficients with one index fixed. At $\theta = 0$ the matrix E_0 is scalar in the color components, and the contraction of the color-equivariant quadratic tensor B_0 with Σ_0 vanishes.

6. *For the unnormalized integral of one step,*

$$\widetilde{F}(\theta) = A_{\mathrm{coord}} e^{-E_{d_0+J}(e^\theta)/g_J^2 - \mathsf{B}_{\mathrm{ref}}(\theta) - R_{\mathrm{ref}}(\theta)} \int_{\Omega_p} e^{-V_\theta(w)}\, dw,$$

we have

$$D \log \widetilde{F} = -D\big(E_{d_0+J}/g_J^2 + \mathsf{B}_{\mathrm{ref}} + R_{\mathrm{ref}}\big) - \mathbb{E}_\theta DV_\theta.$$

The derivatives of the terms evaluated at the zero-fluctuation reconstruction disappear only from normalized conditional expectations.

The constants depend only on M, J, ρ, a, E_*, A_{w}, the ratios of the couplings, and the fixed domains; they are independent of the side, L, γ, the depth, and the coarse field satisfying the hypotheses. Converting volume-normalized column bounds into bounds for operators in counting coordinates costs a fixed factor depending on J.

Proof. We use the coefficient bounds of Theorem 13.2 throughout; the conditional law is always the kernel on Ω_p of Theorem 13.8. We first prove (3) and (4), then the bounds on the means and on the derivative of the potential by Lemma 13.7, and finally the statements about the reconstruction.

Step 1: differentiation and the mixed derivatives. With the couplings, and hence the radii of the balls, fixed, the potential V_θ and its derivatives in θ are continuous on a neighborhood of the closed product, and Lemma 13.6 applies and proves (3).

We differentiate the series of (13.23) once in a coordinate θ_u of the coarse field and once in a fluctuation variable w_i. A derivative in θ on the larger product of coarse fields preserves the powers of the coupling and the coefficient bounds. A classical term of degree n leaves $n-1$ fluctuation factors after the derivative in w_i, so its sum is bounded by

$$Ctp^2 \sum_{n\geq 3} n(Ctp)^{n-3} \leq \frac{Ctp^2}{(1-Ctp)^2}.$$

The Haar density and determinant terms and the terms from R give at most $C(1+E_*)t/(1-Ctp)^2$, which is absorbed in the same bound since E_* is fixed and $p \geq 1$. Keeping both indices i and u in the network of each coefficient gives the factor $e^{-b\,\mathrm{dist}(i,u)}$. Reducing the coupling threshold so that Ctp is below a fixed margin, we obtain

$$\sup_{\Omega_p} |\partial_{w_i} \partial_{\theta_u} V_\theta| \leq Ctp^2 e^{-b\,\mathrm{dist}(i,u)}. \tag{13.30}$$

The Gaussian term contributes nothing to this derivative in θ, taken with all couplings fixed, since the normalization by the constrained Hessian made it equal to $|w|^2/2$ for every coarse field.

The density of the indices and the covariance bound of Theorem 13.8 satisfy the hypotheses of Lemma 13.9 with a fixed D_0 depending only on the fixed data, and by

(13.30) we may take $A_{\mathrm{sc}} = Ctp^2$. The proof of that lemma is linear in A_{sc}, and it yields the bound $Ctp^3 e^{-b_1\tau_3}$ for the derivative of Σ. We keep an exponential weight in the final sums. Since $\operatorname{dist}(i,j) \le \tau_3$ by the triangle inequality, we may choose $0 < b' < b_1/2$ and absorb $e^{b' \operatorname{dist}(i,j)}$ into half of the exponential of the tree. The remaining sums over two-edge trees converge by the fixed density. Integrating along the segment of coarse fields, we obtain

$$\|\Sigma_\theta - \Sigma_0\|_{b',\mathrm{row+col}} \le Ctp^3 \|\theta\|_\infty. \tag{13.31}$$

Applying the variance bound of Theorem 13.8 to $\sum_i v_i w_i$, we find $v^{\mathsf{T}}\Sigma_\theta v \le 2|v|^2$, hence $\|\Sigma_\theta\|_{\mathrm{op}} \le 2$. This proves (4), except for the structure of Σ_0, which is proved in Step 5.

Step 2: the conditional means. The concentration bound used in (13.24) implies, on Ω_p, that $\|w_i\|_{L^4} \le C(1 + m(s))$, where now $m(s) = \max_i |\mathbb{E}_{s\theta} w_i|$. We set $\dot V_s = \sum_u \theta_u \partial_{\theta_u} V_{s\theta}$ and take one derivative in w in its joint series. Every coarse field $s\theta$ lies in B_r, so the support-inclusion hypothesis holds along the whole segment. The larger product of coarse fields of Theorem 13.5 controls the derivative in θ, also when $\|\theta\|_\infty$ is close to r. The couplings, the radii of the balls, and the parameters internal to R are fixed while s varies. From a classical term of degree $n \ge 3$ we keep two of the remaining factors in L^4 and bound the other $n-3$ by p, which gives the coupling factor $t^{n-2}p^{n-3} = t(tp)^{n-3}$. The derivative in θ and its column sum give the factor $\|\theta\|_\infty$. Thus

$$\sup_j \|\partial_{w_j} \dot V_s\|_2 \le Ct\|\theta\|_\infty (1 + E_* + m(s)^2), \tag{13.32}$$

with all norms in $L^2(k(e^{s\theta}, \cdot))$. More precisely, we keep the index j of w and a scalar coarse-field index v in the network of each coefficient before contracting v with θ_v. The exponential weight then gives the factor $e^{b \operatorname{dist}(j,v)}$, while the two remaining fluctuation factors are estimated in L^4. The same summation shows that

$$\|\partial_{w_j} \dot V_s\|_{L^2(k(e^{s\theta},\cdot))} \le Ct(1 + E_* + m(s)^2) \sum_v e^{-b \operatorname{dist}(j,v)} |\theta_v|, \qquad \sup_j \sum_v e^{-b \operatorname{dist}(j,v)} \le C, \tag{13.33}$$

the last sum being over coarse-field indices of fixed density, bounded uniformly in the side by the count used in (13.27). The Haar density and determinant terms and the terms from R contribute $Ct(1 + E_*)\|\theta\|_\infty$, since one derivative in w of a term of degree $n \ge 1$ leaves $t^n p^{n-1} = t(tp)^{n-1}$. The margins in the coefficient bounds absorb all multiplicities of the derivatives. Summing the exponential covariance kernel against this profile costs only a constant depending on the density.

At the identity coarse field, a constant color conjugation rotates every three-component block of w and preserves the balls and the potential. A vector fixed by all such rotations vanishes, so $m(0) = 0$. We apply Lemma 13.7 to $V_s = V_{s\theta}$, with the nonnegative exponential kernel and the constant Λ_0 of the covariance bound of Theorem 13.8 and

with $\beta = Ct\|\theta\|_\infty(1+E_*)$, by (13.32) and $1+E_*+m^2 \le (1+E_*)(1+m^2)$. Since $\|\theta\|_\infty < \rho$, after one fixed reduction of the coupling threshold we have $2\Lambda_0\beta \le Ct\rho(E_*+2) < 1$, and the lemma implies that $m(s) < 1$ and $m(1) \le Ct\|\theta\|_\infty$. This proves the first bound in (1), for the interacting conditional means. Inserting $m(s) < 1$ in (13.32) and (13.33), and absorbing the factor E_*+2 into C, we obtain

$$\sup_j \|\partial_{w_j} \dot V_s\|_{L^2(k(e^{s\theta},\cdot))} \le Ct\|\theta\|_\infty \qquad (0 \le s \le 1),$$

which is (2). It uses the same coupling threshold as the bound on the means, and no norm of the extensive function $\dot V_s$.

Step 3: the mean of the reconstruction. Let $G_e(\theta, w) = \varphi_{\theta,e}(w) - \varphi_{\theta,e}(0)$. Its coefficients of degree n in w carry the factor t^n, and every term has positive degree in w. The same holds after a derivative in θ on the larger product. Its rows in the fluctuation variables are bounded by Ct on Ω_p. For $\dot G_e = dG_e(s\theta, w)/ds$, the expectation of the part of degree one is at most $Ct\|\theta\|_\infty m(s)$. For degrees at least two we keep two fluctuation factors in L^4 and bound the others by p. Summing the series with one index fixed, we obtain

$$|\mathbb{E}_{s\theta} \dot G_e| \le C\|\theta\|_\infty \big\{ tm(s) + t^2(1+m(s)^2) \big\}. \tag{13.34}$$

The covariance of G_e with $\dot V_s$ is at most $Ct^2\|\theta\|_\infty(1+E_*+m(s)^2)$, by the bound Ct on the rows of G_e, the profile (13.32), and the summable covariance kernel. By Step 2, $tm(s) \le Ct^2\|\theta\|_\infty$. Applying (13.19) to G_e, we find

$$\Big| \frac{d}{ds} \mathbb{E}_{s\theta} G_e(s\theta, w) \Big| \le Ct^2\|\theta\|_\infty.$$

At the identity coarse field $\Omega(0) = I$, and the reconstructed logarithm is color equivariant by Theorem 13.2(2). Its expectation is then a vector invariant under all rotations of the color components, which must vanish. Integrating from 0 to 1 proves the second bound in (1). The reference value $\varphi_\theta(0) = \delta\overline{A}_{d_0,J}(\theta)$ is the zero-fluctuation reconstruction.

Step 4: the expansion at the conditional mean. Since each block of the mean lies in its closed convex ball, the segment $m_\theta + v\xi$, $0 \le v \le 1$, lies in Ω_p whenever $m_\theta + \xi = w \in \Omega_p$. Three derivatives in w of the reconstruction have row sums at most Cg^3, since the ratios g_i/g are fixed. By Taylor's formula, we have

$$\mathcal{R}_\theta(\xi) = \frac{1}{2} \int_0^1 (1-v)^2 D_w^3 \varphi_\theta(m_\theta + v\xi)[\xi,\xi,\xi]\, dv,$$

and since $\|\xi\|_\infty \le 2p$, we obtain $\|\mathcal{R}_\theta\|_\infty \le Cg^3p^3$. The first two Taylor coefficients are exactly E_θ and B_θ, including the factor $1/2$ in the latter.

The row bounds and the volume-normalized column bounds of E_θ and B_θ follow from the absolute coefficient series of the reconstruction. Replacing the volume factors by

counting measures costs only a fixed factor depending on J. By Lemma 13.6(3), we have $\|\mathsf{E}_\theta\|_{\mathrm{op}} \le C$. The quadratic tensor satisfies $\sup_e \sum_{i,j} |b_{eij}| \le C$ and $\sup_i \sum_{e,j} |b_{eij}| \le C$; the second bound implies $\sup_{i,j} \sum_e |b_{eij}| \le C$, and Lemma 13.6(3) implies the Hilbert–Schmidt bound.

The normalized first and second derivatives of the reconstruction have bounded first derivatives, in their coefficient norms with one index fixed, on a still larger product. Comparing them at $(\theta, (g_i m_{\theta,i})_i)$ and at $(0,0)$ along the straight segment and integrating their derivatives, we obtain the bound

$$C\{\|\theta\|_\infty + g\|m_\theta\|_\infty\} \le C\|\theta\|_\infty.$$

The same bound holds for their rows and their columns, so the first derivative also satisfies the operator bound in (5). No derivative of the mean as a function of the coarse field is needed for this comparison.

Step 5: color structure and contractions. At the identity coarse field, the potential and the gauge-transformed reconstruction commute with every constant rotation of the color components, and $m_0 = 0$ by Step 2. Therefore each 3×3 block of Σ_0 and of E_0 commutes with every rotation. Such a matrix is a multiple of the identity: rotations by π about the coordinate axes force its off-diagonal entries to vanish, and rotations exchanging two axes equate its diagonal entries. This proves $\Sigma_0 = \Sigma_{\mathrm{sp}} \otimes I_3$ and that E_0 is scalar in the color components.

We expand

$$\mathsf{E}_\theta \Sigma_\theta \mathsf{E}_\theta^{\mathsf{T}} - \mathsf{E}_0 \Sigma_0 \mathsf{E}_0^{\mathsf{T}} = (\mathsf{E}_\theta - \mathsf{E}_0)\Sigma_\theta \mathsf{E}_\theta^{\mathsf{T}} + \mathsf{E}_0(\Sigma_\theta - \Sigma_0)\mathsf{E}_\theta^{\mathsf{T}} + \mathsf{E}_0 \Sigma_0 (\mathsf{E}_\theta - \mathsf{E}_0)^{\mathsf{T}}.$$

The bounds of Step 4, $\|\Sigma_\theta\|_{\mathrm{op}} \le 2$, and (13.31) give the bound $C\|\theta\|_\infty(1 + tp^3)$.

For one scalar output component e, let $B_{\theta,e}$ be the symmetric matrix of the quadratic form $\mathsf{B}_{\theta,e}$. Each scalar matrix unit has nuclear norm one, so the sum of the absolute coefficients bounds the nuclear norm, and

$$\|B_{\theta,e}\|_* \le C, \qquad \|B_{\theta,e} - B_{0,e}\|_* \le C\|\theta\|_\infty.$$

The contraction of the color-equivariant quadratic tensor at the identity coarse field with the color-scalar matrix Σ_0 is a vector invariant under all rotations of the color components, hence zero. This includes all spatial covariances of the kernel at the identity. Subtracting this zero contraction, we obtain

$$|\mathbb{E}_\theta \mathsf{B}_{\theta,e}(\xi,\xi)| \le \|B_{\theta,e} - B_{0,e}\|_* \|\Sigma_\theta\|_{\mathrm{op}} + \|B_{0,e}\|_* \|\Sigma_\theta - \Sigma_0\|_{\mathrm{op}} \le C\|\theta\|_\infty(1 + tp^3) \le C\|\theta\|_\infty,$$

where in the last inequality we used the reduced coupling threshold. This proves (5).

Step 6: the unnormalized integral. The constant A_{coord} does not depend on the coarse field. Differentiating $\log \widetilde{F}$ and using the formula for the derivative of the logarithm of the normalization in (3), we obtain (6). It keeps the derivatives of the classical, determinant, and Haar density terms and of R_{ref}, evaluated at the zero-fluctuation reconstruction, which cancel only in normalized conditional expectations. All estimates used sums with one index fixed, at a fixed density and fixed J. The constants therefore have the stated dependence and do not depend on the depth or the volume. □

SECTION 14

Small-field conditioning and partition-function bounds

This section connects the analytic recursion of Section 13 with the Wilson measure conditioned on the small-field event. We prove four results. First, consider one RG step and a fine configuration such that it and its coarse field both lie in the gauge-invariant small-field domain D_r. After a hierarchical tree gauge fixing, every such configuration has unique normalized fluctuation coordinates, whether or not it satisfies the fluctuation cutoff (Theorem 14.3). Second, with the parameters chosen in Definition 14.4, the recursion of Theorem 13.5, started at the Wilson action, produces effective interactions R_k whose densities are exactly those of the pushforwards of the Wilson measure restricted by the successive tests of the small-field event $S_{N,u,\gamma}$. Every normalization constant is accounted for (Theorem 14.6). Third, for coarse fields in D_r, if $d_t < 1$ and $\epsilon_t < 1$, then imposing the fluctuation cutoff changes the unnormalized density by a factor whose reciprocal lies between 1 and $(1-\epsilon_t)^{-1}$, with explicit errors d_t and ϵ_t (Theorem 14.7). Fourth, on the stopping lattice of side n, we bound the partition function of the stopped measure from below by a tree-gauge trial integral over the same domain D_r. We also bound exponential moments of the Wilson action under the stopped measure with a single boundary term $9n^2 \log(1/g)$ (Theorem 14.8). Finally, every flat configuration, including those whose holonomies form one of the eight central triples, belongs to the small-field event once the coarse side is large enough (Lemma 14.9).

Two points need care. First, the effective interactions are holomorphic on the ball B_ρ of configurations with link logarithms of norm less than ρ, while the small-field event uses a smaller radius $r < \rho/8$. On all of B_ρ, the recursion is defined by an auxiliary integral over the fluctuation cutoff domain. This integral is defined because the reconstruction maps the whole cutoff domain into $B_{\rho/2}$, where the incoming effective interaction is analytic. For coarse fields in B_r, the auxiliary integral coincides with the fiber integral of the restricted Wilson density. For coarse fields in $B_\rho \setminus B_r$, it is only an analytic continuation, with no probabilistic meaning. Second, the fiber of the incoming restricted measure over a coarse field need not be convex. However, it is contained in a product domain $\mathcal{K}_t$, independent of the coarse field, on which the conditional fluctuation potential is uniformly convex. Concentration for the normalized measure on $\mathcal{K}_t$ then passes to the fiber by conditioning, since the two densities have the same prefactor, which depends on

the coarse field but not on the fluctuation variables.

In the partition-function bounds, the denominator is bounded below on the same domain D_r as the stopped measure. Only the numerator is enlarged, to an integral over an open cube. After tree gauge fixing, the periodic lattice has $2n^3 + 1$ independent link variables and the open cube has $2n^3 - 3n^2 + 1$. Since each variable contributes three powers of g, the comparison leaves exactly the factor g^{-9n^2}.

We use the following inputs. Sections 5 to 7 supply the coefficient calculus, tree gauges, the Haar disintegration over the block averaging constraint, the partition-function bound on an open box, and the local inverse branch of the block averaging map. Sections 10 and 11 supply the classical background fields, the nested minimization identity for the effective classical action, its comparison with the Wilson action, and its gauge invariance on chart overlaps. Section 12 supplies the joint coordinate calculus and the sequential density formula. Section 13 supplies the reconstruction gauge and its coefficient majorant, the invariant analytic ball of the recursion, the cutoff identity for the restricted density, and the convexity of the conditional fluctuation potential. In turn, Section 15 uses the exact recursion and the conditional fluctuation kernels; Sections 18 and 21 to 23 use the fiber coordinates, the classical lower bound, the normalization, and the cutoff comparison; and Sections 33 to 36 use the estimates on the stopping lattice and the flat configurations. This section does not show that the small-field event has probability close to one; that is done in Section 23. In particular, we do not estimate here the ratio of auxiliary integrals that bounds the exit probability of the coarse field in Theorem 14.7.

Separating the field into regular gauge-field coordinates and then performing successive convergent integrations is the constructive lattice gauge program of Bałaban [14, 18]. Within this framework, we prove the coordinates for every point of the small-field fiber and the normalization identities below for the specific recursion and event used in this paper.

Section 14.1 fixes notation. Section 14.2 collects the classical estimates on a common domain and derives the exact density of one RG step in fluctuation coordinates. Section 14.3 proves the coordinate theorem and states the choice of parameters and the small-field event. Section 14.4 identifies the recursion with the restricted Wilson measure, and Section 14.5 proves the cutoff comparisons. Section 14.6 contains the partition-function bounds, and Section 14.7 treats flat configurations.

14.1 Conventions

One RG step. Fix an odd integer $M \geq 3$ and an integer $J \geq 1$, and set $B = M^J$. One RG step maps a configuration on the lattice of side $Bm = M^J m$ to a configuration on the lattice of side $m \geq 4$ by T_M^J. Its levels are indexed by $i = 0, \dots, J$; the integrated intermediate scales have $i < J$. The lattice at level i, which we also call a scale, has side

$M^{J-i}m$. We write c_i for the configuration at level i, so that c_0 is the fine configuration and $c_J = c$ is the coarse one, and we write $c = e^{\theta}$ when c lies in a chart of the identity. If the fine lattice is at classical depth d_0, the averaging step from scale i to scale $i+1$ is performed at depth $d_0 + i$. The couplings satisfy $g_{i+1}^2 = Mg_i^2$. The integrated couplings are $g_0, \dots, g_{J-1}$, and we write

$$t = \max_{0 \le i < J} g_i = g_{J-1}, \qquad t^2 = \frac{\gamma}{Mm}, \qquad \lambda_* = M^{-(J-1)/2} \le \frac{g_i}{t} \le 1, \qquad g_J^2 = Mt^2 = \frac{\gamma}{m}.$$

The normalized fluctuation variables w_i of the step from scale i to scale $i+1$ are defined by

$$z_i = z_i^*(c_{i+1}) + g_i K_i(c_{i+1})^{-1/2} w_i,$$

where z_i are the free logarithmic coordinates, z_i^* is the conditional constrained minimizer, and K_i is the constrained Hessian (Section 14.2). A block index (i, e) labels one vector $w_{i,e} \in \mathbb{R}^3$; a scalar index also specifies its color component. Distances are measured in units of the coarse lattice of side m. For fixed M and J, the number of coordinate labels in a ball of radius R is at most $C_{M,J}(1+R)^3$, uniformly on every periodic lattice, since the smallest label spacing is M^{-J} and there are finitely many scale and orientation types. This bound controls all sums of exponential kernels below.

Norms. For a matrix A indexed by labels and a rate $b > 0$, the weighted row-and-column norm is

$$\|A\|_{b,\mathrm{row+col}} = \max\Big\{ \sup_x \sum_y e^{b\,\mathrm{dist}(x,y)} |A_{xy}|,\ \sup_y \sum_x e^{b\,\mathrm{dist}(x,y)} |A_{xy}| \Big\}.$$

By Schur's test, it bounds the operator norm of A on ℓ^2. This is the maximum of the row bound and the counting column bound. In Section 10, the same two bounds are added instead. That sum lies between this norm and twice it, so the bounds imported from there hold for this norm with the same constants. No column-volume factor enters this comparison, since both conventions use counting columns. For a tensor T, $\|T\|_{b,\mathrm{root}}$ denotes the weighted absolute coefficient sum with one index fixed, maximized over the choice and position of the fixed index, with spatial weight $e^{b\mathsf{t}}$, where t is the length of a shortest connecting network of the coefficient locations (Definition 4.6). Input-fixed sums are volume-normalized unless we say that they are counting sums. For a function R of the link logarithms with $DR(I) = 0$, the weighted analytic coefficient norm is

$$\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R) = \sum_{k \ge 2} \frac{\rho^{k-2}}{k!} \|D^k R(I)\|_{a_{\mathrm{sp}},\mathrm{root}},$$

as in Definition 4.6; it does not control the constant $R(I)$.

Gauge-invariant extensions. Let $B_\rho = \{\exp A : \max_e |A_e| < \rho\}$ and $D_\rho = \mathcal{G}B_\rho$, the set of configurations gauge equivalent to a configuration in B_ρ. A real analytic function R on B_ρ is *gauge invariant on overlaps* if $R(U^k) = R(U)$ whenever U and U^k lie in B_ρ for a periodic lattice gauge transformation k (Definition 13.3). Then $R_{\mathrm{sat}}(U) = R(U^k)$, for any k with $U^k \in B_\rho$, is a well-defined function on D_ρ, which is gauge invariant and real analytic. The same subscript denotes the gauge-invariant extension $E_{d,\mathrm{sat}}$ of the effective classical action from its chart (Theorem 11.6). Global color rotations act by $U_e \mapsto uU_eu^{-1}$ with constant $u \in \mathrm{SU}(2)$, and spatial inversion is $x \mapsto -x$ with the induced action on oriented links.

Constants. Unless a parameter is displayed separately, the constants $C, c, b, \dots$ of this section depend only on M, the fixed J, the larger classical and analytic domains fixed below and the positive distances between them, the positive spatial rates, and the fixed bounds on coefficients and effective interactions. They do not depend on the lattice side, on L or γ, on the depth, or on the number of RG steps. All estimates concern the whole torus; we make no statement about block regions. The value $R(I)$ of an effective interaction at the identity is always kept separately. Only constants explicitly identified as uniform before the choice of J are used to choose J.

Radii. Several radii occur. The following table lists them, and Definition 14.4 fixes the inequalities between them.

Radius	Role
r_{C}	larger domain of the classical estimates (Section 14.2)
ρ	effective interactions are holomorphic on B_ρ
$r < \rho/8$	radius of the small-field domain D_r
$R_{\mathrm{buf}} = (10M)^J r$	$T^J_M(D_r) \subset D_{R_{\mathrm{buf}}}$
$P_{\mathrm{phys}} < Q_{\mathrm{phys}}$	physical radii of products of fluctuations contained in every fiber
$R_{\mathrm{en}} = \mathscr{L}_{\mathrm{en}} r$, $\mathscr{L}'_{\mathrm{en}} r$	physical radii of the enclosing products
$p_{\mathrm{w}}(t) = A_{\mathrm{w}} \log(1/t)$	radius of the fluctuation cutoff in the variables w

A product of fluctuation balls of radius a/t in the variables w is said to have physical radius a; on it $|g_i w_{i,e}| \le a$ for all i, e, since $g_i \le t$.

14.2 Classical coordinates and the conditional density

This subsection puts the classical estimates of Sections 10 to 12 on one common domain, proves the coordinate calculus needed below, and derives the density of one RG step in

the normalized fluctuation variables. We prove the density formula on the whole branch of the local constraint coordinates, before imposing any fluctuation cutoff.

Classical estimates on a larger domain

For an averaging step at depth d, with coarse field c and free logarithmic coordinates z, we write

$$b(c,z) = e^{\Gamma_c(z)} U_0(c), \qquad B(c,z) = \operatorname{Log} b(c,z), \qquad F_d(c,z) = E_d(b(c,z)).$$

Here $U_0(c)$ is the coarse-field lift, which is the identity on block interiors and has the prescribed coarse links on the interface links, and Γ_c are the local constraint coordinates solving the block averaging constraint for the eliminated edges (Lemma 6.3). We always write the lift with its argument, to distinguish it from a fine configuration U_0.

Fix a larger classical ball of radius r_{C} strictly inside the radii of Theorems 10.10, 10.11, 11.2, and 11.6; in particular $r_{\mathrm{C}} < \min(r_{\mathrm{CK}}, \rho_{\mathrm{ov}}, r_*)$, where r_{CK}, ρ_{ov}, and r_* are the radii of Theorem 11.2, Theorem 11.6, and Theorem 10.11. We take the products of coarse fields and free coordinates of one averaging step strictly inside the joint products of Lemma 12.3, and small enough that $B(c,z)$ and every representative related to it by a gauge transformation used below stay in $B_{r_{\mathrm{C}}}$. These reductions depend only on the fixed construction domains, not on the side or the depth. On these products, we use the following data:

$$m_0 I \le K_d^0 \le C_0 I, \qquad \|K_d^0\|_{a_0,\mathrm{row+col}} + \|(K_d^0)^{-1}\|_{a_0,\mathrm{row+col}} \le C_0, \tag{14.1}$$

$$\|D^s E_d\|_{a_0,\mathrm{root}} \le C_0^{s+1} s! \quad (s \ge 2), \qquad E_d(I) = DE_d(I) = 0, \tag{14.2}$$

$$E_{d+1}(c) = MF_d(c, z_d^*(c)), \qquad E_d(b^k) = E_d(b), \tag{14.3}$$

the last identity on the larger overlaps, for periodic gauge transformations k with $b, b^k \in B_{r_{\mathrm{C}}}$. Here

$$K_d^0 = (D_z B(I,0))^{\mathsf{T}} D^2 E_d(I)\, D_z B(I,0),$$

and $z_d^*(c)$ is the conditional constrained minimizer, an interior stationary point. The constants m_0, C_0 and the rate $a_0 > 0$ are independent of d and the side. This spatial rate a_0 is local to the present subsection and unrelated to the trial amplitude a_0 of Theorem 14.8. The lower bound in (14.1) bounds the Hessian in the free coordinates z of the constraint; we assert no lower bound for the quadratic form in the coarse variables.

These data come from the cited results as follows. Theorem 10.10 gives (14.1), the conditional constrained minimizer, and the first identity in (14.3), including the factor M, on the whole real product of free coordinates of that theorem. The minimizing property and the positivity of Hessians are used only for real coarse fields and free coordinates. The stationary equation and the identity for the stationary value then extend holomorphically to smaller complex products, where no minimum is asserted. The sides

in that theorem are Mm and m with $m \geq 4$, and we infer nothing from it about iterated steps. Theorem 10.11 gives the tensors in (14.2) at one rate, and its bound on the first derivative gives $DE_d(I) = 0$. We take only the derivatives of the scalar E_d from that theorem, not its counting input columns for the coordinate maps. The upper bound of Theorem 11.2 at the identity gives $E_d(I) = 0$. We take one common smaller rate a_0 and enlarge C_0 to cover both results. Since the two representatives of each classical overlap lie in $B_{r_C} \subset B_{\rho_{ov}}$, Theorem 11.6 implies the second identity in (14.3) for every periodic gauge transformation, without a global logarithm of the gauge transformation.

Finally, Lemma 12.3 supplies joint tensor bounds for B, F_d, the negative logarithmic Haar density $\mathcal{L}$ defined below, z_d^*, K_d, and $K_d^{\pm 1/2}$ on the chosen products. For a matrix-valued derivative with a fixed coarse-field index, it sums both matrix indices, and its input-fixed column sums are volume-normalized. Since the volume ratios for one averaging step, or for the J steps of one RG step, are fixed powers of M, passing to counting column sums costs only a constant depending on M and J. These bounds control no field-independent value. The exact determinant and the fluctuation interaction $H_{d_0,J}$ on cutoff products are given by Theorem 12.13; below we also derive the underlying pointwise identities on the larger coordinate domain just fixed.

Lemma 14.1. *On the larger domains just fixed, there are smaller radii $r_c, r_z > 0$ with the following properties, for every depth $d \geq 0$ and every averaging step from side Mm to side $m \geq 4$. The conditional constrained minimizer $z_d^*(c)$ is unique, $\|z_d^*(e^\theta)\|_\infty \leq C\|\theta\|_\infty$, and throughout the real product $\|\theta\|_\infty < r_c$, $\|z\|_\infty \leq r_z$ we have*

$$D_z^2 F_d \geq m_0 I/2, \qquad \|D_z^2 F_d\|_{b,\mathrm{row+col}} \leq C,$$
$$\|K_d^{1/2}\|_{b,\mathrm{row+col}} + \|K_d^{-1/2}\|_{b,\mathrm{row+col}} \leq C, \qquad K_d = D_z^2 F_d(c, z_d^*(c)).$$

The minimizer z_d^* and the two square roots extend holomorphically to a common smaller complex product, and their weighted absolute Taylor coefficients of degree s, for output rows and for volume-normalized input columns, are bounded by $C^{s+1}s!$. Compositions of these maps over the J averaging steps of one RG step have the same property, with constants depending on J.

Proof. For every $d \geq 0$ and every averaging step $Mm \to m$ with $m \geq 4$, we apply Theorem 10.10 on the intersection of its product with the larger products fixed above. This gives the unique real interior minimizer, its linear bound in the coarse field, and the Hessian estimate on the whole real product. Keeping the local labels, we have

$$D_z^2 F_d = (D_z B)^{\mathsf{T}} D^2 E_d(B)\, D_z B + DE_d(B)\, D_z^2 B, \tag{14.4}$$

and

$$\|D_z^2 F_d - K_d^0\|_{b,\mathrm{row+col}} \leq C(\|\theta\|_\infty + \|z\|_\infty), \tag{14.5}$$

with $D_z^2 F_d \geq m_0 I/2$ for real arguments. The second term in (14.4), which contains the first derivative of E_d, is kept. Here b is a positive rate smaller than the rates of Theorem 10.10

and of the joint calculus. Combining the upper bound in (14.1) with (14.5), we obtain the upper bound for the Hessian.

Next, we use the clause of Lemma 12.3 for coordinates of fixed physical radius, which does not involve the coupling. It supplies the holomorphic minimizer and the matrices $K_d^{1/2}$ and $K_d^{-1/2}$, with factorial bounds on their weighted absolute coefficients for rows, columns, and coarse-field indices, summing both matrix indices. Its radii and constants are chosen before the number J of averaging steps in an RG step, and they are uniform in d and m. We choose r_z inside those products and then reduce r_c so that $Cr_c < r_z/8$, keeping all earlier strict inclusions. For one averaging step, passing from volume-normalized to counting columns costs the factor M^3, which is included in C. The two square roots are the positive square roots for real coarse fields and their holomorphic continuations; no positivity is asserted for complex coarse fields.

For fixed J, we compose these tensors using Lemma 5.3, with a volume-normalized input column along the branch that contains the fixed input index and output rows elsewhere. Since each contraction attaches an output to an input, the coefficient networks remain connected. We pass to trees on the external indices only at the end. The finite list of meshes in one RG step has label density bounded in terms of M and J, and the volume ratios cancel at contracted indices. A fixed loss in the spatial rate and one fixed smaller radius, both depending on J, then give the factorial bounds for all the compositions. The resulting constant C_J is independent of the side, the depth, L, and γ. □

Haar disintegration and the fluctuation potential

Fix a coarse field c and the block forests rooted at its coarse vertices. By the block version of Lemma 5.1, the passage to forest-fixed coordinates is a unique based change of Haar variables; the tree variables have total mass one, and there is no variable at a coarse vertex. On the branch of the local constraint coordinates, Lemma 6.3, or equivalently the coarea clause of Lemma 12.3, gives the Haar disintegration density

$$\mathcal{J}_c(z) = c_{\mathrm{Haar}}^{f} \frac{\prod_{e \text{ not in the forest}} j_H(\Gamma_{c,e}(z))}{\prod_a \det D_{X_{e_a^*}} \mathsf{C}_{c,a}(\Gamma_c(z))}, \qquad j_H(X) = \operatorname{sinc}^2(|X|/2). \tag{14.6}$$

Here $f = 2(M^3-1)m^3$ is the number of free group variables, $c_{\mathrm{Haar}} = 1/(16\pi^2)$, a runs over the coarse links, e_a^* is the eliminated edge of the constraint $\mathsf{C}_{c,a} = 0$ at a, and $X_{e_a^*}$ is its logarithmic coordinate. The density is taken relative to the product Haar measure on coarse configurations and includes the Haar factor of every eliminated edge. It holds for nonnegative Borel integrands on every measurable subset of this branch, with all indicators of the branch conditions kept. It requires neither smallness of the interaction nor nonvanishing of any partition function.

For the sequential change of variables, we set $S_i = K_i^{-1/2}$ and order the variables from scale $J-1$ down to scale 0. Since c_{i+1} depends only on the fluctuation variables of the

coarser scales $i+1,\dots,J-1$, the Jacobian matrix is block triangular and

$$\det D_w z = \prod_{i=0}^{J-1} g_i^{3f_i} \det S_i(c_{i+1}). \tag{14.7}$$

Here f_i is the number of free group variables at scale i; the off-diagonal derivatives of S_i and z_i^* do not change the triangular determinant. We define

$$\begin{aligned}
\mathcal{L}_i(c,z) &= -\log[\mathcal{J}_i(c,z)/\mathcal{J}_i(I,0)],\\
\mathsf{B}_i(c) &= \mathcal{L}_i(c,z_i^*(c)) + \tfrac12 \log\det K_i(c),\\
\widehat{c}_J &= c, \qquad \widehat{c}_i = b_i(\widehat{c}_{i+1}, z_i^*(\widehat{c}_{i+1})), \qquad \mathsf{B}_{\mathrm{ref}}(c) = \sum_i \mathsf{B}_i(\widehat{c}_{i+1}),\\
U_i^{\mathrm{cl}} &= g_i^{-2}[F_i(c_{i+1},z_i) - F_i(c_{i+1},z_i^*(c_{i+1}))] - \tfrac12 |w_i|^2,\\
H_{d_0,J} &= \sum_i \big[U_i^{\mathrm{cl}} + \mathcal{L}_i(c_{i+1},z_i) - \mathcal{L}_i(c_{i+1},z_i^*(c_{i+1})) + \mathsf{B}_i(c_{i+1}) - \mathsf{B}_i(\widehat{c}_{i+1})\big].
\end{aligned}$$

The fields $\widehat{c}_i$ form the zero-fluctuation reconstruction of c. The determinant term B_i of a finer scale is evaluated at the coarse field c_{i+1} obtained from the given fluctuation variables of the coarser scales. Only its value along the zero-fluctuation reconstruction is subtracted. The nested minimization identity (14.3) and $g_{i+1}^2 = M g_i^2$ give the telescoping identity

$$\frac{E_{d_0}(c_0)}{g_0^2} = \frac{E_{d_0+J}(c_J)}{g_J^2} + \tfrac12 |w|^2 + \sum_i U_i^{\mathrm{cl}}. \tag{14.8}$$

Indeed $F_i(c_{i+1},z_i) = E_{d_0+i}(c_i)$ and $F_i(c_{i+1},z_i^*(c_{i+1})) = E_{d_0+i+1}(c_{i+1})/M$, so the ith term of the sum equals $E_{d_0+i}(c_i)/g_i^2 - E_{d_0+i+1}(c_{i+1})/g_{i+1}^2 - |w_i|^2/2$.

Let $\Phi(\theta,q) = \Phi_{d_0,J}(\theta,q)$ be the logarithm of the fine configuration reconstructed from $c = e^\theta$ and the variables $q_i = g_i w_i$, in the gauge given by the gauge transformation of Theorem 13.2. This gauge transformation depends only on c and is the identity at the coarse vertices, so $T_M^J e^{\Phi(\theta,q)} = e^\theta$. We write gw for $(g_i w_i)_i$ and $R_{\mathrm{ref}}(c) = R(e^{\Phi(\theta,0)})$ for an incoming effective interaction R. Multiplying (14.6) over the scales and by (14.7), and then inserting (14.8), we find the following. On every measurable set of fluctuation variables, the density of the measure $e^{-E_{d_0}/g_0^2 - R}\, dH$ in the coordinates (c,w), relative to $dH(c)\, dw$, has a common prefactor, independent of the fluctuation variables and of the integration subset, namely

$$\prod_i \mathcal{J}_i(I,0) g_i^{3f_i} \exp[-E_{d_0+J}(c)/g_J^2 - \mathsf{B}_{\mathrm{ref}}(c) - R_{\mathrm{ref}}(c)], \tag{14.9}$$

multiplied by $e^{-V_c(w)}$, where $V_c(w) = |w|^2/2 + H_{d_0,J}(\theta,w) + R(e^{\Phi(\theta,gw)}) - R_{\mathrm{ref}}(c)$. To check this, we write $\mathcal{J}_i(c_{i+1},z_i) = \mathcal{J}_i(I,0) e^{-\mathcal{L}_i(c_{i+1},z_i)}$ and $\det S_i = e^{-(\log\det K_i)/2}$, and regroup $\sum_i [\mathcal{L}_i(c_{i+1},z_i) + (\log\det K_i(c_{i+1}))/2]$ as $H_{d_0,J} - \sum_i U_i^{\mathrm{cl}} + \mathsf{B}_{\mathrm{ref}}$. The term of the

effective interaction remaining in the integrand is $R(e^{\Phi(\theta,gw)}) - R_{\mathrm{ref}}(c)$. By gauge invariance on overlaps, at a point of the fiber $R(e^{\Phi(\theta,gw)})$ is the value of the gauge-invariant extension R_{sat} at the fine configuration. Theorem 13.4 states exactly this formula on the cutoff product whenever its hypothesis on the image of the coarse fields in B_r holds, and there the identities agree term by term with Theorem 12.13. The derivation above uses only the branch of the local constraint coordinates. It does not extend the small-interaction or nonvanishing conclusions of Theorem 12.13 to a product of fixed physical radius.

The next lemma counts powers of the coupling in the Taylor coefficients of the potential. We use it for the convexity of the potential on the enclosing product and for the mean bound in Theorem 14.7, where one derivative in the coarse field is needed.

Lemma 14.2. *Fix the ball B_ρ and a function R holomorphic there, with $DR(I) = 0$ and $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R) \le E_*$, gauge invariant on overlaps, and invariant under global color rotations, lattice translations, and spatial inversion. Use fixed smaller products of coarse fields and of free coordinates of fixed physical radius on which the coefficient majorant of Theorem 13.2 holds with image in $B_{\rho/2}$, and on which the classical and coarea conditions hold with strict inequality. Define*

$$V_\theta(w) = \tfrac{1}{2}|w|^2 + H_{d_0,J}(\theta, w) + R(e^{\Phi(\theta,(g_i w_i)_i)}) - R(e^{\Phi(\theta,0)}), \qquad W_\theta = V_\theta - \tfrac{1}{2}|w|^2.$$

After the Taylor series in the coarse field has been summed on a strictly smaller radius, the following holds on these domains. The classical terms of W_θ of total degree k in w vanish for $k \le 2$, and for $k \ge 3$ they have the form t^{k-2} times coefficients whose weighted absolute sums, with any free or coarse-field index fixed and with a fixed positive rate, are at most C_J^{k+1}. The coarea, determinant, and effective-interaction terms of total degree $k \ge 1$ have the form t^k times coefficients with the corresponding bound $C_J^{k+1}(1 + E_*)$. The same statements hold for one derivative in the coarse field, with a further fixed constant. Consequently, on the product $\{|w_{i,e}| \le p\}$ with $tp \le q$, where q is at most the fixed physical radius of these domains and $Cq < 1$,

$$\|D_w^2 W_\theta\|_{b,\mathrm{row+col}} \le \frac{C[q + t^2(1 + E_*)]}{(1 - Cq)^3}. \tag{14.10}$$

Proof. For real coarse fields, the Taylor expansion of $F_i - F_i(z_i^*)$ at the conditional constrained minimizer has no zeroth or first order term, and normalization by the positive square root of K_i makes its second order term exactly $g_i^2|w_i|^2/2$. By the stationary equation and the square-root identity of Lemma 14.1, these coefficient identities extend holomorphically to the smaller complex products. After division by g_i^2, a term of order k in w_i therefore has $k \ge 3$ and the factor g_i^{k-2}. Each dependence on the fluctuation variables of a coarser scale j through the field c_{i+1} carries an additional factor $g_j w_j$. Since $\lambda_* \le g_i/t \le 1$, dividing by two such couplings changes constants by at most the fixed factor λ_*^{-2}. Every classical monomial of total degree k thus carries t^{k-2}. Each difference

of $\mathcal{L}_i$ or of B_i has positive degree in w and no inverse power of the coupling, so it carries t^k.

We control these compositions by the weighted coefficient bounds of Lemma 14.1: we fix the external index, sum the indices of the innermost differentiated map, and proceed outward, using the volume-normalized column at an input index. By the triangle inequality, the union of the intermediate connecting networks bounds the external network length. A fixed loss in the spatial rate absorbs the bounded label density of each of the J kinds of labels. For $\log\det K$, we write, on a smaller domain,

$$\log\det K = \log\det K^0 + \sum_{h\geq 1} \frac{(-1)^{h+1}}{h} \operatorname{tr}\big[((K^0)^{-1}(K-K^0))^h\big].$$

Here the perturbation $(K^0)^{-1}(K-K^0)$ has weighted norm below $1/2$. A derivative of positive order fixes one factor of this cycle, and its two matrix indices can then be summed by the weighted bounds. The constant trace belongs to $\mathsf{B}_{\mathrm{ref}}$ and is not bounded by this calculation. For the effective interaction, since the image of the coefficient majorant lies in $B_{\rho/2}$, the joint pullback bound of Theorem 13.5 applies. Its constant term is subtracted as R_{ref}, and each free input supplies its own factor g_i. The same weighted contractions give the factor t^k.

We divide the factorial Taylor bounds by the Taylor factorial and sum the series in the coarse field on a fixed, strictly smaller radius. This leaves geometric majorants C_J^{k+1}, and one derivative in the coarse field is controlled on the same smaller radius. Two derivatives in w cost at most $k(k-1)$. For the classical part we sum $C^k t^{k-2} p^{k-2}$ over $k \geq 3$, and for the other part we sum $C^k t^k p^{k-2}$ over $k \geq 2$. The identity $\sum_{h\geq 0}(h+1)(h+2)x^h = 2/(1-x)^3$, obtained by differentiating the geometric series twice, then gives (14.10). This is a convergent Taylor calculation at the small physical radius q; it does not assert a cluster expansion on a fluctuation product of radius q/t. □

14.3 Coordinates for the small-field fiber and the choice of parameters

We now show that the normalized fluctuation variables describe every point of the fiber of one RG step whose fine and coarse fields lie in D_u, and not only the points near the conditional constrained minimizers or inside the fluctuation cutoff domain. We then fix the parameters of the construction in a definite order and define the small-field event.

Theorem 14.3. *Fix an odd integer $M \geq 3$, an integer $J \geq 1$, and the larger classical domains and charts of local constraint coordinates of Section 14.2. By the* common branch *we mean the intersection of the branch of the local constraint coordinates (Lemma 7.2) with these classical domains. There exist $r_{\mathrm{geom}}, C_{\mathrm{TG}} > 0$, and a positive distance of all coordinates below from the boundary of the common branch, independent of the depth $d_0 \geq 0$, the coarse side $m \geq 4$, L, γ, and*

the couplings, such that the following holds for every $0 < u < r_{\mathrm{geom}}$. Let U_0 be a configuration on the lattice of side $M^J m$, let $U_i = T_M^i U_0$, a configuration on the lattice of side $M^{J-i} m$, and suppose that $U_0 \in D_u$ and $U_J \in D_u$. Let $c \in B_u$ be any configuration gauge equivalent to U_J.

1. *There is a periodic gauge transformation of the fine lattice, equal to the identity at every coarse vertex when $U_J = c$, after which the intermediate configurations have link logarithms of norm at most $C_{M,J} u$ and every averaging step lies in the common branch. One may take $10M$ as the growth factor of link logarithms in one averaging step, and $C_{M,J} = 2(10M)^J + 1$ before the constants of the forest coordinates are included.*
2. *After the unique hierarchical fixing of the block forests rooted at the coarse vertices, the free logarithmic coordinates and the normalized fluctuation variables*

$$z_i = z_i(U_0), \qquad w_i = g_i^{-1} K_i(c_{i+1})^{1/2} (z_i - z_i^*(c_{i+1})), \qquad g_i \|w_i\|_\infty \le C_{\mathrm{TG}} u,$$

   reconstruct every such fiber point, including points outside the fluctuation cutoff domain. They use one based Haar disintegration and the triangular determinant of Theorem 12.13; no sum over choices of the auxiliary gauge transformation and no multiplicity factor occurs.
3. *For any two configurations $c, c' \in B_u$ gauge equivalent to U_J, the transition between the two coordinate systems is triangular, its diagonal blocks are orthogonal on each three-dimensional color block, and it preserves every $|w_{i,e}|$.*
4. *If $K_i \le C_K I$ and $D_z^2 F_i \ge m_0 I/2$ are the fixed classical bounds on the chart, then*

$$\frac{E_{d_0,\mathrm{sat}}(U_0)}{g_0^2} - \frac{E_{d_0+J,\mathrm{sat}}(c)}{g_J^2} \ge \frac{m_0}{4 C_K} \sum_i \|w_i\|_2^2.$$

   These classical values are evaluated on the larger classical chart, irrespective of the radius ρ of the effective interactions.
5. *Let R be gauge invariant on overlaps, with $DR(I) = 0$ and $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R) \le E_*$. For $0 < \eta < 1$ and $\|\xi\|_\infty \le (1-\eta)\rho$,*

$$\|DR(e^\xi)\|_{a_{\mathrm{sp}},\mathrm{root}} \le C E_* \rho \eta^{-1}, \qquad \|D^2 R(e^\xi)\|_{a_{\mathrm{sp}},\mathrm{root}} \le C E_* \eta^{-2}.$$

   Suppose that U_0 is as above and also lies in $D_{(1-\eta)\rho}$, fix one gauge transformation taking it into $B_{(1-\eta)\rho}$, and hold this gauge transformation fixed while differentiating. Let $U_0(w)$ be the fine configuration reconstructed from c and w. Then, for one fixed smaller rate $b > 0$,

$$\|D_w^2 [R_{\mathrm{sat}}(U_0(w))]\|_{b,\mathrm{row+col}} \le C_J E_* t^2 (\eta^{-2} + \rho \eta^{-1}), \qquad t = \max_i g_i.$$

   For the domain D_r one may take $\eta = 1 - r/\rho$.

The bounds in (5) hold at each point. They do not assert that the fiber is convex, and they do not place the whole fiber in one chart of the effective interaction in the gauge of Theorem 13.2.

The point of (2) is that the coordinates cover the whole fiber over c of the measure restricted to D_u, so that the density formula of Section 14.2 applies at every point of this fiber. Part (4) is a quadratic lower bound for the excess classical action in terms of the normalized fluctuation variables.

Proof. Steps 1 and 2 construct the gauge transformation in (1), using only the local inverse-branch estimate of Lemma 7.2 and the nesting of centered blocks; no classical estimate is used there. Steps 3 to 6 fix the forests, bound the fluctuation variables, and prove (2) and (3). Steps 7 and 8 prove (4) and (5).

Step 1: a small representative and its averages. Let $L_M = 10M$, and fix a periodic gauge transformation k_0 such that $V_0 = U_0^{k_0} \in B_u$. The fine side is $M^J m$ with $m \geq 4$, and scale s has side $M^{J-s}m$. Each of the J averaging steps therefore has an integer coarse side at least $m \geq 4$, as required by the clause of Lemma 7.2 on iterated steps. We choose the threshold r_{geom} so that $(10M)^J u \leq u_M$, where u_M is the radius of that lemma, and so that the finitely many conditions on logarithms of based loop holonomies hold. Then, by that lemma, we have

$$V_s = T_M^s V_0, \qquad \max_e \rho_G((V_s)_e) \leq L_M^s u \qquad (0 \leq s \leq J).$$

Gauge covariance can also be read off from (4.3): every based loop holonomy is conjugated at its basepoint, the starting coarse vertex, and so is its logarithm, while the reference transport acquires the gauge factors at its two endpoints. In particular, the branch of based loop holonomies is preserved.

Step 2: alignment with the given representative. Let h be a gauge transformation of the coarse lattice with $V_J^h = c$; if $U_J = c$, we take $h = (k_0|_{\Lambda_m})^{-1}$. On a coarse bond xy, we have $h_x h_y^{-1} = c_{xy}\, h_y (V_J)_{xy}^{-1} h_y^{-1}$. Since ρ_G is conjugation invariant and satisfies the triangle inequality, we obtain

$$\rho_G(h_x h_y^{-1}) \leq \rho_G((V_J)_{xy}) + \rho_G(c_{xy}) < (L_M^J + 1)u.$$

We lift h to a gauge transformation $\widetilde{h}$ of the fine lattice that is constant on each centered block of M^J sites per direction around a coarse vertex. These blocks partition the fine torus. They are compatible with the blocks at every intermediate scale. Indeed, in one coordinate, the union of the M centered intervals of M^{s-1} sites centered at $M^{s-1}j$, $-R_M \leq j \leq R_M$, where $M = 2R_M + 1$, is exactly the interval with integer endpoints $\pm(M^s - 1)/2$; taking Cartesian products and inducting in s proves the nesting. The nesting implies that a link at scale s either has both endpoints in one block of $\widetilde{h}$ or crosses one boundary between neighboring blocks. In the second case, the increment of $\widetilde{h}$ between its endpoints obeys the preceding bound. Since $(U^k)^l = U^{lk}$, the composite gauge transformation is $\widetilde{h}k_0$, and we obtain

$$\max_e \rho_G((V_s^{\widetilde{h}})_e) \leq L_M^s u + (L_M^J + 1)u \leq (2L_M^J + 1)u.$$

At scale J, the sharper bound $c \in B_u$ holds. When $U_J = c$, the composite gauge transformation is the identity at every coarse vertex. No global logarithm of h is used.

Step 3: forest coordinates. We fix the based block forests successively from the finest scale. Each tree path has at most $3R_M$ links. On a field with link bound v, a link outside the forest has, after forest fixing, distance at most $(6R_M + 1)v$ from the identity. Removing its coarse-field lift increases this bound by at most the bound for the coarse links. Hence all relative logarithms, including those of the eliminated edges, are at most $C_{M,J}u$. We reduce r_{geom} so that these inequalities, and the finitely many inequalities for intermediate logarithms, hold strictly inside the uniqueness neighborhood of Lemma 7.2 and inside the larger classical charts. Since the field satisfies its block averaging constraint, each eliminated-edge coordinate is the value of $\Gamma_{c_{i+1}}(z_i)$ on that branch. This excludes a second local solution for any point of the fiber.

Step 4: bounds on the fluctuation variables. Since the pairs (c_{i+1}, z_i) just obtained lie in the larger products of Section 14.2, Lemma 14.1 implies $\|z_i^*(c_{i+1})\|_\infty \le C_{M,J}u$ and a uniform row bound on $K_i^{1/2}$. By the definition of w_i, we have

$$g_i\|w_i\|_\infty \le \|K_i^{1/2}\|_{\infty\to\infty}(\|z_i\|_\infty + \|z_i^*\|_\infty) \le C_{\mathrm{TG}}u.$$

Starting at $c_J = c$ and recovering z_i and then c_i in decreasing order of i, we recover the input configuration.

Step 5: the based Haar disintegration. The measure statement in (2) requires the based conclusion of Step 2, not just the existence of a small representative. The union of the nested forests has one connected component for each coarse vertex: a vertex reaches the root of its block at each stage, and reaches its coarse vertex after at most J stages. Since this union has no cycle, the based gauge transformation that fixes it is unique. The proof of (14.6) applies at every stage. The auxiliary gauge transformation k_0 serves only to verify membership in the local branch after this unique forest fixing; it is not a coordinate and is not summed over. The single change of free coordinates has the Jacobian (14.7), which is the determinant of Theorem 12.13. Finally, the pointwise identities of Section 14.2 hold on the whole branch, before any fluctuation radius is imposed, and the present coordinates lie in this branch. This proves the measure assertion.

Step 6: change of representative. Let $c, c' \in B_u$ be gauge equivalent to U_J. The connecting gauge transformation has increments less than $2u$ on coarse bonds, and its lift that is constant on blocks keeps both coordinate neighborhoods in the same larger classical domain, after a reduction of r_{geom}. A gauge transformation fixed at the coarse vertices acts on a relative logarithm by the adjoint action at its source block; reversing the orientation of a link permutes the coordinates and changes their sign, with an adjoint factor. These maps are orthogonal on each color block. By uniqueness of the local inverse, they

intertwine the solved coordinates. The classical overlap identity in (14.3) then sends the conditional constrained minimizer and the constrained Hessian to Oz_i^* and OK_iO^{T}. The positive square root is sent to $OK_i^{1/2}O^{\mathsf{T}}$, since the square of the latter is the transformed positive matrix. This gives $w_i' = O_i(c_{i+1})w_i$. Since O_i depends on the field of the coarser scales, the joint change is triangular, and its diagonal blocks have determinants of absolute value one. This proves the norm preservation and the absence of a multiplicity factor.

Step 7: the quadratic lower bound. At each scale, let $h_i = z_i - z_i^*$. By stationarity and the classical Hessian bound, we have

$$\begin{aligned} F_i(c_{i+1}, z_i) - F_i(c_{i+1}, z_i^*) &= \int_0^1 (1-s) D_z^2 F_i(c_{i+1}, z_i^* + sh_i)[h_i, h_i]\, ds \\ &\geq \frac{m_0}{4}\|h_i\|_2^2 \geq \frac{m_0 g_i^2}{4C_K}\|w_i\|_2^2. \end{aligned}$$

In the last inequality, we used $h_i = g_i K_i^{-1/2} w_i$ and $K_i^{-1} \geq C_K^{-1} I$. Both endpoints, and the whole segment between them, lie in the fixed product of free coordinates. Subtracting successive values of the nested minimization identity and using $g_{i+1}^2 = Mg_i^2$, we see that all intermediate values cancel, as in (14.8). This gives (4), with the coefficient $m_0/(4C_K)$.

Step 8: derivatives of the effective interaction. Let $A_s \geq 0$ be the contribution of order s to the weighted coefficient norm, so that $\sum_{s\geq 2} A_s \leq E_*$. On $\|\xi\|_\infty \leq v\rho$ with $v = 1 - \eta$, contracting the undifferentiated indices bounds the first two derivatives by

$$C\rho \sum_{s\geq 2} s v^{s-1} A_s, \qquad C \sum_{s\geq 2} s(s-1) v^{s-2} A_s.$$

The multipliers are bounded by C/η and C/η^2: the first is at most $\sum_{j\geq 0} v^j$, and applying the same comparison to ordered pairs bounds the second by $2(\sum_{j\geq 0} v^j)^2$. This proves the two bounds on DR and D^2R in (5), independently of $R(I)$.

At a point in the strict interior, we fix a gauge transformation k sending it into $B_{(1-\eta)\rho}$ and hold k fixed. Since the image lies at positive distance from the boundary of B_ρ, there exists a neighborhood on which the transformed field stays in B_ρ. On it, gauge invariance on overlaps identifies R_{sat} with this analytic representative. Fixed group multiplications on a link have bounded differentials, and the logarithm has bounded first two differentials on a strictly smaller chart; these operations create no sum over remote links. By the coefficient bounds for the reconstruction in Lemma 14.1, with one or two fluctuation indices fixed, we have

$$\|D_w \xi\|_{b,\mathrm{root}} \leq C_J t, \qquad \|D_w^2 \xi\|_{b,\mathrm{root}} \leq C_J t^2.$$

The two terms of the chain rule are $D^2R(\xi)[D_w\xi, D_w\xi]$ and $DR(\xi)D_w^2\xi$. Summing first at the fixed input indices and using a smaller positive rate, we bound their row and

column sums by $C_J E_* t^2 \eta^{-2}$ and $C_J E_* \rho t^2 \eta^{-1}$. The gauge transformation k has not been differentiated. Taking $\eta = 1 - r/\rho$ gives the stated choice for D_r. □

We now fix the parameters. The order matters: first J, using only constants that are uniform before J; then the fixed-J analytic domains; then the small-field radius r; then the physical radii of fluctuation products; and finally the coupling bound.

Definition 14.4. The parameters of the construction are chosen in the following order.

1. Fix M, the spatial rates, and the support-enlargement, polymer-summability, and coefficient constants of Theorem 13.5, all of which are uniform before J. Choose J once so that
$$C_P(a_{\mathrm{sp}})M^{-J} < 1/4, \qquad C_{\mathrm{cen}}M^{-J} < 1/8,$$
and so that the other conditions on J in Theorem 13.5 hold. Here $q_P = C_P(a_{\mathrm{sp}})M^{-J}$ is the contraction factor of the pullback of the effective interaction to the background field (Theorems 11.10 and 13.5), and C_{cen} is the coefficient constant of the zero-fluctuation background field in Lemma 11.9; both are uniform before J.
2. Fix ρ, ρ_{cl}, s_J, E_*, and the larger construction domains so that the image of the reconstruction majorant and all classical, constraint-coordinate, and coarea conditions of Theorem 13.5 hold. In particular, with the constants r_J, C_J, the analytic-radius enlargement factor K_*, and the majorant $\mathfrak{M}_J$ of Theorem 13.2, we require
$$4K_*(\rho + s_J) < r_J, \qquad C_J 4K_*(\rho + s_J) < \tfrac{1}{2}, \qquad \mathfrak{M}_J(4K_*\rho, 4K_* s_J) < \rho/2. \tag{14.11}$$
These domains contain one open branch for an averaging step. Here $r_{\mathrm{CO}} > 0$ is a fixed radius for the relative logarithms $X = \Gamma_c(z)$, including those of the eliminated edges, chosen so that the branch lies strictly inside the uniqueness domain of Lemma 7.2 and the domain of the Haar disintegration of Lemma 6.3. The branch is
$$\begin{gathered}\|\mathrm{Log}\, c\|_\infty < r_c, \quad \|z\|_\infty < r_z, \quad \|\Gamma_c(z)\|_\infty < r_{\mathrm{CO}}, \\ \det D_{X_{e_a^*}} \mathsf{C}_{c,a}(\Gamma_c(z)) > 0 \quad (a \text{ a coarse link}),\end{gathered}$$
strictly inside the larger construction domains, with r_c, r_z as in Lemma 14.1. The square root in the normalized fluctuation variables is the positive square root of the constrained Hessian at the conditional constrained minimizer. All geometric and Hessian constants on these domains are fixed, including r_{geom} and C_{TG} of Theorem 14.3, which we apply with this branch as its coordinate domain. We decrease r_{geom}, before r is chosen, so that the bounds on all intermediate coarse logarithms, free logarithms, and relative logarithms in the proof of that theorem lie strictly below r_c, r_z, and r_{CO}, respectively, and so that every constraint determinant $\det D_{X_{e_a^*}} \mathsf{C}_{c,a}(\Gamma_c(z))$ is positive. These bounds are linear in u, and the determinants are

continuous and equal to $\det(M^{-2}I_3) > 0$ at the identity, so this is one fixed reduction. Thus, whenever $u < r_{\mathrm{geom}}$ and both endpoint fields lie in D_u, the coordinates of Theorem 14.3 satisfy precisely the branch conditions used in $\mathcal{A}_{k,J}$ below.

3. Put $\lambda_* = M^{-(J-1)/2}$ and $C_{\mathrm{map},J} = (10M)^J$. Choose $\mathscr{L}_{\mathrm{en}} > 2C_{\mathrm{TG}}/\lambda_*$, and choose $\mathscr{L}'_{\mathrm{en}} \geq \mathscr{L}_{\mathrm{en}}$ larger than $2C_{\mathrm{TG}}C_{\mathrm{map},J}/\lambda_*$ and than the fixed geometric enlargement constants of the larger chart of coarse fields.
4. Let $r_{\max} > 0$, depending only on the data fixed so far, be such that every $0 < r \leq r_{\max}$ satisfies the following conditions, where $R_{\mathrm{buf}} = C_{\mathrm{map},J}r$ and $R_{\mathrm{en}} = \mathscr{L}_{\mathrm{en}}r$: $r < \rho/8$; $r < r_{\mathrm{geom}}$ and $R_{\mathrm{buf}} < r_{\mathrm{geom}}$; $C_{\mathrm{map},J}r < \rho/2$; the physical radii R_{en} and $\mathscr{L}'_{\mathrm{en}}r$ lie strictly inside the products of free coordinates fixed in (2);

$$\begin{aligned} R_{\mathrm{buf}} + \mathscr{L}'_{\mathrm{en}}r < r_J, \qquad & C_J(R_{\mathrm{buf}} + \mathscr{L}'_{\mathrm{en}}r) < \tfrac{1}{2}, \\ R_{\mathrm{buf}} < 4K_*\rho, \qquad & \mathscr{L}'_{\mathrm{en}}r < 4K_*s_J; \end{aligned} \tag{14.12}$$

   the inequality

$$\frac{C\mathscr{L}'_{\mathrm{en}}r}{(1 - C\mathscr{L}'_{\mathrm{en}}r)^3} < \frac{1}{4},$$

   with C the constant of (14.10); and $M^{-J}Z(r) < r/4$, where Z is the majorant of the zero-fluctuation reconstruction in Theorem 13.2. Choose $r \in (0, r_{\max}]$.
5. Choose $0 < P_{\mathrm{phys}} < Q_{\mathrm{phys}}$, fixed multiples of r, such that $\mathfrak{M}_J(r, Q_{\mathrm{phys}}) < r/2$ and every point of the product of physical radius Q_{phys} satisfies the intermediate coordinate conditions.
6. Choose $A_{\mathrm{w}} \geq 1$, put $p_{\mathrm{w}}(t) = A_{\mathrm{w}} \log(1/t)$, and choose a coupling bound $t_* \in (0,1)$ such that, for all $0 < t \leq t_*$, the smallness conditions on t in Theorems 13.5, 13.8, and 13.10 and in the proofs of Theorems 14.6 and 14.7 hold. These include $tp_{\mathrm{w}}(t) < P_{\mathrm{phys}}$ and $p_{\mathrm{w}}(t) \geq p_0$, where p_0 is the lower bound for the cutoff radius in Theorem 13.5.

The integer J is not changed after step (1), and r is not changed after step (4).

Let $u \in 4\mathbb{N}$, $K \geq 0$, and $N = uB^K$, put $n_\ell = N/M^\ell$, and let $\gamma > 0$ be such that $t_k^2 = \gamma/(Mn_{(k+1)J}) \leq t_*^2$ for $0 \leq k < K$. Put $V^\ell = T_M^\ell U$. For the kth RG step, from V^{kJ} to $V^{(k+1)J}$, let $\mathcal{A}_{k,J}$ be the event that, in the based inverse coordinates of this step, every pair (c_{i+1}, z_i) lies in the branch of (2) at depth $kJ + i$, with its conditional constrained minimizer and the normalization by the positive square root of its constrained Hessian, and with the classical and coarea domains fixed above. This event is transported between representatives of the coarse field by the coordinate transitions of Theorem 14.3(3), not by choosing a new fiber measure. Let $w_{k,i,e}$ be the normalized fluctuation variables of

this step, with couplings $g_{k,i} = t_k M^{(i-J+1)/2}$. The small-field event and the conditioned Wilson measure are

$$S_{N,u,\gamma} = \{U \in D_r\} \cap \bigcap_{k=0}^{K-1} \Big[\mathcal{A}_{k,J} \cap \{\max_{i,e} |w_{k,i,e}| \le A_{\mathrm{w}} \log(1/t_k)\} \cap \{V^{(k+1)J} \in D_r\} \Big],$$

$$\nu_{N,u,\gamma} = \mu_{N,\gamma}(\,\cdot \mid S_{N,u,\gamma}).$$

This definition makes precise the event of Definition 4.4. There is no D_r test at the intermediate scales of an RG step. For $K = 0$ the event is the initial test $\{U \in D_r\}$. The stopped measure after k RG steps is the normalized pushforward of the Wilson measure restricted by the tests of the first k steps. The conditioned Wilson measure also contains the tests of the remaining coarser steps, so its marginal at an intermediate scale is in general not the stopped measure.

Lemma 14.5. *The choices in Definition 14.4 can be made in the stated order. The integer J depends only on constants uniform before J; ρ and s_J as in step (2) exist; there is $r_{\max} > 0$ as in step (4); in step (5) one can take $Q_{\mathrm{phys}} = \zeta r$ and $P_{\mathrm{phys}} = Q_{\mathrm{phys}}/2$, with $\zeta > 0$ independent of $r \in (0, r_{\max}]$, and then the fluctuation cutoff domain satisfies the same conditions as the product of physical radius Q_{phys} whenever $t \le t_*$; and there is t_* as in step (6). The event $S_{N,u,\gamma}$ is a Borel set invariant under lattice gauge transformations, and for $K = 0$ it equals D_r.*

Proof. Only the constants that are uniform before J enter the choice of J. The additional conditions of Theorem 13.5 on the image of the majorant, on support enlargement, and on polymer summability are of this kind, so we can take one J satisfying all of them and the two displayed contractions. We then fix the larger domains, ρ, s_J, E_*, and every coefficient bound at this J. When choosing the larger domains, we take the strict inclusions of Theorem 13.2 small enough that (14.11) holds. The classical products of Section 14.2 and Theorem 14.3 fix C_{TG} before r is chosen. These choices are made on the larger domains, before r; the contraction of the pullback uses only the constants fixed before J.

Every radius in step (4) is a fixed multiple of r, and the rational expression in step (4) also tends to zero with r. Since there are finitely many strict inequalities, their set of solutions contains an interval $(0, r_{\max}]$ after a strict reduction of its endpoint. The constants used in this reduction have all been fixed already. By the contraction $C_{\mathrm{cen}} M^{-J} < 1/8$ and the form of the majorant Z, the zero-fluctuation term satisfies $M^{-J} Z(r) < r/4$ on a sufficiently small such interval.

We choose $\zeta > 0$ so small that $C_J \zeta / [1 - C_J(r + \zeta r)] < 1/4$ uniformly for $0 < r \le r_{\max}$, that all intermediate conditions hold on the products of the corresponding physical radii, and that $\zeta < \mathscr{L}_{\mathrm{en}}$. We set $Q_{\mathrm{phys}} = \zeta r$ and $P_{\mathrm{phys}} = Q_{\mathrm{phys}}/2$. By (14.12), we have $r + Q_{\mathrm{phys}} < r_J$, the denominator of the majorant is positive, and the corresponding product of coarse fields and free coordinates lies inside the products of step (2). Every

intermediate classical and coarea condition was included in the choice of ζ. The clause of Theorem 13.2 for coarse fields in B_r therefore applies, and with $\delta = M^{-J}$ it gives

$$\mathfrak{M}_J(r, Q_{\mathrm{phys}}) = \delta Z(r) + \frac{C_J Q_{\mathrm{phys}}}{1 - C_J(r + Q_{\mathrm{phys}})} < \frac{r}{4} + \frac{r}{4} = \frac{r}{2}.$$

On the fluctuation cutoff domain, we have $|g_i w_{i,e}| \le t p_{\mathrm{w}}(t) < P_{\mathrm{phys}}$, so this domain is contained in the product of physical radius Q_{phys} and has the same properties.

For any fixed $A_{\mathrm{w}} \ge 1$, all remaining conditions on t compare a fixed positive quantity with expressions $t^{\alpha} \log^h(1/t)$, where $\alpha > 0$ and h is a fixed nonnegative integer. These expressions tend to zero: with $x = \log(1/t)$, the expression is $e^{-\alpha x} x^h$, which the exponential series bounds by $C_{\alpha,h}/x$ for large x. Also, $p_{\mathrm{w}}(t) \to \infty$ as $t \to 0$. We conclude that one $t_* < 1$ enforces every condition, including those of Theorem 13.5. None of them requires increasing J or changing r.

The event keeps the indicators of the branch, determinant, and classical conditions, and then only the initial and coarse D_r tests. Every map in its finite definition is continuous on the open branch and is used together with the Borel indicator of the branch, and the event is false outside the branch. Hence the event is Borel. The orthogonal transitions of Theorem 13.4 on overlaps preserve its coordinate conditions and its fluctuation balls. It is therefore one event invariant under lattice gauge transformations, defined without a measurable choice among auxiliary gauge transformations. For $K = 0$, the intersection over k is empty and only the initial test remains. □

14.4 The restricted recursion and the enclosing product

This subsection identifies the recursion of Theorem 13.5 with the Wilson measure restricted by the small-field event. It also shows that the fiber of the incoming restricted density over a coarse field lies in a product domain on which the conditional fluctuation potential is uniformly convex.

Fix one RG step from depth d_0, with coarse side m and incoming effective interaction R. The incoming restricted density is

$$P_{\mathrm{in}}(U) = \mathbf{1}_{D_r}(U)\, e^{-E_{d_0,\mathrm{sat}}(U)/g_0^2 - R_{\mathrm{sat}}(U)}$$

relative to the product Haar measure, as in Theorem 13.4. For a coarse field $c \in B_{R_{\mathrm{buf}}}$, let S_c be the set of normalized fluctuation variables w such that the pairs (c_{i+1}, z_i) defined successively by $c_J = c$, $z_i = z_i^*(c_{i+1}) + g_i K_i(c_{i+1})^{-1/2} w_i$, and $c_i = b_i(c_{i+1}, z_i)$ lie in the common branch, and the reconstructed fine configuration c_0, with the forest variables in their gauge-fixed position, lies in D_r. For the fixed coarse representative c, Theorem 14.3 gives these coordinates for every configuration $U \in D_r$ with $T_M^J U = c$, modulo fine gauge transformations equal to the identity at every coarse vertex; the hierarchical forest

fixing chooses one representative. We apply the theorem with $u = r$ for $c \in B_r$ and with $u = R_{\mathrm{buf}}$ for $c \in B_{R_{\mathrm{buf}}}$. If the coarse image is only gauge equivalent to c, it is first aligned with c as in that theorem; we do not assert that this auxiliary alignment is unique. The set S_c is Borel, since it is the preimage of the open set D_r under a continuous map on an open domain. Since P_{in} is invariant under lattice gauge transformations, the forest variables integrate out with total mass one (Lemma 5.1), and all densities in w below refer to this reduced integral. They are statements about integrals of gauge-invariant functions, not a pointwise coarea formula for other functions. They do not define a global gauge fixing on the configuration space.

Theorem 14.6. *Use the parameters of Definition 14.4 and start with $R_0 = 0$.*

1. *For every finite number of RG steps, every coarse side $m \geq 4$, and all couplings with $t \leq t_*$ at each step, there are effective interactions R_k, holomorphic on B_ρ, with*

$$DR_k(I) = 0, \qquad \mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_k) \leq E_*,$$

gauge invariant on overlaps and invariant under global color rotations, lattice translations, and spatial inversion.

2. *Consider one RG step from depth d_0, with incoming effective interaction $R = R_k$ and coarse field $c = e^\theta$, and set*

$$\widetilde{F}_+(c) = A_{\mathrm{coord}}\, e^{-E_{d_0+J}(c)/g_J^2 - \mathsf{B}_{\mathrm{ref}}(c) - R_{\mathrm{ref}}(c)} \int_{\Omega_p^{\mathrm{w}}} e^{-V_c(w)}\, dw,$$

$$R_{\mathrm{ref}}(c) = R(e^{\Phi(\theta,0)}), \qquad V_c(w) = \tfrac{1}{2}|w|^2 + H_{d_0,J}(\theta, w) + R(e^{\Phi(\theta,(g_i w_i)_i)}) - R_{\mathrm{ref}}(c),$$

$$A_{\mathrm{coord}} = \prod_i \mathcal{J}_i(I,0) g_i^{3f_i}, \qquad \Omega_p^{\mathrm{w}} = \prod_{i,e} \{|w_{i,e}| \leq p_{\mathrm{w}}(t)\}.$$

For $c \in B_\rho$ this is an auxiliary integral, positive for real c, in which R is evaluated on the image of the reconstruction, which lies in $B_{\rho/2}$. With

$$z_p = \int_{|x| \leq p_{\mathrm{w}}(t)} e^{-|x|^2/2}\, d^3x, \qquad \pi_p^{\mathrm{all}}(dw) = z_p^{-\sum_i f_i} \mathbf{1}_{\Omega_p^{\mathrm{w}}}(w) e^{-|w|^2/2}\, dw,$$

and $\Xi_R = \mathbb{E}_{\pi_p^{\mathrm{all}}} e^{-H_{d_0,J} - R(e^{\Phi(\theta, gw)}) + R_{\mathrm{ref}}}$, we have

$$R_+ = \mathsf{B}_{\mathrm{ref}} + R_{\mathrm{ref}} - \Big(\sum_i f_i\Big) \log z_p - \log \Xi_R, \qquad \widetilde{F}_+ = A_{\mathrm{coord}} e^{-E_{d_0+J}/g_J^2 - R_+}.$$

For real c, $\log \Xi_R$ is the real logarithm; for complex c it is the holomorphic logarithm given by Theorem 13.5.

3. *For every $c \in B_r$, the reconstruction maps the whole fluctuation cutoff domain Ω_p^{w} into D_r, and all coordinate conditions of the step hold there. Consequently $\widetilde{F}_+(c)$ is the density at c of*

the pushforward under T_M^J of the incoming density restricted by the coordinate conditions and the fluctuation cutoff of this step, and the output density, including the coarse test, is $\mathbf{1}_{D_r}\widetilde{F}_{+,\mathrm{sat}}\,dH$. By induction, the stopped density after k RG steps is proportional to

$$\mathbf{1}_{D_r} e^{-E_{kJ,\mathrm{sat}}/g_{kJ}^2 - R_{k,\mathrm{sat}}}\,dH,$$

where $g_{kJ}^2 = \gamma/n_{kJ}$ is the coupling of the lattice of side n_{kJ}.

4. *The field-independent factor of this density is the product of the factors A_{coord} of the steps performed, together with the constants removed by centering, which are transferred to the normalization constant. Precisely, if the incoming effective interaction is centered and the incoming density carries the factor e^{Λ_k}, then centering the output of this step means*

$$R_{k+1} = R_+ - R_+(I), \qquad \Lambda_{k+1} = \Lambda_k + \log A_{\mathrm{coord}} - R_+(I).$$

If R_+ is kept uncentered, its constant stays in the exponent. The normalizing constant is finite and strictly positive. After k RG steps, normalizing the density in (3) gives the pushforward under T_M^{kJ} of the Wilson measure conditioned on the initial D_r test and the tests of the first k steps. After all K steps, this measure is $(T_M^{KJ})_*\nu_{N,u,\gamma}$, with $\nu_{N,u,\gamma}$ the conditioned Wilson measure of Definition 14.4.

5. *Let $b_{\mathrm{w}} = \sum_i f_i = 2(B^3-1)m^3$, so that $\dim_{\mathbb{R}} w = 3b_{\mathrm{w}}$, and define, for $a \in \{P_{\mathrm{phys}}, Q_{\mathrm{phys}}\}$,*

$$\Omega_a^{\mathrm{phys}} = \prod_{i,e}\{|w_{i,e}| \le a/t\}, \qquad \mathcal{K}_t = \prod_{i,e}\{|w_{i,e}| \le R_{\mathrm{en}}/t\}.$$

Then, for every $c \in B_r$,

$$\Omega_p^{\mathrm{w}} \subset \Omega_{P_{\mathrm{phys}}}^{\mathrm{phys}} \subset \Omega_{Q_{\mathrm{phys}}}^{\mathrm{phys}} \subset S_c \subset \operatorname{int}\mathcal{K}_t.$$

6. *The same potential V_c is smooth on a neighborhood of the product $\mathcal{K}_t$, which does not depend on c, and*

$$\|D_w^2(V_c - \tfrac{1}{2}|w|^2)\|_{b,\mathrm{row+col}} \le \frac{C[R_{\mathrm{en}} + t^2(1+E_*)]}{(1-CR_{\mathrm{en}})^3} \le \tfrac{1}{2}, \qquad D_w^2 V_c \ge I/2.$$

7. *For $c \in B_r$, the fiber of the incoming measure $P_{\mathrm{in}}\,dH$ over c, without fluctuation cutoff, has the density*

$$A_{\mathrm{coord}}\, e^{-E_{d_0+J}(c)/g_J^2 - \mathsf{B}_{\mathrm{ref}}(c) - R_{\mathrm{ref}}(c)}\, \mathbf{1}_{S_c}(w) e^{-V_c(w)}\,dw.$$

The prefactor is the same for every subset of S_c that is integrated. The set S_c need not be convex.

8. *On Ω_p^{w} the normalized density is the conditional fluctuation kernel of Theorem 13.8 with the effective interaction R, and the bounds of Theorem 13.10 on means, derivatives of the potential, and covariances apply to it. The tests of the coarser RG steps cancel when one*

conditions on the coarse field. A gauge transformation of the reconstructed fine field that depends only on c and equals the identity at every coarse vertex leaves c, the normalized fluctuation variables, the conditional fluctuation kernels, and the cutoffs unchanged, provided that the coefficient bounds of Theorem 13.2 continue to hold in the new representative.

All constants depend only on the parameters of Definition 14.4 and the larger domains; they do not depend on the side, the coupling, the depth, or the number of RG steps. The values of $\widetilde{F}_+$ at coarse fields outside B_r are not identified with pushforwards of the restricted Wilson measure.

Proof. Steps 1 to 6 concern the recursion and its identification with the restricted Wilson measure; they prove (1) to (4). Steps 7 to 10 concern the fiber without cutoff and prove (5) to (8).

Step 1: the auxiliary integral on B_ρ. The image of the coefficient majorant on the enlarged product was fixed in Theorem 13.2. By (14.11), the enlarged product of coarse fields and free coordinates lies before the pole of the majorant and within $u + v < r_J$, with positive denominator. On the whole auxiliary ball of coarse fields, every reconstructed argument of the effective interaction lies in $B_{\rho/2}$, and every intermediate classical and coarea argument satisfies its conditions with strict inequality. Then the formula in (2) defines the same auxiliary operator as Theorem 13.5, with the present parameters and incoming effective interaction, and that theorem supplies its holomorphic logarithm and the common bound on its analytic norm. Positivity of the integral refers to real coarse fields. For complex coarse fields, $\widetilde{F}_+$ is the holomorphic continuation, and the existence of its logarithm is part of Theorem 13.5, not a consequence of positivity.

Step 2: normalization constants. Since Ω_p^{w} is a product of $\sum_i f_i$ balls in $\mathbb{R}^3$, each of Gaussian mass z_p, substituting V_c gives $\int_{\Omega_p^{\mathrm{w}}} e^{-V_c}\, dw = z_p^{\sum_i f_i} \Xi_R$. Taking the logarithm, with the real branch on real coarse fields, gives the stated R_+ and A_{coord}; this is also the formula of Theorem 13.4. In particular, the normalization z_p is not absorbed into an unspecified term depending on the coarse field. Subtracting $R_+(I)$ changes no nonconstant coefficient, no overlap identity, and no symmetry, and the unnormalized densities agree:

$$e^{\Lambda_k} A_{\mathrm{coord}} e^{-E_{d_0+J}/g_J^2 - R_+} = e^{\Lambda_k + \log A_{\mathrm{coord}} - R_+(I)} e^{-E_{d_0+J}/g_J^2 - [R_+ - R_+(I)]}.$$

This proves the sign and every constant in (4).

Step 3: identification on B_r. Let $c \in B_r$. On the whole cutoff product, we have $\|gw\|_\infty \le t p_{\mathrm{w}}(t) < P_{\mathrm{phys}} < Q_{\mathrm{phys}}$. By Lemma 14.5, the radius Q_{phys} satisfies (14.12), $r + Q_{\mathrm{phys}} < r_J$, the positivity of the denominator of the majorant, and all intermediate conditions. The image bound of Theorem 13.2 for coarse fields in B_r therefore puts the fine field in $B_{r/2}$, in the gauge of that theorem, with all intermediate coordinate conditions. The indicator of D_r for the fine field is identically one there. All hypotheses of Theorem 13.4 now hold:

R is gauge invariant on overlaps, its first derivative at the identity vanishes, its norm is at most E_*, and it has the required symmetries. This implies that, at coarse fields in B_r, the auxiliary integral is the fiber integral of the restricted incoming density, including the branch, coarea, cutoff, and coarse tests; we do not use this conclusion outside B_r.

Step 4: overlaps, symmetries, and the first derivative. On an overlap, the triangular orthogonal change of Theorem 14.3(3) preserves the fluctuation product, Lebesgue measure, the Haar disintegration densities, and the determinants. The two reconstructed arguments of the effective interaction are related by a gauge transformation and both lie in $B_{\rho/2}$, so the values of R agree. A change of variables shows that the two auxiliary integrals are equal, including all reference factors. Translations and spatial inversion act by the corresponding orthogonal permutations, and constant color rotations also preserve the integral. At the identity, each component of the first derivative of R_+ at a link is a vector in $\mathfrak{su}(2)$ fixed by all adjoint rotations, and hence zero: rotations by a half-turn about the coordinate axes reverse each component. This verifies the overlap and first-derivative hypotheses at the next step.

Step 5: the analytic norm. The induction step for the norm is the inequality

$$\begin{aligned}\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_+) &\le C_G + q_P E_* + C_T t^2 E_*(p_{\mathrm{w}}^4 + E_* p_{\mathrm{w}}^2)\\ &\le C_G + \tfrac{1}{2}(1+q_P)E_* \le E_*.\end{aligned}$$

In the first inequality, we used the bound of Theorem 13.5; in the second, its condition $C_T t^2(p_{\mathrm{w}}^4 + E_* p_{\mathrm{w}}^2) \le (1-q_P)/2$; and in the last, $C_G \le (1-q_P)E_*/2$. Since $R_0 = 0$ satisfies all hypotheses, this proves (1) at every finite depth kJ.

Step 6: iteration and the normalizing constant. Iterating these positive operators, and using the last clause of Theorem 13.4, we obtain the pushforward of the Wilson density restricted by exactly the tests of Definition 14.4, and the stopped density after any number of steps. This proves (3). On a finite lattice, the identity configuration and a sufficiently small open neighborhood of it pass all of the finitely many tests strictly. Indeed, the inverse coordinates are continuous on the open branch, the image bound holds on the whole cutoff product, and every normalized fluctuation variable of the identity configuration is zero. That neighborhood has positive Haar measure. All densities are bounded on smaller chart neighborhoods, and the bound on the oscillation of R_{sat} in Theorem 13.4, together with the finiteness of Haar measure on the compact configuration space, gives finiteness. Hence the normalizing constant is finite and strictly positive. When all K tests are imposed, normalizing the restricted Wilson measure before pushforward gives $\nu_{N,u,\gamma}$, and normalizing its pushforward gives the corresponding stopped measure.

Step 7: the enclosure. We now consider the fiber without cutoff. The numbers of free variables at the intermediate scales are

$$f_i = 2(M^3-1)(mM^{J-i-1})^3, \qquad \sum_{i=0}^{J-1} f_i = 2m^3(M^{3J}-1),$$

where the equality follows by summing the finite geometric series. Since there are three real color components per block, we have $\dim_{\mathbb{R}} w = 3b_{\mathrm{w}}$. For a point of S_c, Theorem 14.3 with $u = r$ implies that

$$|w_{i,e}| \le \frac{C_{\mathrm{TG}} r}{g_i} \le \frac{C_{\mathrm{TG}} r}{\lambda_* t} < \frac{R_{\mathrm{en}}}{2t},$$

where in the last inequality we used $\mathscr{L}_{\mathrm{en}} > 2C_{\mathrm{TG}}/\lambda_*$. This proves that S_c lies in the interior of $\mathcal{K}_t$, before any cutoff. Conversely, if $|w_{i,e}| \le Q_{\mathrm{phys}}/t$ for all i, e, then $|g_i w_{i,e}| \le Q_{\mathrm{phys}}$. The image estimate of Theorem 13.2 puts the fine field in $B_{r/2}$, with all intermediate coordinate conditions, on this whole closed product, which is therefore a subset of S_c. The other two inclusions follow from $P_{\mathrm{phys}} < Q_{\mathrm{phys}}$ and $t p_{\mathrm{w}}(t) < P_{\mathrm{phys}}$. Since all inequalities on the coarse field and the branch hold strictly, the assertions also hold on the boundaries of these closed products.

Step 8: convexity on $\mathcal{K}_t$. Throughout $\mathcal{K}_t$, each input $g_i w_{i,e}$ has norm at most $R_{\mathrm{en}} \le \mathscr{L}'_{\mathrm{en}} r$, and together with the coarse-field radius $r \le R_{\mathrm{buf}}$ it satisfies (14.12). The image condition of step (2) of Definition 14.4 therefore puts the image of the reconstruction, and an open neighborhood of it, in the analytic domain of R. The same V_c is therefore smooth there, also at points not in S_c. The clause of Theorem 13.8 for products of fixed physical radius applies with $q_* = R_{\mathrm{en}}$ and gives the Hessian estimate in (6); equivalently, this is the convergent coefficient calculation of Lemma 14.2 with $q = R_{\mathrm{en}}$. The choice of $r_{\max}$ makes the term with R_{en} at most $1/4$, and the choice of t_* then makes the term with $t^2(1+E_*)$ at most $1/4$. By Schur's test, the weighted row-and-column bound controls the operator norm, which gives $D_w^2 V_c \ge I/2$ on the whole convex product, whether or not S_c is convex.

Step 9: the density on the whole fiber. By Theorem 14.3(2) and the discussion before the theorem, the uncut fiber has exactly one representation in the based coordinates. Multiplying (14.6), (14.7), and (14.8) gives the factor (14.9) times $\mathbf{1}_{S_c} e^{-V_c(w)}\, dw$. Gauge invariance on overlaps identifies the value of the effective interaction at every point of S_c. All other factors are contained in (14.9) or in $H_{d_0,J}$, and none of them depends on which subset of the fiber is integrated. This proves (7).

Step 10: conditional kernels and changes of representative. On the cutoff product, the normalized density is the kernel of Theorem 13.8 with the effective interaction just constructed; the hypotheses of that theorem, including the fixed domain Ω_p^{w} and the smallness of $t p_{\mathrm{w}}(t)^3$, were verified above. The effective interaction is holomorphic on B_ρ and gauge invariant on overlaps, and it has vanishing first derivative at the identity,

the required symmetries, and norm at most E_*. Further, the product of coarse fields and free coordinates satisfies the image condition of (14.11). The hypotheses of Lemma 14.2 then also hold, and Theorem 13.10 applies to this kernel, including its local L^2 bound along the interpolation. The segment $s\theta$, $0 \le s \le 1$, stays in B_r, and the product and the couplings are fixed along it. If the Wilson measure conditioned on the whole small-field event is conditioned further on the coarse field of this step, the tests of the coarser steps are functions of that coarse field and of its deterministic averages. Their common factor therefore cancels in the normalized conditional fluctuation kernel wherever these tests pass.

Finally, a gauge transformation depending only on the coarse field and equal to the identity at the coarse vertices changes the representative of the fine field after reconstruction. The free coordinates, all fluctuation balls, the Haar disintegration density, and the triangular Jacobian are unchanged, and by gauge invariance on overlaps the value of the effective interaction agrees. Hence the potential and the kernel are the same. The proviso on coefficient bounds allows the analytic estimates, including those on derivatives of the potential, to be used in the new representative. Every reduction and every bound used only the fixed parameters, and none involved the length of the preceding recursion. □

14.5 Conditional comparisons and exit probabilities

We now compare three normalized measures on the fluctuation variables over a coarse field $c \in B_r$: the conditional fiber measure of the incoming restricted density, its restriction to the fluctuation cutoff domain, and a comparison measure on the enclosing product $\mathcal{K}_t$. The last one has a uniformly convex potential on a convex domain, so it satisfies a logarithmic Sobolev inequality and a local covariance bound, and these estimates pass to the fiber by conditioning. We also bound the probability that the coarse field leaves D_r by a ratio of auxiliary integrals.

Theorem 14.7. *Use the parameters of Definition 14.4, consider one RG step from depth d_0 with incoming effective interaction R given by Theorem 14.6, and for every $c = e^\theta \in B_r$ define the normalized enclosing-product comparison measure ν_c and the conditional fiber measure κ_c^{old} by*

$$\nu_c(dw) = \frac{\mathbf{1}_{\mathcal{K}_t}(w) e^{-V_c(w)}\, dw}{\int_{\mathcal{K}_t} e^{-V_c(w)}\, dw}, \qquad \kappa_c^{\mathrm{old}}(dw) = \frac{\mathbf{1}_{S_c}(w) e^{-V_c(w)}\, dw}{\int_{S_c} e^{-V_c(w)}\, dw}.$$

1. *Uniformly in the depth, the side, and c,*

$$\sup_i |\mathbb{E}_{\nu_c} w_i| \le Ct \|\theta\|_\infty, \qquad \kappa_c^{\mathrm{old}} = \nu_c(\,\cdot \mid S_c).$$

2. *Put $m_{\mathrm{cv}} = 1/2$ and*

$$d_t = 6 b_{\mathrm{w}} e^{-m_{\mathrm{cv}} \mathrm{Q}_{\mathrm{phys}}^2/(24t^2)}, \qquad \delta_t = 6 b_{\mathrm{w}} e^{-m_{\mathrm{cv}} p_{\mathrm{w}}(t)^2/24}, \qquad \epsilon_t = \frac{\delta_t}{1 - d_t}.$$

If $d_t < 1$, then

$$\kappa_c^{\mathrm{old}}\big((\Omega^{\mathrm{phys}}_{P_{\mathrm{phys}}})^c\big) \le \frac{6b_{\mathrm{w}}e^{-m_{\mathrm{cv}}P_{\mathrm{phys}}^2/(24t^2)}}{1-d_t}, \qquad \kappa_c^{\mathrm{old}}\big((\Omega_p^{\mathrm{w}})^c\big) \le \epsilon_t.$$

3. *Let σ be the probability measure $Z_{\mathrm{in}}^{-1}P_{\mathrm{in}}\,dH$, where $Z_{\mathrm{in}} = \int P_{\mathrm{in}}\,dH$; this is the normalized incoming restricted density of this step. Let $G(c)$ be the density at c of the pushforward of the unnormalized measure $P_{\mathrm{in}}\,dH$ under T_M^J, given by the based coarea formula of Theorem 14.6(7), and let $\widetilde{F} = \widetilde{F}_+$ be the auxiliary integral of Theorem 14.6(2), both with the same convention for field-independent factors. Then, on D_r,*

$$\frac{\widetilde{F}(c)}{G(c)} = \kappa_c^{\mathrm{old}}(\Omega_p^{\mathrm{w}}),$$

without any smallness assumption, and $1 \le G(c)/\widetilde{F}(c) \le (1-\epsilon_t)^{-1}$ if $d_t < 1$ and $\epsilon_t < 1$.

4. *If $d_t < 1$, the normalized measures $\mathbf{1}_{D_r}G\,dH/\int_{D_r} G\,dH$ and $\mathbf{1}_{D_r}\widetilde{F}\,dH/\int_{D_r}\widetilde{F}\,dH$ differ in total variation $\sup_A|\mu(A)-\nu(A)|$ by at most ϵ_t, and*

$$\sigma(\text{the next RG step fails}) \le \sigma(T_M^J U \notin D_r) + \epsilon_t,$$

where the next RG step fails if U violates at least one of the coordinate conditions of the step, the fluctuation cutoff, and the condition $T_M^J U \in D_r$.

5. *We have $T_M^J(D_r) \subset D_{R_{\mathrm{buf}}}$ with $R_{\mathrm{buf}} = (10M)^J r$. Let $\mathcal{K}_t'$ be the product of physical radius $\mathscr{L}_{\mathrm{en}}' r$, and define*

$$H(c) = C(c)\int_{\mathcal{K}_t'} e^{-V_c(w)}\,dw, \qquad C(c) = A_{\mathrm{coord}}\,e^{-E_{d_0+J}(c)/g_J^2 - \mathsf{B}_{\mathrm{ref}}(c) - R_{\mathrm{ref}}(c)},$$

with the same convention for field-independent factors as G and $\widetilde{F}$. If $\delta_t < 1$, then

$$G(c) \le H(c) \le \frac{\widetilde{F}(c)}{1-\delta_t} \qquad (c \in D_{R_{\mathrm{buf}}}),$$

and, with $Z_{\mathrm{aux}}(A) = \int_A e^{-E_{d_0+J,\mathrm{sat}}/g_J^2 - R_{+,\mathrm{sat}}}\,dH$,

$$\sigma(T_M^J U \notin D_r) \le \frac{1}{1-\delta_t}\,\frac{Z_{\mathrm{aux}}(D_{R_{\mathrm{buf}}} \setminus D_r)}{Z_{\mathrm{aux}}(D_r)}.$$

In (5) no inclusion of the cutoff product in S_c is required for coarse fields in $D_{R_{\mathrm{buf}}} \setminus D_r$. The pointwise statements refer to the explicit density given by the based coarea formula; for an arbitrary disintegration they hold almost everywhere. The constants do not depend on the volume, but the explicit factor b_{w} and the conditions $d_t < 1$, $\epsilon_t < 1$, and $\delta_t < 1$ cannot be dropped. At fixed L and $\gamma > 0$, along refinement of the lattice, $b_{\mathrm{w}} = O_{M,J,\gamma}(t^{-6})$, so the errors d_t, δ_t, and ϵ_t are smaller than every power of the mesh. The theorem gives no bound on the ratio of auxiliary integrals in (5).

The mean bound in (1) concerns the comparison measure on the enclosing product, not the kernel on the cutoff product, whose means are bounded in Theorem 13.10. Its proof must avoid the large radius R_{en}/t of $\mathcal{K}_t$. Heuristically, a classical cubic term in the potential has size tw^3, so its mixed derivative in w and in the coarse field has size tw^2, whose L^2 norm is at most $t\|w\|_4^2$. The fourth moments are bounded independently of the radius of the product, by concentration. In a term of degree $k \geq 3$ the remaining $k-3$ factors are bounded by R_{en}/t, which leaves $t^{k-2}(R_{\mathrm{en}}/t)^{k-3} = tR_{\mathrm{en}}^{k-3}$, a summable series. Bounding all factors by the radius of the product, or using a global Cauchy–Schwarz bound for the extensive derivative of the potential, would lose this smallness.

Proof. Steps 1 to 4 prove the mean bound in (1): Step 1 recalls the convexity input, Step 2 derives concentration and fourth moments, Step 3 bounds the mixed derivative of the potential, and Step 4 integrates along the segment from 0 to θ. Steps 5 and 6 prove the conditioning identity and (2). Steps 7 and 8 prove (3) and (4). Steps 9 and 10 prove (5), and Step 11 proves the remaining statements.

Step 1: inputs. We use the coefficient bounds of Lemma 14.2. They apply because the effective interaction, constructed in Theorem 14.6, has the required holomorphy, vanishing first derivative, gauge invariance on overlaps, symmetries, and norm bound. The whole enclosing product and the segment of coarse fields satisfy (14.12). The convexity and the product inequalities are supplied by the clause of Theorem 13.8 for products of fixed physical radius, which rests on Theorem 5.4. Their constants depend on the lower Hessian bound $m_{\mathrm{cv}} = 1/2$ and on the weighted bounds on the interaction, but not on the radius R_{en}/t of the product or on the dimension. These inequalities go back to Gross [103], Bakry and Émery [8], and Helffer and Sjöstrand [110]; the version for reflecting boundary conditions on products of balls is proved in Section 5.

Step 2: concentration of one coordinate. Let X be a scalar coordinate. The logarithmic Sobolev inequality of Step 1 reads $\mathrm{Ent}(f^2) \leq (2/m_{\mathrm{cv}})\mathbb{E}|\nabla f|^2$. We apply it to $f = e^{\lambda X/2}$, for which $|\nabla f|^2 = \lambda^2 e^{\lambda X}/4$, and set $\psi(\lambda) = \log \mathbb{E}e^{\lambda X}$. Dividing by $\mathbb{E}e^{\lambda X}$, we obtain

$$\lambda\psi'(\lambda) - \psi(\lambda) \leq \frac{\lambda^2}{2m_{\mathrm{cv}}}.$$

The left side is λ^2 times the derivative of $\psi(\lambda)/\lambda$, whose limit at $\lambda = 0$ is $\mathbb{E}X$. Integrating from 0 to λ gives $\log \mathbb{E}e^{\lambda(X-\mathbb{E}X)} \leq \lambda^2/(2m_{\mathrm{cv}})$. This is the argument of Herbst; see [123, Section 2.3]. The exponential Markov inequality with $\lambda = m_{\mathrm{cv}}v$ gives

$$\mathbb{P}(|X - \mathbb{E}X| \geq v) \leq 2e^{-m_{\mathrm{cv}}v^2/2}. \tag{14.13}$$

The calculation is valid for either sign of λ on the bounded product. Integrating $4v^3$ times this tail bound gives

$$\|X\|_4 \leq C(1 + |\mathbb{E}X|). \tag{14.14}$$

In particular, the estimates below contain no factor equal to the radius of the product.

Step 3: the mixed derivative of the potential. Let $\theta_s = s\theta$ for $0 \le s \le 1$, let v_s be the corresponding comparison measure, and let $M(s) = \max_\alpha |\mathbb{E}_{v_s} w_\alpha|$, the maximum over scalar coordinates. In this proof, the running maximum $M(s)$ of the means should not be confused with the odd integer M. Since the product $\mathcal{K}_t$ does not depend on s, differentiating the finite positive integral by the quotient rule gives

$$\frac{d}{ds}\mathbb{E}_{v_s} w_\alpha = -\operatorname{Cov}_{v_s}(w_\alpha, \partial_s V_{\theta_s}), \tag{14.15}$$

and there is no boundary term.

In a classical monomial of total degree $k \ge 3$ in w, the derivative $D_w \partial_s V$ leaves $k-1$ fluctuation factors. We keep two of them in L^4 and bound the other $k-3$ by $p = R_{\mathrm{en}}/t$. By Hölder's inequality and (14.14), the L^2 norm of their product is at most $C(1+M(s))^2 p^{k-3}$, and the coupling factor of the monomial becomes

$$t^{k-2} p^{k-3} = t R_{\mathrm{en}}^{k-3}.$$

Since the derivative in the coarse field is taken in the fixed direction θ, the summation on a strictly smaller radius in Lemma 14.2 shows that the summed weighted majorant in the coarse field costs $C\|\theta\|_\infty$. A nonclassical term of degree one gives $Ct(1+E_*)\|\theta\|_\infty$ directly. A term of degree two gives $Ct^2(1+E_*)(1+M(s))\|\theta\|_\infty$, from its single L^2 factor. For degree $k \ge 3$ the preceding argument with two factors in L^4 gives the coupling factor $t^k p^{k-3} = t^3 R_{\mathrm{en}}^{k-3}$. Summing these convergent geometric series, and the weighted sums over the indices in the coarse field, we obtain the local weighted estimate

$$\sup_\alpha \|D_{w_\alpha} \partial_s V_{\theta_s}\|_{2,\mathrm{loc}} \le Ct\|\theta\|_\infty (1 + E_* + M(s)^2). \tag{14.16}$$

Here the local norm fixes the index α of the derivative in w and sums all coefficient labels and indices in the coarse field with their weights $e^{b\mathfrak{t}}$, and the L^2 norm is taken under v_s. This definition and the weighted coefficient bounds prevent a volume factor in this estimate.

Step 4: the mean bound. We apply the local covariance bound of Step 1 to (14.15). The gradient of w_α is the unit vector at α, and the exponentially weighted sum over the other index is finite by the bound on the number of labels in a ball. We obtain

$$\Big|\frac{d}{ds}\mathbb{E}_{v_s} w_\alpha\Big| \le Ct\|\theta\|_\infty (1 + E_* + M(s)^2).$$

At $s = 0$, every vector mean vanishes and $M(0) = 0$, since the potential and each color ball are invariant under simultaneous adjoint rotations. At fixed finite volume, the map

$s \mapsto M(s)$ is continuous. If $M(s)$ first reached the value one at some $s_0 \le 1$, integration up to s_0 would give $M(s_0) \le Ctr(2 + E_*) < 1/2$, after the corresponding reduction of t_* in Definition 14.4(6), a contradiction. Hence $M(s) < 1$ for all $s \in [0,1]$. Inserting this into the last differential inequality, we obtain $M(1) \le Ct\|\theta\|_\infty$. The constants may absorb the fixed E_*. This proves the mean bound in (1).

Step 5: the conditioning identity. By the description of the support and the density of the fiber in Theorem 14.6(5) and (7),

$$\kappa_c^{\mathrm{old}}(A) = \frac{v_c(A \cap S_c)}{v_c(S_c)}$$

for every Borel set A. The denominator is strictly positive, since $\Omega^{\mathrm{phys}}_{Q_{\mathrm{phys}}} \subset S_c$ has positive Lebesgue measure and the density of v_c is positive. This identity requires no convexity of S_c, and it proves the second statement of (1).

Step 6: tail bounds. We reduce t_* so that every scalar mean under v_c is at most $P_{\mathrm{phys}}/(2\sqrt{3}t)$ and at most $p_{\mathrm{w}}(t)/(2\sqrt{3})$. This is possible since the means are $O(tr)$ by Step 4, P_{phys} is a fixed positive multiple of r, and $p_{\mathrm{w}}(t) \ge p_0$. Let $a = P_{\mathrm{phys}}$ or $a = Q_{\mathrm{phys}}$. If $|w_{i,e}| \ge a/t$, then one of its three scalar coordinates has magnitude at least $a/(\sqrt{3}t)$, and hence deviates from its mean by at least $a/(2\sqrt{3}t)$. Applying (14.13) to both tails of each scalar coordinate and summing over the $3b_{\mathrm{w}}$ scalar coordinates, we obtain

$$v_c\big((\Omega_a^{\mathrm{phys}})^c\big) \le 6b_{\mathrm{w}} e^{-m_{\mathrm{cv}} a^2/(24t^2)}. \tag{14.17}$$

The same calculation with the threshold $p_{\mathrm{w}}(t)$ gives

$$v_c\big((\Omega_p^{\mathrm{w}})^c\big) \le 6b_{\mathrm{w}} e^{-m_{\mathrm{cv}} p_{\mathrm{w}}(t)^2/24} = \delta_t. \tag{14.18}$$

Now suppose $d_t < 1$. Since $\Omega^{\mathrm{phys}}_{Q_{\mathrm{phys}}} \subset S_c$, (14.17) with $a = Q_{\mathrm{phys}}$ implies $v_c(S_c) \ge 1 - d_t$. Dividing the bounds (14.17) with $a = P_{\mathrm{phys}}$ and (14.18) by this denominator and using Step 5, we obtain both bounds in (2), the second with exactly ϵ_t.

Step 7: density ratios. Let $C(c)$ denote the prefactor (14.9), as in (5), with the chosen convention for constants; it depends on c but not on w. By Theorem 14.6(2) and (7), on B_r we have

$$G(c) = C(c) \int_{S_c} e^{-V_c}\, dw, \qquad \widetilde{F}(c) = C(c) \int_{\Omega_p^{\mathrm{w}}} e^{-V_c}\, dw.$$

Since the cutoff product is a subset of S_c, dividing proves the identity in (3) without any smallness condition. If $d_t < 1$ and $\epsilon_t < 1$, then (2) implies the two-sided bound in (3). Both formulas are compatible with the orthogonal changes of representative of Theorem 14.3(3), and hence hold on D_r for this explicit density.

Step 8: total variation and failure of the next step. For the comparison of normalized measures and the failure bound, we assume only $d_t < 1$, so that ϵ_t is a nonnegative upper bound; the condition $\epsilon_t < 1$ is not needed. Let η be the joint law of the coarse field and the fluctuation variables under the uncut fiber densities, conditioned on $c \in D_r$, and let A be the event that $w \in \Omega_p^{\mathrm{w}}$. Integrating the second bound of (2) over c, we obtain $\eta(A^c) \le \epsilon_t$. For any probability measure η and any event A of positive probability, $\eta = \eta(A)\eta(\cdot \mid A) + \eta(A^c)\eta(\cdot \mid A^c)$, and the two conditional measures are carried by disjoint events. Hence

$$\sup_B |\eta(B) - \eta(B \mid A)| = \eta(A^c) \sup_B |\eta(B \mid A^c) - \eta(B \mid A)| = \eta(A^c).$$

Taking the image under a measurable map does not increase this distance, since an event for the coarse field pulls back to an event in the joint space. The images of η and $\eta(\cdot \mid A)$ under the projection to the coarse field are the two normalized measures in (4), so they differ in total variation by at most ϵ_t. For the failure bound, note that σ is carried by D_r. By Theorem 14.3 with $u = r$, and the reduction of r_{geom} in step (2) of Definition 14.4, every configuration $U \in D_r$ with $T_M^J U \in D_r$ satisfies the coordinate conditions of the step, so the next step can fail only if $T_M^J U \notin D_r$ or if $T_M^J U \in D_r$ and the fluctuation cutoff fails. The probability of the second event is $\sigma(T_M^J U \in D_r)\, \eta(A^c) \le \epsilon_t$. This proves (4).

Step 9: the larger coarse fields. We now prove (5), without using any inclusion of the cutoff product in S_c for coarse fields outside D_r. Since the fine side is $M^J m$ and the coarse side is $m \ge 4$, each averaging step has coarse side $M^{J-i-1} m \ge 4$. Moving an input configuration in D_r into B_r and applying Lemma 7.2 J times, we find, by gauge covariance, $T_M^J(D_r) \subset D_{R_{\mathrm{buf}}}$ with $R_{\mathrm{buf}} = (10M)^J r$. For $c \in B_{R_{\mathrm{buf}}}$, applying Theorem 14.3 with $u = R_{\mathrm{buf}}$ and using $D_r \subset D_{R_{\mathrm{buf}}}$, we obtain $|w_{i,e}| \le C_{\mathrm{TG}} R_{\mathrm{buf}}/(\lambda_* t)$ for every point of S_c. Since $\mathscr{L}'_{\mathrm{en}} > 2C_{\mathrm{TG}} C_{\mathrm{map},J}/\lambda_*$, the set S_c lies in the interior of $\mathcal{K}'_t$.

Both $\mathcal{K}'_t$ and the fluctuation cutoff domain satisfy the conditions fixed for the larger coarse fields in Definition 14.4. More precisely, by (14.12), we have $R_{\mathrm{buf}} + \mathscr{L}'_{\mathrm{en}} r < r_J$, the denominator of the majorant is at least $1/2$, and both radii lie in the products of step (2). Therefore the image condition of Theorem 13.2 also holds on this larger product. The Hessian argument of Theorem 14.6(6) applies with the physical radius $\mathscr{L}'_{\mathrm{en}} r$ in place of R_{en}, using the inequality for $C\mathscr{L}'_{\mathrm{en}} r$ in step (4) of Definition 14.4. Steps 2 to 4 apply with the coarse-field radius R_{buf} in place of r, with the fixed product and the weighted sums otherwise unchanged. These are the conditions imposed when choosing $r_{\max}$ and t_*. They give scalar means of size at most $Ct R_{\mathrm{buf}}$ and the tail bound (14.18) on the larger product, with the same exponent. With $H(c) = C(c) \int_{\mathcal{K}'_t} e^{-V_c}\, dw$ as in (5), the inclusion $S_c \subset \mathcal{K}'_t$ implies $G(c) \le H(c)$, also when S_c is empty. The ratio $\widetilde{F}(c)/H(c)$ is the probability of the cutoff product under the normalized measure on $\mathcal{K}'_t$, so the concentration bound gives

$\widetilde{F}(c)/H(c) \geq 1-\delta_t$, that is, $H(c) \leq \widetilde{F}(c)/(1-\delta_t)$ when $\delta_t < 1$. No inclusion of the cutoff product in S_c has been used outside D_r.

Step 10: the exit probability. Assume $\delta_t < 1$. The law of the coarse field under σ has density $G/\int G\,dH$, and by Step 9 it is carried by $D_{R_{\mathrm{buf}}}$. Its exit probability satisfies

$$\frac{\int_{D_{R_{\mathrm{buf}}}\setminus D_r} G\,dH}{\int_{D_{R_{\mathrm{buf}}}} G\,dH} \leq \frac{1}{1-\delta_t}\,\frac{\int_{D_{R_{\mathrm{buf}}}\setminus D_r} \widetilde{F}\,dH}{\int_{D_r} \widetilde{F}\,dH}.$$

In the numerator, we used the upper bound of Step 9, and in the denominator, we used $G \geq \widetilde{F}$ on D_r, from (3). Since $\widetilde{F} = A_{\mathrm{coord}} e^{-E_{d_0+J}/g_J^2 - R_+}$, the common constant A_{coord} cancels, and we obtain the ratio of the integrals Z_{aux} in (5). The same cancellation holds for any convention for centering.

Step 11: versions of the density and asymptotics. All pointwise statements used the explicit density given by the based coarea formula. Any other disintegration agrees with it almost everywhere on the set of coarse fields where it is positive, which gives the stated qualification. The explicit factor b_{w} cannot be absorbed into a constant independent of the volume. Along a refinement at fixed γ, we have $t^2 = \gamma/(Mm)$ and hence $m^3 = (\gamma/M)^3 t^{-6}$, so that

$$b_{\mathrm{w}} = 2(B^3-1)(\gamma/M)^3 t^{-6}.$$

With $x = \log(1/t)$, the logarithm of δ_t is at most $C + 6x - cA_{\mathrm{w}}^2 x^2$, which is below $-hx$ for every fixed $h > 0$ once x is large. The tail with a physical radius has the stronger exponent $-c/t^2$. Since the mesh is $L/m = (LM/\gamma)t^2$, both errors are smaller than every fixed power of the mesh along such a sequence, and the denominators $1-d_t$ tend to one. □

14.6 Partition-function bounds on the stopping lattice

After k RG steps, the stopped measure lives on the stopping lattice Λ_n, $n = n_{kJ}$, at depth $d = kJ$. This subsection bounds its partition function from below and the exponential moments of the Wilson action under it from above. It also compares effective classical actions with the Wilson action at every depth, records an exact identity for normalization constants, and bounds derivatives of the centered effective interactions in fixed charts. The lower bound is a trial integral over the same domain D_r as the stopped measure, in a periodic tree gauge with all non-tree link variables of size $a_0 g$. The upper bound enlarges only the numerator, to an integral over an open cube, for which Lemma 6.10 gives an explicit bound. The ranks of the two gauge-fixed integrals are as follows.

Integral	Group variables	Power of g
periodic tree trial inside D_r	$2n^3+1$	$g^{3(2n^3+1)}$
open cube, upper bound for the numerator	$2n^3-3n^2+1$	$g^{3(2n^3-3n^2+1)}$
ratio	difference $3n^2$	g^{-9n^2}

Since the numerator and the denominator are each estimated once, the boundary term $9n^2\log(1/g)$ appears once. These bounds, obtained by elementary gauge integration, are in the tradition of the stability estimates of Faria da Veiga and O'Carroll [64, 65]; here we need the precise periodic correction.

Theorem 14.8. *Use the parameters of Definition 14.4. There are $\kappa_*, a_0, g_* > 0$ and $C_A, C_R, C_\# > 0$, independent of the side $n \geq 4$, of the depths $d = kJ$ reached by the recursion, of the number of RG steps, and of $0 < g \leq g_*$, with the following properties. The integration domain is exactly D_r on the stopping lattice Λ_n. Let $R = R_k$ be the effective interaction of Theorem 14.6 at depth $d = kJ$, and put*

$$D = 3n^3, \qquad b_n = 2n^3+1, \qquad c = R(I), \qquad \overline{R} = R - c,$$

$$F_g = \frac{E_0}{g^2} = \frac{4}{g^2}\sum_p q(U_p), \qquad Z^{\mathrm{raw}} = \int_{D_r} e^{-E_{d,\mathrm{sat}}/g^2 - R_{\mathrm{sat}}}\, dH_n, \qquad \widehat{Z}_1 = e^c Z^{\mathrm{raw}}.$$

Here D is the number of links, and c is a constant, not a coarse field.

1. *For every integer $d \geq 0$, $E_{d,\mathrm{sat}} \geq \kappa_* E_0$ on the gauge-invariant extension of the larger classical domain, whether or not an effective interaction is attached to the depth d.*
2. *For the effective interactions of the stopped measures, $|\overline{R}| \leq C_R D E_* \rho^2$ on D_r. On the trial set of configurations which, in a periodic spanning tree gauge based at a root, have every non-tree link logarithm of norm at most $a_0 g < \min(r/2, 1)$,*

$$E_d \leq C_A D a_0^2 g^2, \qquad |\overline{R}| \leq C_R D E_* a_0^2 g^2,$$

$$Z^{\mathrm{raw}} \geq \Big(\frac{a_0 g - \sin(a_0 g)}{2\pi}\Big)^{b_n} e^{-c - C_A D a_0^2 - C_R D E_* a_0^2 g^2}.$$

3. *Let $\widehat{\nu} = \widehat{Z}_1^{-1} \mathbf{1}_{D_r} e^{-E_d/g^2 - \overline{R}}\, dH_n$ be the stopped measure, and put $\lambda_{\mathrm{en}} = \kappa_*/2$. Then*

$$\widehat{\nu}(F_g \geq u) \leq \exp(C_\# D + 9n^2\log(1/g) - \lambda_{\mathrm{en}} u), \qquad u \geq 0,$$

$$\mathbb{E}_{\widehat{\nu}} e^{sF_g} \leq \exp(C_\# D + 9n^2\log(1/g)), \qquad 0 \leq s \leq \lambda_{\mathrm{en}},$$

$$\mathbb{E}_{\widehat{\nu}} F_g \leq [C_\# D + 9n^2\log(1/g) + 1]/\lambda_{\mathrm{en}}.$$

The open cube with n vertices per side has rank $b_n^{\mathrm{op}} = 2n^3 - 3n^2 + 1$. Only an upper bound for a numerator is enlarged to the Haar integral over this open cube; the denominator remains the trial integral over D_r. The unmatched power of the coupling is exactly $g^{-3(b_n - b_n^{\mathrm{op}})} = g^{-9n^2}$.

4. *Fix $0 < \lambda_0 \le 1$, let $\lambda \in [\lambda_0, 1]$, and put*

$$\widehat{Z}_\lambda = \int_{D_r} e^{-\lambda E_d/g^2 - \lambda \overline{R}}\, dH_n, \qquad d\tau^{(\lambda)} = \widehat{Z}_\lambda^{-1} \mathbf{1}_{D_r} e^{-\lambda E_d/g^2 - \lambda \overline{R}}\, dH_n.$$

   After one reduction of g_* depending on λ_0, for $0 \le s \le \lambda_0 \kappa_*/2$,

$$\log \mathbb{E}_{\tau^{(\lambda)}} e^{sF_g} \le CD + 9n^2 \log(1/g), \qquad \log\Big\{ \frac{\widehat{Z}_\lambda}{\widehat{Z}_1} \mathbb{E}_{\tau^{(\lambda)}} e^{sF_g} \Big\} \le CD + 9n^2 \log(1/g).$$

   The second bound is obtained from one numerator and one denominator, not as the sum of bounds for the two factors.

5. *For every fixed $\alpha_0 > 0$ and $0 < \lambda_0 \le \lambda \le \lambda_1 < \infty$,*

$$\log \frac{\int_{\mathcal{U}_n} e^{-(\lambda\alpha_0 - s)F_g}\, dH_n}{\widehat{Z}_1} \le C_{\lambda_0,\lambda_1,\alpha_0} D + 9n^2 \log(1/g), \qquad 0 \le s \le \lambda_0 \alpha_0/2,$$

   where g_* is reduced so that the effective inverse coupling $4(\lambda\alpha_0 - s)/g^2$ is at least one. No condition on charts or small fields is imposed on this numerator.

6. *Let an initial probability density with unnormalized normalizing constant $\mathcal{Z}_{\mathrm{base}}$ be restricted by the small-field tests and pushed forward by finitely many RG steps of Theorem 14.6 to the lattice Λ_n, and suppose that the resulting subprobability measure is written in the centered convention as*

$$d\xi_T = \mathcal{Z}_{\mathrm{base}}^{-1} e^{\Lambda_T^{\mathbb{T}}} \mathbf{1}_{D_r} e^{-E_d/g^2 - \overline{R}}\, dH_n, \qquad p_T = \xi_T(\mathcal{U}_n) \le 1.$$

   Then, exactly,

$$\frac{e^{\Lambda_T^{\mathbb{T}}}}{\mathcal{Z}_{\mathrm{base}}} = \frac{p_T}{\widehat{Z}_1} = \frac{p_T e^{-c}}{Z^{\mathrm{raw}}} \le \widehat{Z}_1^{-1}.$$

   All normalization factors of integrated Gaussian coordinates, coarea constants, constant terms of cluster expansions, and constants removed from effective interactions belong to this same normalization constant $\Lambda_T^{\mathbb{T}}$.

7. *The constants depend only on the parameters of the recursion, the constants of Theorem 11.2 and Lemma 6.10, and the displayed parameters $\lambda_0, \lambda_1, \alpha_0$. For every fixed $\gamma_0 > 0$, one minimum side makes these estimates hold simultaneously for $g^2 = \gamma/n$, all $0 < \gamma \le \gamma_0$, and every larger side. The estimates involve no block regions.*

8. *The effective interactions $R_{d,\gamma} = R_k$ satisfy $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_{d,\gamma}) \le E_*$ and $DR_{d,\gamma}(I) = 0$, and they are gauge invariant on overlaps, as in Theorem 14.6. Fix a side n, a number $0 < \eta < 1$, and a finite family of smooth charts Ψ_α of configurations on Λ_n, defined on parameter domains $\widetilde{W}_\alpha$, with relatively compact subdomains $W_\alpha \Subset \widetilde{W}_\alpha$ and smooth based gauge transformations, such that the charts and the gauge transformations extend smoothly to neighborhoods of the*

closures $\overline{W}_\alpha$ and the gauge-transformed representatives of $\Psi_\alpha(y)$, $y \in W_\alpha$, lie in $B_{(1-\eta)\rho}$. Then every derivative of fixed positive order of $\overline{R}_{d,\gamma,\mathrm{sat}} \circ \Psi_\alpha$ on W_α is bounded uniformly in $d = kJ$ and $0 < \gamma \le \gamma_0$. In link logarithms, the bound of order $j \ge 1$ in the weighted norm is $C_j E_* \rho^{2-j} \eta^{-j}$, with $C_j = j!$. Passing to a fixed chart costs its fixed derivative bounds and a norm conversion in fixed finite dimension. The charts are composed with fixed smooth gauge transformations, never with a differentiated Borel selection of gauges. The constants may depend on n, j, η, the charts, and the larger domains, but not on the depth or the coupling.

9. *The law of the coarsest field $V^{KJ} = T_M^{KJ} U$, a configuration on Λ_u, under the conditioned Wilson measure $\nu_{N,u,\gamma}$ is the stopped measure after all K RG steps.*

Part (1) holds at every integer depth, and part (8) gives bounds on derivatives from the analytic coefficient norm itself; a bound on the oscillation of $\overline{R}$ alone would not control its derivatives. Any later comparison of normalization constants on block regions must be made with the normalization constant $\Lambda_T^{\mathbb{T}}$ of part (6) on the whole torus.

Proof. Step 1 relates the stopping lattice to the recursion. Steps 2 and 3 prove (1) and the first bound in (2). Step 4 proves the trial lower bound, and Step 5 the open-cube upper bound. Steps 6 to 8 combine them to prove (3) to (5), Step 9 proves (6), and Step 10 proves (7). Steps 11 and 12 prove (8), and Step 13 proves (9).

Step 1: depths and couplings. At a depth $d = kJ$, the effective interaction in this proof is the function $R_{d,\gamma} = R_k$ of Theorem 14.6, in its chosen convention for constants. By that theorem, it is holomorphic on B_ρ and gauge invariant on overlaps, with $DR_{d,\gamma}(I) = 0$ and $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_{d,\gamma}) \le E_*$, uniformly in k and in the coupling. Its real density is the stopped density on D_r. Subtracting the value at the identity changes no derivative of positive order and no analytic norm. We take g_* so small that $g_*/\sqrt{M} \le t_*$. Since $g_J^2 = Mt^2$, at the stopping coupling g the largest integrated coupling of the last RG step is $g/\sqrt{M}$, and all earlier integrated couplings are smaller. This implies that every run of the recursion in the theorem satisfies the conditions on the coupling in Definition 14.4; with zero RG steps there is no such condition.

Step 2: the classical lower bound. We apply the comparison of Theorem 11.2 at one stopping field and one mesh, for every integer depth, without reference to an effective interaction. With the larger radius r_{C} fixed in Section 14.2, the comparison product of that theorem satisfies

$$P_\infty \le \exp\Big(C r_{\mathrm{C}} \sum_{j \ge 0} M^{-2(j+1)} \Big) < \infty.$$

We conclude that $E_d \ge \kappa_* E_0$ with $\kappa_* = P_\infty^{-1}$. For an argument in the gauge-invariant extension of the classical domain, we fix a gauge transformation taking it into the corresponding classical ball inside $B_{r_{\mathrm{C}}}$ and use the clause of Theorem 11.2 on transport by a fixed gauge transformation. Theorem 11.6 identifies the transported values with $E_{d,\mathrm{sat}}$

for every $d \geq 0$, while E_0 is gauge invariant. This proves (1) on the whole gauge-invariant domain and at every integer depth. Only the assertions involving $R_{d,\gamma}$ restrict the depth to the values $d = kJ$ reached by the recursion. If the larger radius requires a smaller κ_*, it is fixed before the final reductions of the coupling bound.

Step 3: oscillation of the effective interaction. Let $A_s \geq 0$ denote the summand of order s in the weighted coefficient norm of R, so that $\sum_{s\geq 2} A_s \leq E_*$. For $\|\xi\|_\infty \leq \epsilon \leq \rho$ we expand $R(e^\xi) - R(I)$, fix one scalar link and color label in each coefficient, and sum the remaining labels. Since there are $3D$ choices of the fixed label and the spatial weights are at least one, absolute summation of the Taylor series gives

$$|R(e^\xi) - c| \leq C_R D\epsilon^2 \sum_{s\geq 2} A_s(\epsilon/\rho)^{s-2} \leq C_R D E_* \epsilon^2. \tag{14.19}$$

By gauge invariance on overlaps, this bound holds at every representative. With $\epsilon = r < \rho$, we obtain the bound $|\overline{R}| \leq C_R D E_* \rho^2$ on D_r. No estimate of c is involved.

Step 4: the trial lower bound. We choose a spanning tree of the periodic lattice graph and a root. By Lemma 5.1, the integral of a gauge-invariant integrand over a gauge-invariant set is an integral over exactly $b_n = D - (n^3 - 1) = 2n^3 + 1$ independent non-tree link variables, each with the Haar probability measure; the tree variables have total mass one, no root variable is integrated, and no volume factor of a stabilizer appears. We fix $a_0 > 0$ and reduce g_* so that $\epsilon = a_0 g < \min(r/2, 1)$ for all $0 < g \leq g_*$. Since all tree-fixed logarithms on the trial set are at most ϵ, the trial set lies strictly inside the same domain D_r. By the upper bound of Theorem 11.2 at radius ϵ, we have $E_d \leq C_A D\epsilon^2$ uniformly in d and n, and (14.19) implies $|\overline{R}| \leq C_R D E_* \epsilon^2$. By (4.2), the exact Haar mass of the ball for one non-tree link is

$$m(\epsilon) = \frac{1}{16\pi^2} \int_{|X|<\epsilon} \operatorname{sinc}^2(|X|/2)\, d^3X = \frac{1}{\pi} \int_0^\epsilon \sin^2(s/2)\, ds = \frac{\epsilon - \sin\epsilon}{2\pi}.$$

Integrating the lower bound for the density over the product of these b_n balls gives the lower bound for Z^{raw} in (2), with the factor e^{-c} kept.

We will use the weaker form

$$\widehat{Z}_1 \geq e^{-C_L D} g^{3b_n}. \tag{14.20}$$

To prove it, note that $\operatorname{sinc}(s/2) \geq \operatorname{sinc}(1/2) > 0$ for $0 \leq s \leq 1$, since the numerator $x\cos x - \sin x = -\int_0^x y \sin y\, dy$ of the derivative of $\sin x/x$ is nonpositive on $[0, 1/2]$. The radial integral therefore gives $m(\epsilon) \geq c_{\mathrm{ball}}\epsilon^3$, with $c_{\mathrm{ball}} = \operatorname{sinc}^2(1/2)/(12\pi)$. Since $b_n \leq D$ and $g_* \leq 1$, all fixed factors in the trial bound have logarithms bounded in absolute value by a fixed multiple of D. This proves (14.20).

Step 5: the open-cube upper bound. For $\alpha \geq \alpha_{\min} > 0$, let

$$I_\alpha(g) = \int_{\mathcal{U}_n} e^{-\alpha F_g}\, dH_n.$$

Since $q \geq 0$, deleting every plaquette that crosses a periodic seam can only increase the integrand. The remaining complex has n vertices per direction, $3(n-1)n^2$ links, and n^3 vertices, so its tree rank is

$$b_n^{\mathrm{op}} = 3(n-1)n^2 - n^3 + 1 = 2n^3 - 3n^2 + 1.$$

Each unused seam link contributes a Haar probability integral equal to one. Lemma 6.10, applied to this open cube at inverse coupling $\beta = 4\alpha/g^2$, which is legitimate when $4\alpha_{\min}/g_*^2 \geq 1$, gives

$$I_\alpha(g) \leq c_G^{b_n^{\mathrm{op}}} (4\alpha/g^2)^{-3b_n^{\mathrm{op}}/2} \leq e^{C_U D} g^{3b_n^{\mathrm{op}}}, \tag{14.21}$$

where $c_G = \sqrt{2/\pi}$ is the constant of that lemma. The constant C_U depends on $\alpha_{\min}$ and c_G, and is independent of n, d, and g.

Step 6: moments under the stopped measure. We use (1) and the oscillation bound of Step 3 in the numerator. For $0 \leq s \leq \lambda_{\mathrm{en}} = \kappa_*/2$ we have $-E_d/g^2 + sF_g \leq -(\kappa_* - s)F_g$, and hence

$$\int_{D_r} e^{-E_d/g^2 - \overline{R} + sF_g}\, dH_n \leq e^{C_R D E_* \rho^2} I_{\kappa_* - s}(g) \leq e^{C_U D} g^{3b_n^{\mathrm{op}}},$$

after including the oscillation constant in C_U. Here $\alpha_{\min} = \kappa_*/2$ works, including at the endpoint $s = \lambda_{\mathrm{en}}$. Dividing by (14.20) leaves exactly

$$3(b_n - b_n^{\mathrm{op}}) = 9n^2$$

unmatched powers of g^{-1}. This proves the bound on the exponential moment in (3), with $A = C_\# D + 9n^2 \log(1/g)$, after enlarging $C_\#$ if necessary. The exponential Markov inequality at $s = \lambda_{\mathrm{en}}$ gives the tail bound. Since $A \geq 0$, integrating the minimum of the tail bound and one gives

$$\mathbb{E}_{\widehat{\nu}} F_g \leq \int_0^\infty \min(1, e^{A - \lambda_{\mathrm{en}} u})\, du = \frac{A+1}{\lambda_{\mathrm{en}}}.$$

The exponential moment at the endpoint $s = \lambda_{\mathrm{en}}$ was proved through its defining integral, not by integrating a tail bound. In the uncentered convention, the same factor e^{-c} appears in the numerator and in the denominator and cancels.

Step 7: tempered measures. Fix $\lambda_0 \leq \lambda \leq 1$. On the same tree trial set, the exponent $\lambda E_d/g^2 + \lambda \overline{R}$ is bounded above by CD, uniformly in λ, and hence

$$\widehat{Z}_\lambda \geq e^{-CD} g^{3b_n}. \tag{14.22}$$

For $0 \le s \le \lambda_0\kappa_*/2$, the numerator is bounded above by

$$e^{CD} I_{\lambda\kappa_* - s}(g) \le e^{CD} g^{3b_n^{\mathrm{op}}}, \qquad \lambda\kappa_* - s \ge \lambda_0\kappa_*/2,$$

and one fixed reduction of g_* makes the inverse coupling of Lemma 6.10 at least one throughout this interval. Dividing by (14.22) gives the first bound in (4). For the second bound, we keep the exact identity

$$\frac{\widehat{Z}_\lambda}{\widehat{Z}_1} \mathbb{E}_{\tau^{(\lambda)}} e^{sF_g} = \frac{\int_{D_r} e^{-\lambda E_d/g^2 - \lambda\overline{R} + sF_g}\, dH_n}{\widehat{Z}_1},$$

and use the last upper bound for the numerator and (14.20), once each. The difference of ranks is still $3n^2$, so the exponent is again $9n^2 \log(1/g)$. Estimating the two factors on the left separately would count this term twice.

Step 8: the unrestricted numerator. Let $\alpha = \lambda\alpha_0 - s \ge \lambda_0\alpha_0/2$. Applying (14.21) to the unrestricted Wilson numerator and (14.20) to $\widehat{Z}_1$ proves (5), after the corresponding fixed reduction of g_*. The constants may depend on λ_0, λ_1, and α_0, but not on the depth or the side.

Step 9: the identity for normalization constants. Integrating the subprobability measure in (6) gives exactly

$$p_T = \mathcal{Z}_{\mathrm{base}}^{-1} e^{\Lambda_T^{\mathbb{T}}} \widehat{Z}_1.$$

Both $\mathcal{Z}_{\mathrm{base}}$ and $\widehat{Z}_1$ are positive. The total mass p_T is at most one, since restricting a probability measure and pushing it forward cannot increase its total mass. Solving this equality, and using $\widehat{Z}_1 = e^c Z^{\mathrm{raw}}$, proves the identities and the inequality in (6). Removing a Gaussian coordinate, a reference Haar disintegration factor, a constant term, or the constant of an effective interaction changes the representation of the density and the normalization constant together; it cannot change this identity for the total mass.

Step 10: uniformity in the coupling. All constants so far were chosen from the parameters of the recursion and the constants of Theorem 11.2 and Lemma 6.10. For a fixed $\gamma_0 > 0$, we take a minimum side at least γ_0/g_*^2, rounded up to an integer, and to a multiple of four when the RG steps require it. Then $g^2 = \gamma/n \le g_*^2$ for every larger side and every $0 < \gamma \le \gamma_0$. Since the earlier integrated couplings of the recursion are smaller, the same reductions hold at every depth. This proves (7).

Step 11: derivatives in link logarithms. We write $\mathcal{R}_{d,\gamma}(\xi) = R_{d,\gamma}(e^\xi) - R_{d,\gamma}(I)$ and

$$A_{k,d,\gamma} = \frac{\rho^{k-2}}{k!} \|D^k \mathcal{R}_{d,\gamma}(0)\|_{a_{\mathrm{sp}},\mathrm{root}}, \qquad \sum_{k\ge 2} A_{k,d,\gamma} \le E_*.$$

Let $j \geq 1$, $v = 1 - \eta$, and $\|\xi\|_\infty \leq v\rho$. We differentiate the absolutely convergent Taylor series on this strictly smaller ball. Contracting its $k - j$ undifferentiated indices does not increase the weight of the network on the remaining indices, so

$$\|D^j \mathcal{R}_{d,\gamma}(\xi)\|_{a_{\mathrm{sp}},\mathrm{root}} \leq \rho^{2-j} \sum_{k \geq \max(2,j)} A_{k,d,\gamma} \frac{k!}{(k-j)!} v^{k-j}.$$

Each multiplier satisfies

$$\frac{k!}{(k-j)!} v^{k-j} = j! \binom{k}{j} v^{k-j} \leq j! \eta^{-j},$$

because $\binom{k}{j}\eta^j v^{k-j}$ is one nonnegative term of $(\eta + v)^k = 1$. It follows that

$$\|D^j \mathcal{R}_{d,\gamma}(\xi)\|_{a_{\mathrm{sp}},\mathrm{root}} \leq j! E_* \rho^{2-j} \eta^{-j} \qquad (j \geq 1). \tag{14.23}$$

The uncontrolled constant $R_{d,\gamma}(I)$ disappears through differentiation; no derivative bound is deduced from the oscillation bound alone.

Step 12: derivatives in charts. For $y \in W_\alpha$, we write the gauge-transformed representative of $\Psi_\alpha(y)$ as $e^{\xi_\alpha(y)} \in B_{(1-\eta)\rho}$. The chart, the subdomain, and the gauge transformation are fixed independently of d and γ. By continuity, the extended representatives on $\overline{W}_\alpha$ lie in the closed ball of radius $(1 - \eta)\rho$, strictly inside the domain of the logarithm, and compactness gives a neighborhood of $\overline{W}_\alpha$ on which the same logarithm is smooth. For $1 \leq h \leq j$, let

$$C_{\alpha,h} = \sup_{y \in \overline{W}_\alpha} \|D^h \xi_\alpha(y)\|_{\mathrm{op},\infty} < \infty;$$

finiteness follows from continuity of these derivatives on the compact closure. The derivatives of the gauge transformation, of the group multiplication, and of the logarithm are included in these constants. By gauge invariance on overlaps, $\overline{R}_{d,\gamma,\mathrm{sat}} \circ \Psi_\alpha = \mathcal{R}_{d,\gamma} \circ \xi_\alpha$ on W_α. The chain rule for higher derivatives gives one term for each partition π of $\{1, \ldots, j\}$, with outer derivative $D^{|\pi|}\mathcal{R}_{d,\gamma}$ and inner factors $D^{|B|}\xi_\alpha$, $B \in \pi$; this follows by induction, since a new derivative either joins an existing block or forms a new singleton block. Since there are $9n^3$ scalar link and color labels, fixing the first outer index and summing the others bounds a full contraction by $9n^3$ times the weighted norm. Using (14.23), we obtain

$$\|D^j(\overline{R}_{d,\gamma,\mathrm{sat}} \circ \Psi_\alpha)\|_{\mathrm{op}} \leq 9n^3 E_* \sum_\pi |\pi|! \, \rho^{2-|\pi|} \eta^{-|\pi|} \prod_{B \in \pi} C_{\alpha,|B|}. \tag{14.24}$$

Every factor on the right is fixed before the depth and the coupling vary, and for a finite family of charts we take the maximum. To cover a compact subset of the gauge-invariant

domain with this interior property, we choose at each of its points a local chart and a fixed gauge transformation whose representatives stay in $B_{(1-\eta)\rho}$. Since these conditions are open, there exists a smaller parameter neighborhood with compact closure inside the chart on which they still hold. These neighborhoods cover the compact set, and a finite subcover gives subcharts of the required kind, with extensions of the charts and gauge transformations past their closures. We include the derivatives of their logarithmic charts in the same maximum. This proves (8).

Step 13: the coarsest marginal. At the coarsest lattice Λ_u, no tests of coarser RG steps remain. The small-field event is then exactly the event whose normalized pushforward defines the stopped density after K steps, so the law of V^{KJ} under $\nu_{N,u,\gamma}$ is this stopped measure. □

14.7 Flat configurations

A configuration U is flat if $U_p = I$ for every plaquette p. Flat configurations are the minima of the Wilson action, and the weak-coupling analysis of Sections 33 to 36 takes place near them. The lemma below first records the classification of flat configurations on a periodic lattice by their holonomies; this is the usual description of flat connections on $\mathbb{T}_L^3$ by representations of $\pi_1(\mathbb{T}_L^3) = \mathbb{Z}^3$, and we include an elementary proof on the lattice. The rest of the lemma is specific to our construction: all flat configurations, including those whose holonomies form one of the eight central triples, satisfy every test of the small-field event, with vanishing fluctuation variables, once the coarse side is large. The reason is that a flat configuration is gauge equivalent to a constant configuration with link variables $e^{H_i^{\log}/n}$, which are close to the identity when n is large, although the holonomies $e^{H_i^{\log}}$ around the cycles of the torus can be far from it.

Lemma 14.9. *1. On every periodic lattice Λ_n, the flat configurations modulo periodic lattice gauge transformations are classified by their commuting holonomies around the three coordinate cycles, up to simultaneous conjugation:*

$$\mathrm{Hom}(\mathbb{Z}^3, \mathrm{SU}(2))/\mathrm{SU}(2) \simeq (\mathbb{R}/4\pi\mathbb{Z})^3/\{\boldsymbol{\vartheta} \sim -\boldsymbol{\vartheta}\},$$

where $\boldsymbol{\vartheta}$ parametrizes the triple $(e^{\vartheta_1 u}, e^{\vartheta_2 u}, e^{\vartheta_3 u})$ for a unit vector $u \in \mathfrak{su}(2)$. There are exactly eight central points, the central triples, at which each coordinate is 0 or 2π modulo 4π. Every flat configuration is gauge equivalent to a configuration with constant commuting link variables $e^{H_i^{\log}/n}$ in direction i, where the $H_i^{\log} \in \mathfrak{su}(2)$ commute, $|H_i^{\log}| \le 2\pi$, and $e^{H_i^{\log}}$ are the cycle holonomies. The block averaging map T_M raises these link variables to their Mth powers and preserves the three cycle holonomies. Taking commuting Mth roots gives exact flat refinements.

2. *Fix $r_{\mathrm{flat}} > 0$ strictly smaller than r and than the radii of all real coordinate charts and gauge transformations of one RG step fixed in Definition 14.4. If the coarse side u satisfies $2\pi/u < r_{\mathrm{flat}}$, then, for every $K \geq 0$, $N = uB^K$, and every coupling allowed by Definition 14.4, every flat configuration on Λ_N belongs to the small-field event $S_{N,u,\gamma}$. In the successive based forests the coarse-field lift is flat, and*

$$z_i = 0, \qquad z_i^*(c_{i+1}) = 0, \qquad w_i = 0, \qquad E_{d,\mathrm{sat}}(c_i) = 0$$

at every intermediate scale and every depth d. The same holds for products of fluctuations of any positive physical radius that fit the fixed domains. All initial and coarse D_r tests and all intermediate classical and coarea conditions hold. Changes of representative based at the coarse vertices preserve the holonomies and the membership in the event. The gradient of the Wilson action vanishes at flat configurations, so they are stationary for the Wilson flow, and their three cycle holonomies are unchanged at every time.

3. *Under the side and parameter hypotheses of (2), at each fixed finite $N = uB^K$ and each allowed coupling, the compact set of flat configurations has an open neighborhood contained in $S_{N,u,\gamma}$; equivalently, there is $\delta_{N,u,\gamma} > 0$ with*

$$\{\max_p \rho_G(U_p) < \delta_{N,u,\gamma}\} \subset S_{N,u,\gamma}.$$

No bound on $\delta_{N,u,\gamma}$ uniform in N or in the coupling is asserted. Separately, on a fixed stopping lattice whose side n satisfies $2\pi/n < r_{\mathrm{flat}}$, the set of flat configurations lies in the open set D_r, with a neighborhood that depends only on n and r, not on the depth or the coupling.

No central triple is removed, and no projectively commuting or twisted flat data are introduced: all gauge transformations are periodic and all cycle holonomies commute.

Proof. Steps 1 to 4 prove (1), Steps 5 to 8 prove the membership statement in (2), Step 9 proves the statement on the Wilson flow, and Step 10 proves (3).

Step 1: path independence. We lift the periodic configuration to $\mathbb{Z}^3$. If all plaquette variables are the identity, the transport along a path is unchanged when an edge followed by its reverse is deleted, and when two adjacent coordinate steps are replaced by the other two sides of their elementary square. These moves connect any two paths with the same endpoints in $\mathbb{Z}^3$: one interchanges neighboring steps in different directions until the steps are grouped in coordinate order, and then cancels opposite steps in each group. This implies that a path and its reverse define inverse transports, and the transport $P_U(x)$ from the origin to a vertex x of the lift does not depend on the path.

Step 2: the holonomy triple. The cycle holonomies are $P_U(ne_i)$. By periodicity, the transport from ne_i to $ne_i + ne_j$ equals $P_U(ne_j)$, so path independence applied to the two orders of going around the i and j directions implies $P_U(ne_i)P_U(ne_j) = P_U(ne_j)P_U(ne_i)$.

A periodic loop whose lift ends at $n(k_1, k_2, k_3)$ has transport $P_U(ne_1)^{k_1} P_U(ne_2)^{k_2} P_U(ne_3)^{k_3}$. A periodic gauge transformation conjugates the triple by its value at the origin.

A commuting triple in SU(2) lies in one maximal torus. Indeed, suppose that one of the matrices is not central. Then it is unitarily diagonalizable with two distinct eigenvalues, and a matrix commuting with it preserves both eigenlines and is diagonal in this basis. The determinant condition then puts all three diagonal matrices in the same circle. If all three are central, any orthonormal basis works. Hence we can choose commuting logarithms $H_i^{\log} \in \mathfrak{su}(2)$ with $e^{H_i^{\log}} = P_U(ne_i)$ and $|H_i^{\log}| \le 2\pi$, and we set $a_i = e^{H_i^{\log}/n}$.

Step 3: an explicit gauge equivalence. Let $P_a(x)$ be the transport of the constant configuration with link variables a_i on $\mathbb{Z}^3$, and set $k_x = P_a(x)^{-1} P_U(x)$. By flatness and periodicity, we have $P_U(x + ne_i) = e^{H_i^{\log}} P_U(x)$, and the same identity holds for P_a, since $a_i^n = e^{H_i^{\log}}$. Since the two factors cancel in k_{x+ne_i}, the gauge transformation k is periodic. On an edge xy, we have $P_U(y) = P_U(x) U_{xy}$, so

$$k_x U_{xy} k_y^{-1} = P_a(x)^{-1} P_U(x) U_{xy} P_U(y)^{-1} P_a(y) = P_a(x)^{-1} P_a(y) = a_{xy}.$$

This gauge transformation is the identity at the origin. Conversely, a constant commuting configuration is flat and has the given cycle holonomies. Hence two flat configurations with the same based holonomy triple are equivalent under a gauge transformation based at the origin, and flat configurations modulo all periodic gauge transformations are classified by their triples modulo simultaneous conjugation.

Step 4: the angle coordinates. Writing the common element of the Cartan subalgebra as a multiple of a unit vector u gives the three angles, which have period 4π in our normalization. A change of the common eigenbasis either fixes the two eigenlines or interchanges them, and the interchange reverses all three angles. There is no independent change of sign for a single noncentral coordinate. At a central triple each angle is 0 or 2π modulo 4π, which gives exactly $2^3 = 8$ points. The sign involution fixes these points and removes none of them. This proves the stated quotient, including the central points.

For constant commuting link variables, every displaced contour in (4.3) and its straight reference path have the same net displacement Me_i, and hence the same transport a_i^M. The corresponding based loop holonomy is the identity, so the block averaging map involves no exceptional logarithm and returns a_i^M. The holonomy around a cycle of the coarse lattice is $(a_i^M)^{n/M} = a_i^n$, so the three cycle holonomies are preserved. Taking $a_i = e^{H_i^{\log}/(Mn')}$ refines a constant configuration on the lattice of side n' exactly to the lattice of side Mn'. This completes the proof of (1).

Step 5: flat lifts. We now check the minimizer and the membership statements on the larger classical products of Section 14.2. The coarse-field lift $U_0(c)$ of a flat coarse field

c is flat. Indeed, a fine plaquette inside one block has only identity factors, a plaquette crossing one interface has two equal and opposite interface factors, and a plaquette crossing two interfaces has exactly the four factors of a coarse plaquette. In all three cases, the product is the identity.

Step 6: zero classical action. For a constant commuting coarse field on a lattice of side n, there exists a zero-action configuration at every depth d, obtained by placing $e^{H_i^{\log}/(nM^d)}$ on the links of the finer lattice. Its logarithmic potential in units of the coarse lattice is the constant $H_i^{\log}/n$, with vanishing differences. Since the coarse link logarithms have norm at most $2\pi/n < r_{\text{flat}}$, this configuration, together with all the fixed changes of chart and of gauge, lies strictly inside the domains of the classical minimization. Its Wilson action is zero. Since the effective classical action is nonnegative and is defined as a constrained minimum, its value at this coarse field is zero at every depth. To transport this value to the coarse-field lift, we use Theorem 11.6: by the choice of r_{flat}, the constant representative and the forest-fixed representative both lie strictly inside B_{r_C}.

Step 7: vanishing fluctuation variables. Consider one averaging step. The block-tree gauge transformation of the constant configuration is based at every coarse vertex. If $x = v + \mathsf{r}$ lies in the centered block of the coarse vertex v, the value of this gauge transformation there is $\prod_j a_j^{\mathsf{r}_j}$. On a link inside a block, the commuting factors cancel to the identity. On an interface link in direction i, the offsets of the two endpoints differ by $1 - M$ in the ith coordinate, and the transformed value is $a_i^M = c_i$. Hence the forest-fixed configuration is exactly $U_0(c)$, and all its relative logarithms, including those of the eliminated edges, vanish. Its free coordinate is $z = 0$, which is a zero of the nonnegative function $F_d(c, \cdot)$ on the branch. The strict convexity and the uniqueness in Lemma 14.1 force $z_d^*(c) = 0$, and the normalization by the positive square root of K_d then gives $w = 0$. This proves the statement on minimizers.

Step 8: all tests. At every scale with side $n_s \geq u$, the constant link variables have logarithms of norm at most $2\pi/n_s \leq 2\pi/u < r_{\text{flat}} < r$. This proves the initial and coarse D_r tests, with strict inequality. The choice of r_{flat} below the radii of all fixed charts and gauge transformations of one RG step gives every intermediate classical, constraint-coordinate, and coarea condition. There are no further D_r tests at intermediate scales, and every product of fluctuation balls of positive radius contains the zero vector. These facts hold for every number of RG steps, since the smallest coarse side controls the same inequalities at each step. An arbitrary flat configuration is periodically gauge equivalent to such a constant configuration, and the coordinate transitions on overlaps and the gauge invariance of the event (Lemma 14.5) carry the membership over to it. A change of representative based at the coarse vertices leaves the based cycle holonomies fixed and preserves the norms of the fluctuation variables and the event. A change at the common

root only conjugates the triple simultaneously.

Step 9: the Wilson flow. We vary one link in a Lie algebra direction. At a flat configuration, each differentiated plaquette variable is the identity, and its derivative is tangent to $\mathrm{SU}(2)$ at the identity, hence traceless. Thus $Dq(I) = 0$, every summand of the gradient of the Wilson action vanishes, and the constant trajectory solves the Wilson flow equation. The Wilson flow is the flow of a smooth vector field on the compact manifold $\mathcal{U}_N$, so its solutions are unique. Indeed, locally, iterating the integral equation h times bounds the difference of two solutions with the same initial value by $C^h t^h / h!$ times a fixed supremum, which tends to zero, and the argument can be repeated on successive time intervals. Hence flat configurations are stationary, and their cycle holonomies are unchanged at every time.

Step 10: neighborhoods. Assume the hypotheses of (2), and fix a finite $N = uB^K$ and an allowed coupling. At each flat configuration, all classical and coarea inequalities hold strictly by Steps 5 to 8, the domains D_r for the fine and coarse fields are open, and every fluctuation vector is zero, inside a ball of positive radius. The maps defining the event and the inverse coordinates are continuous on their open branches. A finite intersection of their preimages therefore gives an open neighborhood of this configuration contained in the event, after replacing the fluctuation balls by smaller open balls around zero. The union of the gauge images of an open set is open, since each gauge transformation acts by a homeomorphism. Taking the union of these neighborhoods gives an open set $\mathcal{O}$ with $\mathcal{F}_N \subset \mathcal{O} \subset S_{N,u,\gamma}$, where $\mathcal{F}_N$ is the set of flat configurations.

The configuration space is compact, and $f(U) = \max_p \rho_G(U_p)$ is continuous with zero set exactly $\mathcal{F}_N$. If $\mathcal{O}^c$ is nonempty, f attains a strictly positive minimum on this compact set; otherwise any positive threshold works. Choosing $\delta_{N,u,\gamma}$ below this minimum proves the inclusion in (3). The minimum is taken separately at each N and each coupling, and the argument gives no uniform lower bound for it.

On a fixed stopping lattice whose side satisfies the same condition, Step 8 shows that the compact set of flat configurations lies in D_r. The set D_r is open, being a union of gauge images of the open set B_r. For any fixed metric on the finite product, the compact set of flat configurations therefore has positive distance from the closed complement of D_r, unless this complement is empty. The resulting neighborhood depends only on n and r; neither set involves the depth or the coupling. Throughout the argument all gauge transformations were periodic and all cycle holonomies commuted, so no projectively commuting or twisted data have been introduced. □

SECTION 15

Conditional kernels and reconstruction maps

In this section we prove that the renormalization group construction on the small-field event converges at every fixed resolution. That is, we fix the side n_0 of the coarse lattice and a number l of RG steps counted from the coarse side, and we let the total number k of RG steps tend to infinity. At a fixed resolution all objects are finite dimensional. In Theorem 15.6, we show that one RG step contracts effective interactions in the weighted analytic coefficient norm, uniformly in the lattice side and in the preceding depth, and we deduce the convergence of the effective interactions and of the stopped measures at each fixed level. Theorem 15.9 proves the convergence of the conditional fluctuation kernels, and Lemma 15.10 writes the conditioned Wilson measure as an iteration of these kernels. In Theorem 15.12, we construct the reconstruction maps $\widehat{\mathscr{R}}$, and in Theorem 15.13 we prove that the finite-scale reconstructions converge in law. Lemma 15.15 gives amplitude bounds for the reconstruction that are uniform in the mesh and in the coupling, and Theorem 15.16 makes the convergence uniform for the coupling in compact subintervals of $(0, \infty)$. The inputs are the classical convergence and the bounds for the zero-fluctuation reconstruction of Theorem 11.2 and Lemma 11.9, and the density and the cluster expansion of one RG step (Theorems 12.7 and 12.13 and Corollary 12.8). We also use the gauge transformations and the invariant ball of Theorems 13.2 and 13.5, and the identification of the auxiliary integral with the conditioned Wilson measure (Theorems 14.3 and 14.6). The later sections approximate the flowed field by the field reconstructed from finitely many RG steps (Sections 3.3 and 3.6). Sections 16, 17, 26 to 29, and 31 to 36 use the reconstruction maps, the conditional kernels, the convergence of finite-scale reconstructions, and the amplitude bounds, and Section 23 uses the deterministic constants and the order in which they are chosen.

The splitting of the fine field into a constrained minimizer and normalized fluctuations, and the integration of the fluctuations scale by scale, are Bałaban's [15, 16, 18]. We combine the standard renormalization group contraction with the cluster expansion estimates of Section 12 to obtain the limits of the conditional kernels and a compatible family of representatives for this construction. These estimates go back to Kotecký and Preiss [120] and use the finite tree-graph bound in Dimock's exposition [68, Appendix B]. The selection of a holomorphic subsequence is the normal-family argument in finitely many variables, and the limits follow from the contraction in the usual way.

15.1 Scales, measures, and conventions

Throughout this section $L > 0$ is fixed, $M \geq 3$ is odd, $J \geq 1$, and $B = M^J$. One averaging step is one application of the block averaging map T_M of Definition 4.3, and one RG step consists of J averaging steps. We fix the side $n_0 \in 4\mathbb{N}$ of the coarse lattice, let $H = L/n_0$, and for $j \geq 0$ set

$$n_j = n_0 B^j, \qquad a_j = HB^{-j}, \qquad g_j^2 = \frac{\gamma}{n_j} = g_3^2 a_j.$$

We call Λ_{n_j} the lattice of level j. If the finest lattice has level k, the lattices form the chain

$$\Lambda_{n_0} \xleftarrow{T_M^J} \Lambda_{n_1} \xleftarrow{T_M^J} \cdots \xleftarrow{T_M^J} \Lambda_{n_k}.$$

The fluctuations are integrated from right to left, toward coarser lattices, and the fine field is reconstructed from left to right. The number of averaging steps between the finest lattice and level j is

$$d_j^k = J(k - j),$$

and we call it the preceding depth at level j. The RG step from level j to level $j-1$ has J intermediate scales, indexed by $0 \leq i < J$, with couplings

$$g_{j,i} = t_j M^{(i-J+1)/2}, \qquad t_j = M^{(J-1)/2} g_j = g_{j-1}/\sqrt{M}.$$

Here t_j is the largest of these couplings, and the ratios $g_{j,i}/t_j$ are fixed powers of M. With $p(t) = A_{\mathrm{w}} \log(1/t)$ we write $p_j = p(t_j)$. The normalized fluctuation variables $w_j = (w_{j,i,e})$ of this RG step are restricted to the fluctuation cutoff domain Ω_{p_j}, the product of the three-dimensional balls $\{|w_{j,i,e}| \leq p_j\}$; it does not depend on k. We write $q_{j,i} = g_{j,i} w_{j,i}$ for the coupling-scaled fluctuation inputs of the reconstruction. Since the inverse square roots of the constrained Hessians remain inside the reconstruction maps, $q_{j,i}$ is not a free logarithmic coordinate of the fiber.

The three measures. Let

$$\nu^k = \nu_{n_0 B^k, n_0, \gamma}$$

be the conditioned Wilson measure of Definition 4.4, with the small-field event of (4.6) and Definition 14.4. In the comparison notation, the comparison index s gives $n_s = n_* B^s$, $H_s = L/n_s$, and $\nu_{K,s} = \nu_{N_K, n_s, \gamma}$ with $N_K = n_* B^K$. Then $n_0 = n_s$ and $k = K - s$, the meshes of the reconstruction are $a_j = H_s B^{-j}$, $0 \leq j \leq K - s$, and the preceding depths are $J(K - s - j)$. At level j three different measures occur.

1. The marginal of ν^k at level j, that is, the law of $V^{d_j^k}$ under ν^k.
2. The stopped measure $\widehat{\nu}_j^k$ of Theorem 15.6. It is obtained by integrating out the finer levels and imposing the small-field restrictions only up to level j.

3. The conditional fluctuation kernel $k_j^k(\theta, dw)$ of Theorem 15.9, the conditional law of the fluctuation variables of the RG step from level j to level $j-1$ given the field e^θ at level $j-1$.

The marginal in (1) also carries the restrictions at the coarser levels $j-1,\dots,0$, and in general it differs from the stopped measure. At the coarse level $j=0$ no coarser restriction remains, and (1) and (2) coincide (Lemma 15.11). The kernel (3) does not change when coarser restrictions are imposed, once the field at level $j-1$ has been fixed (Theorem 15.9).

Effective interactions. We write functions of a configuration near the identity in logarithmic coordinates, $R(e^\xi)$, and use the norm

$$\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R) = \sum_{m\geq 2} \frac{\rho^{m-2}}{m!} \|D^m R(0)\|_{a_{\mathrm{sp}},\mathrm{root}}$$

of Definition 4.6. The tensor norm fixes one index, sums the absolute values of the coefficients over the remaining indices with the weight $e^{a_{\mathrm{sp}}\mathsf{t}}$, where t is the length of a shortest connected network through the locations of the indices, and takes the supremum over the fixed index. For maps between lattices of different meshes the input-fixed sums carry the volume factor $a_{\mathrm{out}}^3/a_{\mathrm{in}}^3$ of Definition 4.6; we call them volume-normalized column sums. A function R on B_ρ is invariant under gauge transformations within B_ρ if $R(U^h) = R(U)$ whenever U and U^h both lie in B_ρ, as in Definition 13.3; then $R_{\mathrm{sat}}(U) = R(U^h)$ for $U^h \in B_\rho$ defines its gauge-invariant extension to D_ρ. For a lattice Λ and the parameters ρ, a_{sp}, E fixed in Theorem 15.6, let $\mathcal{A}_E = \mathcal{A}_E(\Lambda)$ be the set of functions R given by an absolutely convergent Taylor series on B_ρ that are real on real configurations, invariant under lattice translations, the spatial inversion, global color rotations, and gauge transformations within B_ρ, and satisfy

$$R(I) = 0, \qquad DR(I) = 0, \qquad \mathcal{B}_{\rho,a_{\mathrm{sp}}}(R) \leq E.$$

These are the symmetries of the recursion of Theorems 13.5 and 14.6. The norm $\mathcal{B}_{\rho,a_{\mathrm{sp}}}$ vanishes on constants.

Constants. A constant denoted C_J, c_J, or similar depends only on M, J, the fixed larger construction domains and their radius ratios, the spatial exponents, the factor K_*, and the norm ceilings. It is independent of the lattice side and of the preceding depth; this is the dependence described in item (2) of Definition 4.14. A subscript Λ allows, in addition, dependence on a fixed lattice pair. Such constants occur only in convergence moduli and never in the estimates that are used to choose J. We write $\|\mu-\nu\|_{\mathrm{TV}} = \sup_A |\mu(A)-\nu(A)|$ for the total variation distance.

15.2 Finite-dimensional analytic bounds and product domains

We begin with three elementary facts about total variation, which are used repeatedly below.

Lemma 15.1. *1. Let μ be a σ-finite measure on a measurable space X, and let V, V' be real measurable functions on X with $\sup_X |V - V'| \le \delta$ and $0 < \int e^{-V} d\mu < \infty$. Let π and π' be the probability measures proportional to $e^{-V}\mu$ and $e^{-V'}\mu$. Then the ratio of their normalizers lies in $[e^{-\delta}, e^{\delta}]$, the density $d\pi'/d\pi$ takes values in $[e^{-2\delta}, e^{2\delta}]$, and*

$$\|\pi - \pi'\|_{\mathrm{TV}} \le e^{2\delta} - 1.$$

2. Let η, η' be probability measures on a measurable space X_0, and for $1 \le j \le l$ let K_j, K_j' be probability kernels from $X_0 \times \cdots \times X_{j-1}$ to X_j. Then $P = \eta K_1 \cdots K_l$ and $P' = \eta' K_1' \cdots K_l'$ satisfy

$$\|P - P'\|_{\mathrm{TV}} \le \|\eta - \eta'\|_{\mathrm{TV}} + \sum_{j=1}^{l} \sup_h \|K_j(h,\cdot) - K_j'(h,\cdot)\|_{\mathrm{TV}}.$$

3. Let P, P' be probability measures on a measurable space X, and let F, F' be measurable maps from X into a set $\mathcal{K}$ of diameter at most D_* in a finite-dimensional normed space. Put $\|F - F'\|_\infty = \sup_X \|F - F'\|$. For every bounded real function f that is uniformly continuous on $\mathcal{K}$, with modulus of continuity ω_f,

$$\left| \int f(F)\, dP - \int f(F')\, dP' \right| \le 2\|f\|_\infty \|P - P'\|_{\mathrm{TV}} + \omega_f(\|F - F'\|_\infty),$$

and

$$W_1(F_*P, F_*'P') \le \|F - F'\|_\infty + D_* \|P - P'\|_{\mathrm{TV}}.$$

Proof. For (1), let Z, Z' be the two normalizers. Since $e^{-\delta}e^{-V} \le e^{-V'} \le e^{\delta}e^{-V}$, we have $e^{-\delta}Z \le Z' \le e^{\delta}Z$. The density $d\pi'/d\pi = e^{V-V'}Z/Z'$ therefore lies in $[e^{-2\delta}, e^{2\delta}]$. For an event A we have $|\pi(A) - \pi'(A)| \le \int |1 - d\pi'/d\pi|\, d\pi \le e^{2\delta} - 1$, where we used $1 - e^{-2\delta} \le e^{2\delta} - 1$.

For (2), first observe that a measurable function u with values in $[0,1]$ satisfies $|\int u\, d\mu - \int u\, d\mu'| \le \|\mu - \mu'\|_{\mathrm{TV}}$ for probability measures μ, μ'; indeed $u = \int_0^1 \mathbf{1}_{\{u > s\}}\, ds$. We replace first η by η', and then the kernels one at a time. Fix an event A in the product space. Since the function obtained by integrating $\mathbf{1}_A$ against $K_1 \cdots K_l$ takes values in $[0,1]$, the first replacement changes the probability of this event by at most $\|\eta - \eta'\|_{\mathrm{TV}}$. In the replacement of K_j by K_j', the integral of $\mathbf{1}_A$ against the later kernels is again a $[0,1]$-valued function of (h, x_j), and the change is at most $\sup_h \|K_j(h,\cdot) - K_j'(h,\cdot)\|_{\mathrm{TV}}$. Summing these changes proves (2).

For (3), we have

$$\left| \int f(F)\, dP - \int f(F')\, dP' \right| \le \int |f(F) - f(F')|\, dP + \left| \int f(F')\, dP - \int f(F')\, dP' \right|.$$

The first term is at most $\omega_f(\|F - F'\|_\infty)$. For the second, the function $(f(F') + \|f\|_\infty)/(2\|f\|_\infty)$ takes values in $[0,1]$, and the observation in the proof of (2) bounds it by $2\|f\|_\infty \|P - P'\|_{\mathrm{TV}}$. For the Wasserstein bound, let $\lambda = P + P'$, let u, u' be the densities of P, P' with respect to λ, and set $m = \min(u, u')$ and $\vartheta_0 = \int m \, d\lambda = 1 - \|P - P'\|_{\mathrm{TV}}$. If $\vartheta_0 = 1$ then $P = P'$ and we couple x with itself. Otherwise let Γ be the sum of the image of $m\lambda$ under $x \mapsto (x, x)$ and of the product measure $(1 - \vartheta_0)^{-1}(u - m)\lambda \otimes (u' - m)\lambda$. Its marginals are P and P', and it gives mass at least ϑ_0 to the diagonal. Then

$$\int \|F(x) - F'(x')\| \, d\Gamma(x, x') \le \|F - F'\|_\infty + (1 - \vartheta_0) D_*,$$

and $(F \times F')_* \Gamma$ couples $F_* P$ and $F'_* P'$. This completes the proof. □

In particular, for the bounded-Lipschitz distance, whose test functions are bounded by one and have Lipschitz constant at most one, part (3) gives the bound $2\|P - P'\|_{\mathrm{TV}} + \|F - F'\|_\infty$.

Box supports. The cluster expansion of Section 12 assigns interactions to connected sets of boxes. We partition each periodic coordinate direction of the coarse lattice into intervals of integer length between $\mathscr{L}$ and $2\mathscr{L}$, or use one interval when the direction is shorter than $\mathscr{L}$, as in Definition 12.1. The products of these intervals are the boxes. Each scalar variable has a fixed location in the torus, as in Definition 4.6; the coarse field has nine scalar components (three orientations and three colors) at each vertex. The first lemma bounds the length of a network through the locations of the coarse-field variables in a connected set of boxes.

Lemma 15.2. *Fix an integer $\mathscr{L} \ge 1$ in units of the coarse lattice. There exists a constant $C_{\mathrm{box}}(\mathscr{L})$, depending only on $\mathscr{L}$ and on the fixed metric and location conventions, such that every nonempty connected set Y of boxes satisfies*

$$\mathsf{t}(\textit{locations of the coarse-field variables in } Y) \le C_{\mathrm{box}}(\mathscr{L})|Y|. \tag{15.1}$$

The constant is independent of the side of the torus, the preceding depth, J, the couplings, the degree of a coefficient, and the density of the fluctuation variables. The bound also holds for every subset or repeated list of these locations, and for every union of connected box sets whose intersection graph is connected.

Proof. Set $q = 2\mathscr{L} + 2$, and let $c_{\mathrm{met}} \ge 1$ bound the length of a coordinate segment of unit length and the distance from the location of a link variable to an endpoint of the link. A lifted box, together with a collar of one cell for the locations of its link variables, lies in an integer cube of side at most q. The coordinate grid of this cube has at most $3q(q+1)^2$ edges. There are at most $9(q+1)^3$ locations of scalar variables in the cube, and we attach each of them to a grid point by a segment of length at most c_{met}. This gives a connected network of length at most $12 c_{\mathrm{met}}(q+1)^3$ containing every such location in the box.

Fix a grid vertex in each box. A traversal of the connected box graph selects $|Y| - 1$ adjacencies that connect all boxes. For each selected adjacency we join the two chosen grid vertices by a periodic coordinate path. Since the boxes are adjacent, this path has length at most $c_{\mathrm{met}}(6q + 3) \le 9c_{\mathrm{met}}q$. These paths and the grids form one connected network containing all these locations in Y, so we may take

$$C_{\mathrm{box}}(\mathscr{L}) = c_{\mathrm{met}}\{12(q+1)^3 + 9q\}.$$

In a periodic direction shorter than $\mathscr{L}$ we project the grid of the cube to the torus, which can only decrease its length; for an adjacency across the periodic boundary we use a shortest periodic coordinate path, which obeys the same bound. No lower bound on the side in terms of $\mathscr{L}$ was used. Repeated labels occupy the same location, and restricting the list of locations requires no new segment. Finally, a union of connected box sets whose intersection graph is connected is itself a connected box set, so the bound applies to it with its own cardinality. □

The next lemma makes the support assignment of Lemma 12.9 explicit. It assigns a connected box set to a coefficient and bounds the resulting support-counting factor by the length of the network of the coefficient.

Lemma 15.3. *Fix deterministic choices of shortest paths. Let $N \ge 1$ points be given, together with a connected network of length ℓ containing them. Join the points by a minimal spanning tree, replace each edge of the tree by its three coordinate segments along shortest periodic displacements, and let Y be the set of boxes met by the resulting network, including the boxes of the points. Then Y is a nonempty connected box set. There exist constants $c_0, C_{\mathrm{geom}} \ge 1$ depending only on the metric conventions, and a constant $C_{\mathscr{L}}$ depending only on $\mathscr{L}$ and the metric conventions, such that*

$$|Y| \le c_0\Big(N + 1 + \frac{C_{\mathrm{geom}}\ell}{\mathscr{L}}\Big), \qquad \operatorname{dist}(x,u) \le C_{\mathrm{geom}}\ell + C_{\mathscr{L}} \tag{15.2}$$

for every box $x \in Y$ and every given point u, where the distance is measured from a fixed point of the box. Consequently, for $h, \mu > 0$ and

$$K \ge e^{hc_0}, \qquad \beta \ge C_{\mathrm{geom}}\Big(\frac{hc_0}{\mathscr{L}} + \mu\Big), \qquad C_h = e^{hc_0 + \mu C_{\mathscr{L}}},$$

we have

$$\mathbf{1}_{\{x \in Y\}} e^{h|Y|} \le C_h K^N e^{\beta\ell} e^{-\mu \operatorname{dist}(x,u)}. \tag{15.3}$$

Proof. A minimal spanning tree on the N points has at most $N - 1$ edges, and its length is at most twice the length of any connected network containing the points; indeed, traversing such a network twice and shortcutting between successive points gives a path through all of them. The comparison between coordinate segments and the metric, together with this factor two, is included in C_{geom}. A coordinate segment of length l'

meets at most a fixed multiple of $2 + l'/\mathscr{L}$ boxes. Summing over the at most $3(N-1)$ segments gives the first bound in (15.2). The second follows by moving along the network from u to the box x and then inside the box. Inserting (15.2) into $e^{h|Y|}$ and using $\mu \operatorname{dist}(x,u) \le \mu C_{\mathrm{geom}} \ell + \mu C_{\mathscr{L}}$, we obtain (15.3). □

Order of the spatial choices. We now fix the spatial parameters, in an order that keeps them independent of J. Fix a decay rate $b > 0$ strictly below the common spatial rate of the classical and image bounds of Lemma 11.9 and Theorems 13.2 and 13.5. We choose $\mathscr{L}$ using this rate alone, so that $8c_0 C_{\mathrm{geom}}/\mathscr{L} \le b/4$. We fix $\mu > 0$ with $C_{\mathrm{geom}}\mu \le b/4$; this sets aside a part of b for summing over the distance between a box and the location of a variable. With $h = 8$ and $K = e^{8c_0}$ in Lemma 15.3, the factor K^N is absorbed by multiplying every input radius by K; we take the factor $K_* \ge 2$ of Theorem 13.5 so large that $K < 4K_*$, so that these enlarged radii stay inside the products of Lemma 15.4 below. Next we choose the spatial exponent a_{sp} of the effective interactions so that

$$\begin{aligned} 0 < a_{\mathrm{sp}} < \min\{b/4, a_{\mathrm{cen}}/8\}, \qquad & a_{\mathrm{sp}} C_{\mathrm{box}}(\mathscr{L}) \le 2, \\ C_P(a_{\mathrm{sp}})/B < 1/4, \qquad & C_{\mathrm{geom}} b/B \le a_{\mathrm{sp}}, \end{aligned} \tag{15.4}$$

where C_P is the constant of Theorem 11.10. The condition $a_{\mathrm{sp}} < a_{\mathrm{cen}}/8$, where a_{cen} is the rate of Lemma 11.9, is the restriction imposed in Theorem 13.5. Indeed, the zero-fluctuation reconstruction used below is the representative of Lemma 11.9, and Theorem 11.10 gives the contraction for this representative only at output rates below $a_{\mathrm{cen}}/8$, with the constant $C_P(a_{\mathrm{sp}})$ at the rate a_{sp}. The first two conditions determine a_{sp} after $\mathscr{L}$. Only then do we choose J, so that the last two conditions and the condition $M^{-J} Z(4K_*\rho) \le \rho/4$ of Theorem 13.5 hold. All constants in these conditions are fixed before J, and $M^{-J} \to 0$, so they hold for all large J. The scale $\mathscr{L}$ is not chosen again after a_{sp} or J, and no exponent is decreased during the iteration. In the common parameter choice of Theorem 23.2, the torus exponent denoted a_{sp} in this section is $a_{\mathbb{T}}$, distinct from the smaller regional boundary exponent chosen after J. By (15.1), these choices give

$$a_{\mathrm{sp}} \mathsf{t} \le 2|Y|$$

for the locations of the coarse-field variables in every connected box set Y, including subsets and repetitions of these locations. This inequality does not involve a radius.

Nested analytic product domains. The next lemma fixes the complex products on which the reconstruction is controlled.

Lemma 15.4. *Let $C_{\mathrm{im},J}$ and r_J be the constants of Theorem 13.2, and let*

$$\mathfrak{M}_J(u,v) = B^{-1} Z(u) + \frac{C_{\mathrm{im},J} v}{1 - C_{\mathrm{im},J}(u+v)}$$

be its row majorant. Before the radius r of the small-field domain and the coupling ceiling are chosen, the common product of coarse-field and fluctuation-input variables can be fixed with radii $u_\circ = 4K_*\rho$ *and* $v_\circ = 4K_* s_J$*, such that*

$$\begin{aligned} u_\circ + v_\circ < r_J, \qquad & C_{\mathrm{im},J}(u_\circ + v_\circ) \le 1 - \eta_{\mathrm{im}} < 1, \\ B^{-1}Z(u_\circ) \le \rho/4, \qquad & \mathfrak{M}_J(u_\circ, v_\circ) < \rho/2 \end{aligned} \tag{15.5}$$

for a fixed $\eta_{\mathrm{im}} > 0$*, and every intermediate classical, logarithm, and Haar disintegration domain condition holds with a margin. Every smaller product lies in this domain and has denominator at least* η_{im}*. For each* $0 < r \le \rho$ *there exists* $Q_{\mathrm{act}} > 0$*, depending on r, at most* s_J*, and at most any previously chosen positive bound on the inputs q, such that*

$$r + Q_{\mathrm{act}} < r_J, \qquad 1 - C_{\mathrm{im},J}(r + Q_{\mathrm{act}}) > 0, \qquad \mathfrak{M}_J(r, Q_{\mathrm{act}}) < r/2. \tag{15.6}$$

After the coupling ceiling is reduced so that $tp(t) \le Q_{\mathrm{act}}$*, these conditions hold on every product* $\{\|\theta\|_\infty < r\} \times \{\max_i \|g_i w_i\|_\infty \le tp(t)\}$ *used in the construction. All these choices are deterministic and independent of the coupling, the lattice side, and the preceding depth.*

Proof. The series Z of Lemma 11.9 is chosen before J, and the choice of J in Theorem 13.5 gives $B^{-1}Z(4K_*\rho) \le \rho/4$. After J has been fixed, we take ρ strictly below $r_J/(8K_*)$ and so small that $4K_* C_{\mathrm{im},J}\rho < 1/4$, within the common classical and Haar disintegration domains. Then we choose $s_J > 0$ so small that $u_\circ + v_\circ < r_J$, that $C_{\mathrm{im},J}(u_\circ + v_\circ) < 1/2$, and that the second term of $\mathfrak{M}_J(u_\circ, v_\circ)$ is strictly below $\rho/4$. This reduction keeps the intermediate margins of Theorem 13.2. No radius is changed during a recursion. We denote the positive margin of the denominator by η_{im}. Since the coefficients of all majorants are nonnegative, the domain and denominator conditions remain valid on smaller products.

The ratio $Z(u)/u$ is nondecreasing, because the series of Z has nonnegative coefficients and no constant term. Hence $B^{-1}Z(r) \le r/(16K_*)$ for $r \le \rho$. We take Q_{act} strictly below

$$\min\Big\{ s_J,\ \frac{r_J - r}{2},\ \frac{1 - C_{\mathrm{im},J} r}{2C_{\mathrm{im},J}},\ \frac{r(1 - C_{\mathrm{im},J} r)}{16 C_{\mathrm{im},J}} \Big\},$$

and below any previously chosen bound on the inputs; every entry of the minimum is positive. The denominator is then at least $(1 - C_{\mathrm{im},J} r)/2$, and the second term of $\mathfrak{M}_J(r, Q_{\mathrm{act}})$ is less than $r/8$. Thus $\mathfrak{M}_J(r, Q_{\mathrm{act}}) < r/(16K_*) + r/8 < r/2$. Since the product lies in the outer product, it has all intermediate margins. Finally, $tp(t) \to 0$ as $t \downarrow 0$, so one ceiling works on the whole interval of smaller couplings. □

A Taylor tail estimate. The last lemma of this section compares values, derivatives, and coefficient norms at a fixed lattice size.

Lemma 15.5. *On a fixed finite lattice Λ with edge set $\mathcal{E}_\Lambda$, let $D_\Lambda = 3|\mathcal{E}_\Lambda|$. Every function F given by a Taylor series in logarithmic coordinates with $F(I) = 0$ and $DF(I) = 0$ satisfies*

$$\sup_{\|\xi\|_\infty \le \rho} |F(e^\xi)| \le D_\Lambda \rho^2 \mathcal{B}_{\rho, a_{\mathrm{sp}}}(F).$$

The same bound holds on D_ρ if F is invariant under gauge transformations within B_ρ. Values on a closed coordinate ball mean the continuous extension of the absolutely convergent Taylor series. For $0 < \sigma < 1$ and $s \ge 1$, the sum over all indices of the absolute values of the coefficients of $D^s F$ at points of $B_{\sigma\rho}$ is at most

$$s!\, D_\Lambda \rho^{2-s} (1-\sigma)^{-s} \mathcal{B}_{\rho, a_{\mathrm{sp}}}(F).$$

Suppose a family F_α has a common bound on $\mathcal{B}_{\rho_1, a_{\mathrm{sp}}}$ for some $\rho_1 > \rho$, with the same spatial exponent. If each fixed Taylor coefficient tensor of F_α is Cauchy, uniformly in an additional parameter, then F_α is Cauchy in $\mathcal{B}_{\rho, a_{\mathrm{sp}}}$, uniformly in that parameter. This also holds for vector-valued maps and for joint products of coarse-field and fluctuation-input variables, including every volume-normalized column sum and every fixed spatial difference, provided the inner and outer radii of each group of variables have a common ratio less than one.

Proof. We write $F(e^\xi) = \sum_{s \ge 2} D^s F(0)[\xi^{\otimes s}]/s!$. Summing first over one scalar coordinate and then over the remaining ones gives at most D_Λ times the supremum of the sums with one fixed index. Dropping the spatial weights, which are at least one, and using $|\xi_e| \le \rho$, we obtain the value bound. Differentiation produces the falling factorial $m(m-1)\cdots(m-s+1)$ in degree m. Its product with σ^{m-s} is at most $s!(1-\sigma)^{-s}$, because $\binom{m}{s}(1-\sigma)^s \sigma^{m-s} \le 1$ is one term of the binomial expansion of $((1-\sigma)+\sigma)^m = 1$. Summing against the coefficient norms gives the derivative bound. Gauge invariance within B_ρ changes none of these values, since a single gauge transformation is used at the point of evaluation.

Let $u_m = \|D^m F(0)\|_{a_{\mathrm{sp}}, \mathrm{root}}/m!$. If $\mathcal{B}_{\rho_1, a_{\mathrm{sp}}}(F) \le C$, then

$$\sum_{m > h} \rho^{m-2} u_m \le C(\rho/\rho_1)^{h-1}. \tag{15.7}$$

For a difference of two members of the family we use twice the common bound. For fixed h there are finitely many coefficients, indices, and labels, and their weighted sums converge. We choose h first in (15.7) and then the indices of the family. This proves the Cauchy property without decreasing ρ or a_{sp}.

For a joint vector series we group the monomials by total degree. If the ratio of each inner radius to the corresponding outer radius is at most $\zeta < 1$, the part of degree greater than h has norm at most $C\zeta^{h+1}$. A fixed input contributes a degree factor, which is absorbed by using an intermediate ratio between ζ and one. At a fixed lattice size the volume factors, the spatial weights, and the difference matrices are fixed finite numbers, so the argument applies to all these sums and differences. It also shows that locally

uniform holomorphic convergence, together with a common absolute bound on a larger product, gives convergence in these norms. □

Here and below the Cauchy formula in several variables means the iterated one-variable formula on circles inside the polydisc. If a function is bounded by C on these circles, the formula bounds the coefficient of ξ^α by $Cr^{-\alpha}$. In coordinate dimension D there are $\binom{m+D-1}{D-1}$ multi-indices of degree m, a polynomial in m. On every strictly smaller polydisc, the sums of the absolute values of the coefficients are then finite. This justifies the finite-dimensional uses of locally uniform holomorphic convergence below.

15.3 Contraction and limits at fixed resolution

The auxiliary transformation. Fix a lattice pair of one RG step: a coarse lattice of side $m \geq 4$ and the fine lattice of side Bm, with $d \geq 0$ preceding averaging steps. Fix $0 < t \leq g_*$, and let $g_i = t\lambda_i$ with $\lambda_i = M^{(i-J+1)/2}$ for $0 \leq i < J$. We write $c = e^\theta$ for the coarse field and $q_i = g_i w_i$ for the inputs. Let $\mathscr{C}_{\mathrm{raw}\,d}(\theta, q)$ be the reconstruction of the fine field in the block axial gauge, built from the conditional constrained minimizers, the constrained Hessians, and their inverse square roots, as in Lemma 12.3 and Theorem 12.13. Let $\Omega_d(\theta)$ be the gauge transformation of Theorem 13.2; it depends only on θ and equals the identity at the vertices of the coarse lattice. Define

$$\phi_d(\theta, q) = \mathrm{Log}\big[\mathscr{C}_{\mathrm{raw}\,d}(\theta, q)^{\Omega_d(\theta)}\big], \qquad P_d R(\theta) = R(e^{\phi_d(\theta,0)}).$$

Thus $P_d R$ is the pullback of R by the zero-fluctuation reconstruction. Let $H_{d,J}(\theta, w)$ be the fluctuation exponent of Theorem 12.13. It contains the classical remainder, the nonconstant parts of the Haar disintegration densities, and the differences of the determinant terms; the determinant of a finer intermediate scale is evaluated at the argument determined by the coarser fluctuation variables. Let π_p be the normalized product of standard Gaussian measures on $\mathbb{R}^3$ restricted to balls of radius $p = p(t)$, one factor for each three-dimensional block of fluctuation variables. Let

$$z_p = \int_{\{v \in \mathbb{R}^3 : |v| \leq p\}} e^{-|v|^2/2}\, dv,$$

let f_i be the number of free group variables at the intermediate scale i, so that the cutoff domain is a product of $\sum_i f_i$ balls, and let $\mathsf{B}_{\mathrm{ref}}(\theta)$ be the zero-fluctuation Jacobian term of Theorem 12.13. For an input effective interaction R, produced by the integrations at finer

scales, we set

$$\begin{aligned} A_R(\theta, w) &= R(e^{\phi_d(\theta, (g_i w_i))}) - P_d R(\theta), \\ \Xi_R(\theta) &= \int e^{-H_{d,J}(\theta, w) - A_R(\theta, w)} \, d\pi_p(w), \\ D_d R &= -\log \Xi_R + \log \Xi_0, \\ Q_d &= \mathsf{B}_{\mathrm{ref}} - \Big(\sum_i f_i\Big) \log z_p - \log \Xi_0. \end{aligned} \tag{15.8}$$

By Theorems 12.13 and 14.6, $Q_d + P_d R + D_d R$ is the effective interaction produced by one RG step from R, before normalization at the identity. The three terms are the newly generated effective interaction, the pullback at zero fluctuation, and the fluctuation correction to the pullback. In the gauge of ϕ_d, they are the terms $Q^{\mathrm{w}}_{d,J}$, $\mathcal{P}_\delta R$, and $\mathcal{D}_J R$ of (13.9), with $d_0 = d$, up to field-independent constants. We define the auxiliary transformation

$$\widehat{\mathcal{M}}_{d,t} R = (Q_d + P_d R + D_d R) - (Q_d + P_d R + D_d R)(I).$$

The field-independent factors $\prod_i \mathcal{J}_i(I, 0) g_i^{3 f_i}$, the Haar disintegration density at the identity, and the powers of the couplings, are kept in the normalization constant of Theorem 14.6, together with the subtracted value at the identity; they are never estimated by $\mathcal{B}_{\rho, a_{\mathrm{sp}}}$. The integral Ξ_R carries no indicator of D_r on the fine lattice, and it is defined for complex θ in the larger analytic product domain of Lemma 15.4. At a coarse field in B_r, the image condition of the next theorem implies that this indicator would equal one on the whole cutoff domain. There Ξ_R is the normalized Gaussian fluctuation factor in the fiber formula of Theorem 14.6(2). Multiplying it by the classical, zero-fluctuation, Gaussian, and coordinate prefactors in that formula gives the density of the pushforward under T^J_M, before global normalization (Theorem 14.6).

Theorem 15.6. *Fix odd $M \geq 3$, $J \geq 1$, $B = M^J$, and the parameters of Theorems 13.5 and 14.6: the radii $0 < r < \rho$, the spatial exponent $a_{\mathrm{sp}} > 0$, the ceiling E for effective interactions, the coefficient $A_{\mathrm{w}} > 0$, and the coupling ceiling $g_* > 0$, with $p(t) = A_{\mathrm{w}} \log(1/t) > 0$ for $0 < t \leq g_*$. Fix a lattice pair of one RG step with coarse side $m \geq 4$, a coupling $0 < t \leq g_*$, and the couplings $g_i = t\lambda_i$ of its intermediate scales. Assume that the image under ϕ_d of the complex product of Lemma 15.4, with radii $4K_* \rho$ and $4K_* s_J$, lies strictly inside $B_{\rho/2}$; that for $\|\theta\|_\infty < r$ the real product $\{\max_i \|q_i\|_\infty \leq t p(t)\}$ is mapped into $B_{r/2}$; and that all intermediate classical, logarithm, and Haar disintegration domain conditions hold. Then, after one initial reduction of g_*, all $R_1, R_2 \in \mathcal{A}_E$ satisfy*

$$\begin{aligned} \mathcal{B}_{\rho, a_{\mathrm{sp}}}(\widehat{\mathcal{M}}_{d,t} R_1 - \widehat{\mathcal{M}}_{d,t} R_2) &\leq \{q_{\mathrm{pr}} + C_J t^2 [p(t)^4 + (\epsilon_1 + \epsilon_2) p(t)^2]\} \mathcal{B}_{\rho, a_{\mathrm{sp}}}(R_1 - R_2) \\ &\leq \vartheta \, \mathcal{B}_{\rho, a_{\mathrm{sp}}}(R_1 - R_2), \end{aligned}$$

where $\epsilon_i = \mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_i)$, $0 \le q_{\mathrm{pr}} < 1/4$, *and* $\vartheta = (1+q_{\mathrm{pr}})/2 < 1$. *The reduction of* g_* *imposes* $p(t) \ge 1$, *by taking* $g_* \le e^{-1/A_{\mathrm{w}}}$, *and*

$$t[p(t)^3 + 2Ep(t)] \le c_J/2, \qquad C_J t^2[p(t)^4 + 2Ep(t)^2] \le (1-q_{\mathrm{pr}})/2$$

for all $0 < t \le g_*$. *At this fixed lattice pair and fixed* t,

$$\sup_{R\in\mathcal{A}_E} \mathcal{B}_{\rho,a_{\mathrm{sp}}}\big(\widehat{\mathcal{M}}_{d,t}R - \widehat{\mathcal{M}}_{d',t}R\big) \longrightarrow 0 \qquad (d,d' \to \infty),$$

at the same radius and exponent. The conditional constrained minimizers, the constrained Hessians, the analytic branches of their square roots and inverse square roots that are positive at real arguments, the Haar disintegration densities, and the reconstructions $\mathscr{C}_{\mathrm{raw}\,d}$ *converge locally uniformly and holomorphically on smaller product domains, with every fixed derivative.*

Now fix $n_0 \in 4\mathbb{N}$ *and* $\gamma > 0$ *for which the construction of Theorem 14.6 applies, and use the hierarchy of Section 15.1. For* $0 \le j \le k$ *let* R_j^k *be the effective interaction at level* j *given by Theorem 14.6; thus* $R_k^k = 0$, $R_{h-1}^k = \widehat{\mathcal{M}}_{J(k-h),t_h} R_h^k$ *for* $1 \le h \le k$, *and* $R_h^k \in \mathcal{A}_E(\Lambda_{n_h})$. *The stopped measure at level* j *is*

$$d\widehat{\nu}_j^k = \widehat{Z}_{j,k}^{-1} \mathbf{1}_{D_r} \exp\{-E_{J(k-j),\mathrm{sat}}/g_j^2 - R_{j,\mathrm{sat}}^k\}\, dH_{n_j}, \qquad R_j^k(I) = 0.$$

For every fixed j *there exists* $R_j^\infty \in \mathcal{A}_E(\Lambda_{n_j})$ *such that*

$$\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_j^k - R_j^\infty) \longrightarrow 0, \qquad \|\widehat{\nu}_j^k - \widehat{\nu}_j^\infty\|_{\mathrm{TV}} \longrightarrow 0 \qquad (k \to \infty),$$

where $\widehat{\nu}_j^\infty$ *has the density of the same form with* $E_{\infty,\mathrm{sat}}$ *and* $R_{j,\mathrm{sat}}^\infty$, *the same indicator* $\mathbf{1}_{D_r}$, *and a positive finite normalizer. The contraction constants have the dependence described in item (2) of Definition 4.14; they are uniform in the side and in the preceding depth for fixed analytic parameters. The continuity moduli and the convergence thresholds may in addition depend on the fixed lattices and on* j, t, $p(t)$, L, *and* γ. *No rate that is uniform in the resolution, in the number of RG steps, or as* $\gamma \to 0$ *is asserted.*

Here E_∞ is the limit of the effective classical actions E_d at the fixed lattice (Theorem 11.2), and $E_{\infty,\mathrm{sat}}$ is its gauge-invariant extension.

Remark 15.7. The second-order gain in the coupling has the following heuristic origin. Suppose that a reconstruction has the expansion $F(\theta, tw) = F(\theta,0) + tL_\theta w + O(t^2)$. For a difference Δ of two effective interactions we then have

$$\Delta(F(\theta,tw)) - \Delta(F(\theta,0)) = tD\Delta(F(\theta,0))[L_\theta w] + O(t^2).$$

Since the first term is linear in w, it has mean zero under the reference measure π_p, which is invariant under $w \mapsto -w$. The derivative of the negative logarithm of the fluctuation

integral in the direction Δ is the expectation of this difference under the interacting conditional measure. Its leading term is the reference expectation, which vanishes, and the interaction contributes another factor of t. Lemma 15.8 and the cluster expansion of Theorem 12.7 make this argument uniform in the volume and in the degree of the coefficients, in the norm $\mathcal{B}_{\rho,a_{\mathrm{sp}}}$. The cancellation is a property of the reference measure on each support; it does not use any symmetry of the interacting conditional measure.

Local interaction decompositions. For a family $\boldsymbol{A} = (A_Y)$ indexed by nonempty connected box sets Y, where $A_Y(\theta, w) = \sum_\nu A_{Y,\nu}(w)\theta^\nu$ depends only on the coarse-field and fluctuation variables located in Y, we use the norm

$$\|\boldsymbol{A}\|_{\mathscr{S}_h} = \sup_x \sum_{Y \ni x} e^{h|Y|} \sum_\nu \rho^{|\nu|} \sup_{w \in \Omega_p} |A_{Y,\nu}(w)| \tag{15.9}$$

of Theorem 12.7, with coarse-field radius ρ and the cutoff radius $p \geq 1$ of the RG step; the supremum is over boxes x. The next lemma gives an explicit decomposition of the fluctuation interactions into such families, with a bound on the difference family that is linear in the norm of the difference.

Lemma 15.8. *Assume the hypotheses of Theorem 15.6 at a fixed lattice pair and preceding depth d, with $p = p(t) \geq 1$. Let $R_1, R_2 \in \mathcal{A}_E$, $\Delta = R_1 - R_2$, $\delta = \mathcal{B}_{\rho,a_{\mathrm{sp}}}(\Delta)$, $\epsilon_i = \mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_i)$, and $R_s = R_2 + s\Delta$ for $0 \leq s \leq 1$. For $z \in \mathbb{C}$ replace the couplings g_i by $z\lambda_i$, both in the inputs $q_i = z\lambda_i w_i$ of ϕ_d and in the classical remainder of $H_{d,J}$, as in Definition 12.15, and keep fixed the cutoff radius p and all parameters on which the input effective interaction depends. There exists C_J such that, for $C_J|z|p < 1$, there exist families $\boldsymbol{H}(z)$, $\boldsymbol{A}_s(z)$, and $\boldsymbol{A}_\Delta(z)$, holomorphic in z with values in $\mathscr{S}_8$, with the following properties.*

1. *Their sums over Y are, respectively, the exponent $H_{d,J}$ with $g_i = z\lambda_i$, the function $R_s(e^{\phi_d(\theta,(z\lambda_i w_i))}) - R_s(e^{\phi_d(\theta,0)})$, and the same function with R_s replaced by Δ.*
2. *$\boldsymbol{A}_s = \boldsymbol{A}_0 + s\boldsymbol{A}_\Delta$, and $\boldsymbol{H}(0) = \boldsymbol{A}_s(0) = \boldsymbol{A}_\Delta(0) = 0$.*
3. *On each Y the coefficient of z in $A_{\Delta,Y}(z)$ is a linear function of the fluctuation variables.*
4. *They satisfy*

$$\begin{aligned} \|\boldsymbol{H}(z)\|_{\mathscr{S}_8} &\leq \frac{C_J|z|(p^3+p)}{1 - C_J|z|p}, \\ \|\boldsymbol{A}_s(z)\|_{\mathscr{S}_8} &\leq \frac{C_J|z|(\epsilon_1+\epsilon_2)p}{1 - C_J|z|p}, \\ \|\boldsymbol{A}_\Delta(z)\|_{\mathscr{S}_8} &\leq \frac{C_J|z|\delta p}{1 - C_J|z|p}. \end{aligned} \tag{15.10}$$

Supports that wrap around the torus are allowed.

Proof. The family $\boldsymbol{H}$ is the local interaction decomposition, constructed in the proof of Lemma 12.16, of the auxiliary fluctuation interaction of Definition 12.15 at the parameter $\zeta = z$; it is built from the decompositions of Lemma 12.9, whose item (4) allows a complex parameter. By stationarity of the conditional constrained minimizers and the normalization of the fluctuation variables by the constrained Hessians, the classical remainder has no terms of degree zero, one, or two in the fluctuation variables, and its coefficients of degree $m \geq 3$ carry the factor z^{m-2}. The coefficients of the Haar disintegration and determinant terms of degree $m \geq 1$ carry the factor z^m. The coefficient bounds of Lemma 12.9(4) are therefore bounds for a power series in z, and the bound (12.30) in the proof of Lemma 12.16 is the first inequality in (15.10), after enlarging C_J. In particular $\boldsymbol{H}(0) = 0$.

We now construct $\boldsymbol{A}_\Delta$. The construction is linear in the interaction, and we define $\boldsymbol{A}_s$ by the same construction applied to R_s; this proves the first assertion of (2). Since $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_s) \leq (1-s)\epsilon_2 + s\epsilon_1 \leq \epsilon_1 + \epsilon_2$, the bound for $\boldsymbol{A}_s$ follows from the bound for $\boldsymbol{A}_\Delta$ with δ replaced by $\epsilon_1 + \epsilon_2$.

Coefficients. We write

$$\Delta(e^{\xi}) = \sum_{n\geq 2} \frac{1}{n!} \sum_{j_1,\dots,j_n} \Delta_n(j_1,\dots,j_n) \prod_{r=1}^{n} \xi_{j_r}, \qquad \phi_{d,j}(\theta,q) = \sum_{|\alpha|+|\eta|\geq 1} \phi_{j;\alpha\eta}\, \theta^\alpha q^\eta,$$

where j, j_r range over the scalar coordinates of the fine lattice, and α and η are multi-indices in the coarse-field variables and the inputs. Since $\phi_d(0,0) = 0$, substitution gives, for $|\alpha| + |\eta| = N$,

$$[\theta^\alpha q^\eta]\, \Delta(e^{\phi_d(\theta,q)}) = \sum_{n=2}^{N} \frac{1}{n!} \sum_{j_1,\dots,j_n} \sum_{\substack{\alpha_1+\cdots+\alpha_n=\alpha,\ \eta_1+\cdots+\eta_n=\eta \\ |\alpha_r|+|\eta_r|\geq 1}} \Delta_n(j_1,\dots,j_n) \prod_{r=1}^{n} \phi_{j_r;\alpha_r\eta_r}. \tag{15.11}$$

No further multinomial factor occurs, since each $\phi_{j;\alpha\eta}$ is already the coefficient of a monomial. An occurrence o consists of n, the indices $j_1,\dots,j_n$, and an ordered allocation $(\alpha_r,\eta_r)_{r\leq n}$ in (15.11). To $\Delta_n(j_1,\dots,j_n)$ we assign a shortest connected network through the locations of $j_1,\dots,j_n$, and to each $\phi_{j_r;\alpha_r\eta_r}$ a shortest connected network through the location of j_r and the locations of its inputs. The union $\mathcal{N}_o$ is a connected network through the locations of all external variables of o, and its length ℓ_o is at most the sum of the lengths of these networks. Let N_o be the number of external variables of o, counted with multiplicity.

The families. We keep the occurrences with $|\eta| \geq 1$. For such an occurrence, let

$$a_o(z) = \frac{z^{|\eta|}}{n!} \Delta_n(j_1,\dots,j_n) \prod_{r=1}^{n} \phi_{j_r;\alpha_r\eta_r} \prod_{l} \lambda_{i(l)}^{\eta_l},$$

where l runs over the inputs and $i(l)$ is the intermediate scale of the input l. Let Y_o be the box set assigned by Lemma 15.3 to the locations of the external variables of o and the network $\mathcal{N}_o$, and define

$$A_{\Delta,Y}(\theta, w; z) = \sum_{o:\, Y_o = Y} a_o(z)\, \theta^{\alpha} w^{\eta}.$$

The occurrences with $\eta = 0$ sum to $\Delta(e^{\phi_d(\theta,0)})$. Hence, once absolute convergence is established below,

$$\sum_{Y} A_{\Delta,Y}(z) = \Delta(e^{\phi_d(\theta,(z\lambda_i w_i))}) - \Delta(e^{\phi_d(\theta,0)}),$$

which is (1) for $\boldsymbol{A}_\Delta$. Since every coefficient carries a positive power of z, we have $\boldsymbol{A}_\Delta(0) = 0$, and the coefficient of z collects the occurrences with $|\eta| = 1$, which are linear in w. This proves (2) and (3).

Spatial weights. The networks of Δ_n have lengths measured in units of the fine lattice; in units of the coarse lattice these lengths are divided by B. By the last condition in (15.4) and $C_{\mathrm{geom}} \geq 1$, a weight $e^{b\ell}$ on this part, with ℓ in coarse units, is at most the weight $e^{a_{\mathrm{sp}}\mathfrak{t}}$ in fine units, which is included in δ. The networks attached to the coefficients of ϕ_d are weighted by the spatial rate of the bounds of Theorem 13.2, which exceeds b. With $h = 8$, $K = e^{8c_0}$, and the choices of $\mathscr{L}$ and μ made before (15.4), the exponent β in Lemma 15.3 is at most $b/2$, so the weight $e^{\beta\ell_o}$ is covered by these two weights.

The bound. In (15.9) we bound the supremum over $w \in \Omega_p$ by the sum of the absolute values of the coefficients of w^η times $p^{|\eta|}$; since $|\lambda_i| \leq 1$, the input l then has radius at most $|z|p$. For an occurrence o and a box $x \in Y_o$ we apply (15.3), with u the location of an input l of o, and we sum over all inputs l with their multiplicities $\eta_l \geq 1$; this overcounts each occurrence. The factor K^{N_o} is absorbed by multiplying the coarse-field radius ρ and the input radius $|z|p$ by K. For a fixed input l, the weighted sum over the occurrences containing l is bounded by the calculus of nonnegative coefficient bounds of Lemma 5.3. The outer coefficient Δ_n is summed with one index fixed, the branch r containing l is summed by its volume-normalized column sum at l, and the remaining branches by their row sums. Let

$$F_\Delta(y) = \sum_{n \geq 2} \frac{\|D^n \Delta(0)\|_{a_{\mathrm{sp}},\mathrm{root}}}{n!} y^n,$$

let $c_q(U, V)$ be the majorant of the input-fixed column sums of ϕ_d at a fixed free input, in which every input, including the fixed one, is weighted by its radius, as in Theorem 13.2(1), and let

$$\Gamma_J = \max_l \frac{v_l}{v_{\mathrm{fine}}} \leq M^{3J},$$

where v_l is the cell volume at the mesh of the input l and v_{fine} the cell volume of the fine lattice. The factor Γ_J converts the volume-normalized column sum of ϕ_d into the counting sum used in the norm of Δ. Choosing the branch that contains l produces the derivative

of F_Δ. With $S_J(\mu) = D_J \sum_{r\ge 0}(r+2)^3 e^{-\mu r}$, where $D_J(r+2)^3$ bounds the number of inputs at distance between r and $r+1$ from a point, we obtain

$$\|\boldsymbol{A}_\Delta(z)\|_{\mathscr{S}_8} \le C_8 S_J(\mu)\Gamma_J F'_\Delta\big(\mathfrak{M}_J(K\rho, K|z|p)\big)\, c_q(K\rho, K|z|p). \tag{15.12}$$

Let $U_0 = 4K_*\rho$ and $V_0 = 4K_* s_J$ be the radii of Lemma 15.4. Since $\sum_{n\ge 2}\rho^{n-2}\|D^n\Delta(0)\|_{a_{\mathrm{sp}},\mathrm{root}}/n! = \delta$, we have, for $0 \le y \le \rho/2$,

$$F'_\Delta(y) \le \delta\rho \sum_{n\ge 2} n 2^{1-n} = 3\delta\rho.$$

By Theorem 13.2(1), $c_q \le V\partial_V \widetilde{\mathfrak{M}}_J$ for a majorant $\widetilde{\mathfrak{M}}_J(U,V) = B^{-1}\widetilde{Z}(U) + C_{\mathrm{im},J}V/(1 - C_{\mathrm{im},J}(U+V))$ of the same form. Since $\partial_V[C_{\mathrm{im},J}V/(1 - C_{\mathrm{im},J}(U+V))] = C_{\mathrm{im},J}(1 - C_{\mathrm{im},J}U)/(1 - C_{\mathrm{im},J}(U+V))^2$, and the denominator is at least η_{im} on the product of Lemma 15.4, the quantity $L_J = \sup_{0<V\le V_0} c_q(U_0,V)/V$ is at most $C_{\mathrm{im},J}\eta_{\mathrm{im}}^{-2}$. Let

$$B_\Delta = 3\Gamma_J\rho\, C_8 S_J(\mu) L_J K,$$

and choose $C_J \ge \max\{1, B_\Delta, K/V_0\}$. If $C_J|z|p < 1$, then $K|z|p < V_0$, and $K\rho < U_0$ because $K < 4K_*$; hence $\mathfrak{M}_J(K\rho, K|z|p) \le \mathfrak{M}_J(U_0,V_0) < \rho/2$ by (15.5). Inserting these bounds into (15.12), we find

$$\|\boldsymbol{A}_\Delta(z)\|_{\mathscr{S}_8} \le B_\Delta\delta|z|p \le \frac{C_J|z|\delta p}{1 - C_J|z|p}.$$

The factor δ enters through the single tensor Δ_n, never through the sum of two norms. The bound is uniform in $|z| \le r_0$ for every $r_0 < (C_J p)^{-1}$. The series defining $\boldsymbol{A}_\Delta$ therefore converges absolutely in $\mathscr{S}_8$ and is holomorphic in z, and all regroupings used above are justified. This proves (4). □

Proof of Theorem 15.6. The proof has seven steps. Step 1 identifies the transformation. Step 2 extracts the contraction of the pullback P_d from the estimate of Theorem 13.5. Step 3 proves the Lipschitz bound, using Lemma 15.8 and the second-order cancellation. Steps 4 and 5 compare two preceding depths at a fixed lattice pair: Step 4 shows that each fixed coefficient tensor of the output converges, uniformly over $\mathcal{A}_E$, and Step 5 deduces convergence in $\mathcal{B}_{\rho,a_{\mathrm{sp}}}$ from a bound at a larger radius. Step 6 combines the contraction with this continuity to construct R_j^∞, and Step 7 passes to the stopped measures.

Step 1: the transformation. All products used in this proof are subproducts of the products of Lemma 15.4. In particular, on the cutoff domain $\max_i\|g_i w_i\|_\infty \le tp(t) \le Q_{\mathrm{act}}$, so that $r + Q_{\mathrm{act}} < r_J$ and the denominator of the majorant is positive. The complex product of the auxiliary integral satisfies (15.5), with its intermediate domain conditions. Thus the rational bound of Theorem 13.2 is used only inside its domain. As explained before the theorem, $Q_d + P_d R + D_d R$ is the effective interaction produced from R before normalization, $\widehat{\mathcal{M}}_{d,t}R$ subtracts its value at the identity, and at a coarse field in B_r the prefactors of Theorem 14.6(2) times Ξ_R give the conditional fiber density before global normalization.

Step 2: contraction of the pullback. Let F have the symmetries of $\mathcal{A}_E$, be invariant under gauge transformations within B_ρ, and satisfy $F(I) = 0$, $DF(I) = 0$, and $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(F) < \infty$; we do not require $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(F) \le E$. For each fixed $h > 0$, the estimate of Theorem 13.5 applies to the input hF on a sufficiently small interval of couplings, which may depend on h. Its constants C_G, C_T, and q_P are fixed before the ceiling of the invariant ball is chosen. The estimate holds at the rate a_{sp}. Indeed, $a_{\mathrm{sp}} < a_{\mathrm{cen}}/8$ by (15.4), and the pullback P_d is the evaluation at the representative $e^{B^{-1}\overline{A}_{d,J}}$ of Lemma 11.9 (Theorem 13.2), for which Theorem 11.10 applies at every rate below $a_{\mathrm{cen}}/8$. At the fixed lattice pair, as $t \downarrow 0$ with $p = A_{\mathrm{w}} \log(1/t)$, the fluctuation exponent and the term containing the input tend to zero uniformly on a smaller complex product domain: they are bounded by $C_{\Lambda,J}\, t(p^3 + p)$ and $C_{\Lambda,J}\, h\mathcal{B}_{\rho,a_{\mathrm{sp}}}(F)\, tp$, respectively. Here the factors g_i^{-2} in the classical remainder have already canceled against its first two orders in the inputs. Since the coarse-field radius of this product exceeds ρ, Lemma 15.5 implies that the same convergence holds in $\mathcal{B}_{\rho,a_{\mathrm{sp}}}$. This gives $D_d(hF) \to 0$ in this norm. The estimate with zero input implies $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(Q_d) \le C_G$. Using the estimate with input hF and the triangle inequality, we find

$$h\mathcal{B}_{\rho,a_{\mathrm{sp}}}(P_d F) \le 2C_G + q_P h\mathcal{B}_{\rho,a_{\mathrm{sp}}}(F) + C_T t^2 h\mathcal{B}_{\rho,a_{\mathrm{sp}}}(F)\big(p^4 + h\mathcal{B}_{\rho,a_{\mathrm{sp}}}(F)p^2\big) + \mathcal{B}_{\rho,a_{\mathrm{sp}}}(D_d(hF)).$$

The pullback P_d does not depend on t or p. Letting $t \downarrow 0$, we obtain $h\mathcal{B}_{\rho,a_{\mathrm{sp}}}(P_d F) \le 2C_G + q_P h\mathcal{B}_{\rho,a_{\mathrm{sp}}}(F)$. Dividing by h and letting $h \to \infty$, we conclude that

$$\mathcal{B}_{\rho,a_{\mathrm{sp}}}(P_d F) \le q_{\mathrm{pr}} \mathcal{B}_{\rho,a_{\mathrm{sp}}}(F), \qquad q_{\mathrm{pr}} = q_P < 1/4. \tag{15.13}$$

All auxiliary limits in this step are taken on one fixed lattice, and the resulting constant q_P is the constant of Theorem 13.5, which is the same for every lattice and depth. Inputs of arbitrary finite norm were used only in that estimate, before its restriction to $\epsilon \le E$. The order of the two limits matters: the small-coupling limit is taken at fixed h.

Step 3: the Lipschitz bound. Let $R_1, R_2, \Delta, \delta, \epsilon_i, R_s$ be as in Lemma 15.8. The segment R_s stays in the class of real, symmetric, gauge-invariant functions with $R_s(I) = 0$, $DR_s(I) = 0$, and $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_s) \le \epsilon_1 + \epsilon_2$. We hold fixed all parameters of the input effective interaction and the cutoff radius, and we vary only the current couplings, through $g_i = z\lambda_i$. Set

$$R_z = \frac{c_J}{p^3 + (\epsilon_1 + \epsilon_2)p}, \tag{15.14}$$

where $c_J \le \min\{s_J, (2C_J)^{-1}, \eta_0/(8C_J)\}$, with C_J from Lemma 15.8 and η_0 from Theorem 12.7. For $|z| \le R_z$ we have $|z|p \le c_J/p^2 \le c_J$, so $C_J|z|p \le 1/2$, and the inputs with radii enlarged by K stay inside (15.5), with all intermediate domain conditions and denominators keeping strict margins. By (15.10) and $p \le p^3$, the family $\boldsymbol{U}_s(z) = \boldsymbol{H}(z) + \boldsymbol{A}_s(z)$ satisfies

$$\|\boldsymbol{U}_s(z)\|_{\mathscr{S}_8} \le 2C_J|z|(p^3 + p + (\epsilon_1 + \epsilon_2)p) \le 4C_J|z|(p^3 + (\epsilon_1 + \epsilon_2)p) \le 4C_J c_J \le \eta_0/2.$$

This choice depends only on J. Since the sum of $\boldsymbol{U}_s$ at $z = t$ is $H_{d,J} + A_{R_s}$, Theorem 12.7 implies that $-\log \Xi_{R_s} = \sum_Y \mathcal{L}_Y(\boldsymbol{U}_s(t))$. Since $\partial_s \boldsymbol{A}_s = \boldsymbol{A}_\Delta$, the derivative of the fluctuation correction along the segment is given by the family

$$\boldsymbol{F}_s(z) = D\boldsymbol{\mathcal{L}}(\boldsymbol{U}_s(z))[\boldsymbol{A}_\Delta(z)],$$

and by (12.15) and (15.10), we have

$$\|\boldsymbol{F}_s(z)\|_{\mathscr{S}_2} \le C_J |z| \delta p \qquad (|z| \le R_z), \tag{15.15}$$

after enlarging C_J. At $z = t$ the sum of $\boldsymbol{F}_s(t)$ over Y is the expectation of A_Δ under the interacting conditional measure, not under the reference measure.

Both $\boldsymbol{U}_s$ and $\boldsymbol{A}_\Delta$ vanish at $z = 0$. By Lemma 15.8(3), the coefficient of z in $\boldsymbol{A}_\Delta$ is linear in the fluctuation variables on each support, so its expectation under the symmetric reference measure π_p vanishes before the sums over supports and over coefficients are taken. The terms containing a further factor of the interaction, including the differences of the Haar disintegration and determinant terms, are of degree at least two in z. Applying Corollary 12.8 with $a = 2C_J \delta p$, which bounds $\|\boldsymbol{A}_\Delta(z)\|_{\mathscr{S}_8}/|z|$ on the disc by (15.10), and with $R = R_z$, we obtain

$$\|\boldsymbol{F}_s(t)\|_{\mathscr{S}_2} \le C_J t^2 \delta [p^4 + (\epsilon_1 + \epsilon_2) p^2], \qquad 0 < t \le R_z/2, \tag{15.16}$$

after enlarging C_J once more.

The fluctuation correction, its value at zero fluctuation, and its derivative along the segment are invariant under translations and global color rotations, by Theorem 12.13. The coordinate changes map zero fluctuations to zero fluctuations, and the first derivatives with respect to the coarse field vanish at the identity. Every support of the logarithm is a union of supports of the decomposition whose intersection graph is connected. By Lemma 15.2 and (15.4), we have $a_{\mathrm{sp}}\mathrm{t} \le 2|Y|$ for the locations of the coarse-field variables in each such support, including subsets and repetitions. The conversion of local interaction decompositions into the norm $\mathcal{B}_{\rho, a_{\mathrm{sp}}}$ in Theorem 13.5, with nine types of scalar indices, therefore applies to (15.16) at the radius ρ, with the factor $9\rho^{-2}$. We integrate in s and add (15.13). The common term Q_d cancels in the difference, and the subtraction of the values at the identity does not change $\mathcal{B}_{\rho, a_{\mathrm{sp}}}$. This gives the factor

$$q_{\mathrm{pr}} + C_J t^2 [p^4 + (\epsilon_1 + \epsilon_2) p^2],$$

after enlarging C_J. One reduction of g_* imposes $p(t) \ge 1$, by taking $g_* \le e^{-1/A_{\mathrm{w}}}$, together with $t[p(t)^3 + 2Ep(t)] \le c_J/2$, which gives $t \le R_z/2$ when $\epsilon_1 + \epsilon_2 \le 2E$, and $C_J t^2 [p(t)^4 + 2Ep(t)^2] \le (1 - q_{\mathrm{pr}})/2$, for all $0 < t \le g_*$. The factor is then at most $\vartheta = (1 + q_{\mathrm{pr}})/2$.

Step 4: changing the preceding depth. By Theorem 11.2, all classical data of the RG step converge on strictly smaller product domains as the preceding depth tends to infinity. These data are the conditional constrained minimizers, the constrained Hessians, the analytic branches of their square roots and inverse square roots that are positive at real arguments, every Haar disintegration density, and the triangular reconstruction. The Hessians here are those of the intermediate scales, with their couplings g_i; no inverse of a Hessian in the coarse-field variables is needed. In particular $H_{d,J}$ and $\mathsf{B}_{\mathrm{ref}}$ converge with every fixed derivative, since their formulas in Theorem 12.13 are finite compositions of these data on products where all domain conditions hold.

It remains to control the term with the input effective interaction, uniformly in $R \in \mathcal{A}_E$. For two depths d, d' we use the same gauge transformation Ω_d on both reconstructions $\mathscr{C}_{\mathrm{raw}\,d}$ and $\mathscr{C}_{\mathrm{raw}\,d'}$. The arguments stay in the common product (15.5). The product with radii enlarged by K has radii strictly below $u_\circ$ and $v_\circ$, so their sum is less than r_J and the denominator of the majorant is at least η_{im}. Every intermediate map keeps its strict domain margin on this product. The bounds of Theorem 13.2 for the gauge transformation and its inverse, together with the convergence of the reconstructions, put the image $\mathrm{Log}[\mathscr{C}_{\mathrm{raw}\,d'}^{\Omega_d}]$ in $B_{3\rho/4}$ for all sufficiently large pairs of depths, while ϕ_d has image in $B_{\rho/2}$. All these bounds hold on a smaller complex product which still contains the output radius ρ and the cutoff domain. At depth d' we compare $R(\exp \mathrm{Log}[\mathscr{C}_{\mathrm{raw}\,d'}^{\Omega_d}])$ with $R(e^{\phi_{d'}})$. On real inputs these are evaluations of the gauge-invariant extension R_{sat} at two gauge-equivalent representatives of the same reconstruction, both in B_ρ, so they agree. Both functions are holomorphic on the comparison product, and their difference vanishes on an open real box. By the one-variable identity theorem applied in each coordinate, it vanishes identically. We may therefore compare the depths d and d' in the common gauge Ω_d. Since the derivative bound of Lemma 15.5 on $B_{3\rho/4}$ is uniform over $\mathcal{A}_E$, this term and each of its fixed derivatives change by $o(1)$ as $d, d' \to \infty$, uniformly over $\mathcal{A}_E$, without any assumption on the behavior of the sequence Ω_d.

Since the cutoff domain and its couplings do not change, the integrands on this fixed finite product, together with their fixed derivatives in the coarse field, are uniformly Cauchy. By Theorem 12.7, the logarithm of each partition function is the sum of a local interaction decomposition over the finitely many boxes of the lattice, with a bound in $\mathscr{S}_2$. This sum is bounded on the chosen complex product, and the modulus of each partition function has a positive lower bound there. Its branch agrees with the real logarithm at real coarse fields. Comparing the ratio of two close partition functions on a disc about one, we find that the logarithms, normalized at the identity, converge together with every fixed coefficient tensor of the output, uniformly in $R \in \mathcal{A}_E$.

Step 5: convergence in the norm. Fix $\rho < \rho_1 < 2\rho$ so close to ρ that the products with coarse-field radius ρ_1, enlarged by K, still lie in the larger analytic product domain. The argument of the input effective interaction stays below its input radius ρ, also at

the output radius ρ_1. Positive composition and the two expansions of Lemma 12.9 and Theorem 12.6 use the same connected box sets and their unions with connected intersection graph. Hence Lemma 15.2 still gives $a_{\mathrm{sp}}\mathrm{t} \le 2|Y|$ at this larger output radius. The output is translation invariant and has vanishing first derivative at the identity, as in Step 3. The conversion of Theorem 13.5, now with factor $9\rho_1^{-2}$, gives

$$\sup_{d,\, R\in\mathcal{A}_E} \mathcal{B}_{\rho_1,a_{\mathrm{sp}}}\big(\widehat{\mathcal{M}}_{d,t}R\big) \le C_{\Lambda,J,t,p,E}. \tag{15.17}$$

Only sufficiently large d are needed here; the finitely many smaller depths have finite bounds and are included after enlarging the constant. At the radius ρ_1 the bound need not be E. Applying Lemma 15.5 to (15.17) and to the convergent coefficient tensors of Step 4, we obtain the continuity statement at exactly the radius ρ and the exponent a_{sp}. Nothing in this argument identifies the auxiliary integral at coarse fields outside B_r with a conditional integral of the conditioned measure.

Step 6: contraction over finitely many scales. Fix j and a positive integer m. If $k, k' \ge j + m$, the two hierarchies have the same lattices and couplings at the levels $j, \dots, j+m$, and their effective interactions at level $j+m$ lie in $\mathcal{A}_E$ by Theorem 14.6. For $h = j+1, \dots, j+m$, define

$$\varepsilon_h(k,k') = \sup_{R\in\mathcal{A}_E} \mathcal{B}_{\rho,a_{\mathrm{sp}}}\big(\widehat{\mathcal{M}}_{J(k-h),t_h}R - \widehat{\mathcal{M}}_{J(k'-h),t_h}R\big).$$

For fixed m and h this tends to zero as $k, k' \to \infty$, by Step 5. Inserting and subtracting at each level the first operator applied to the second input, and using the contraction and the triangle inequality, we obtain

$$\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_j^k - R_j^{k'}) \le 2E\vartheta^m + \sum_{h=j+1}^{j+m} \vartheta^{h-j-1}\varepsilon_h(k,k'). \tag{15.18}$$

We let $k, k' \to \infty$ at fixed m, and then $m \to \infty$. The space of coefficient sequences with finite norm is complete: each coefficient tensor has a limit, Fatou's lemma bounds the weighted sums of the limit, and the Cauchy property makes the tails uniform. The limit series converges absolutely on the same ball and defines R_j^∞ with $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_j^k - R_j^\infty) \to 0$. Its value and first derivative at the identity vanish. Reality, the symmetries, and the identities expressing gauge invariance within B_ρ pass to the pointwise limit, which defines $R_{j,\mathrm{sat}}^\infty$ on D_ρ. Thus $R_j^\infty \in \mathcal{A}_E$.

Step 7: stopped measures. The stopped density in the statement is the density of Theorem 14.6 after $k - j$ RG steps, with preceding depth $J(k-j)$. Its classical term converges by Theorem 11.2 on this fixed lattice, and the gauge-invariant extension preserves the

uniform bound on B_r. Combining this with Step 6 and the value bound of Lemma 15.5, we obtain

$$\delta_{j,k} = \sup_{D_r} \Big| \frac{E_{J(k-j),\mathrm{sat}} - E_{\infty,\mathrm{sat}}}{g_j^2} + R^k_{j,\mathrm{sat}} - R^\infty_{j,\mathrm{sat}} \Big| \longrightarrow 0. \tag{15.19}$$

Here $g_j > 0$ is fixed. At this finite volume, the limiting weight is bounded above and below by positive constants on D_r. Since D_r contains a real open neighborhood of the identity of positive Haar measure, the limiting normalizer is positive and finite. By Lemma 15.1(1), the total variation distance between $\widehat{\nu}^k_j$ and $\widehat{\nu}^\infty_j$ is at most $e^{2\delta_{j,k}} - 1$, which proves the convergence of the stopped measures. The identification $n_0 = n_s$, $k = K - s$ follows from Definition 4.4. All the nonuniform constants introduced in (15.17)–(15.19) concern fixed finite resolutions or fixed positive couplings, as asserted. □

15.4 Conditional fluctuation kernels and the coarse-level measure

We now identify the conditional law of the fluctuation variables of one RG step, given the field at the coarser level, and prove its convergence. We then write the conditioned Wilson measure as an iteration of these kernels, starting from its marginal on the coarse lattice.

Theorem 15.9. *In the hierarchy of Theorem 15.6, fix $j \geq 1$ and $k \geq j$, and recall $d^k_j = J(k-j)$, $t_j = M^{(J-1)/2} g_j$, $p_j = p(t_j)$, and the cutoff domain Ω_{p_j} of the RG step from level j to level $j-1$, which does not depend on k. For a field $c = e^\theta \in B_r$ at level $j-1$, the conditional fluctuation kernel of level j is*

$$k^k_j(\theta, dw) = \frac{\mathbf{1}_{\Omega_{p_j}}(w)\, e^{-V^k_j(\theta,w)}\, dw}{\int_{\Omega_{p_j}} e^{-V^k_j(\theta,v)}\, dv},$$

with the conditional fluctuation potential

$$\begin{aligned} V^k_j(\theta, w) = {} & \tfrac{1}{2}|w|^2 + H_{d^k_j, J}(\theta, w) \\ & + R^k_{j,\mathrm{sat}}\big(\mathscr{C}_{\mathrm{raw}\, d^k_j}(\theta, (g_{j,i} w_i)_i)\big) - R^k_{j,\mathrm{sat}}\big(\mathscr{C}_{\mathrm{raw}\, d^k_j}(\theta, 0)\big). \end{aligned}$$

Here $H_{d,J}$ is the fluctuation exponent of Theorem 12.13, including every difference of determinant terms that depends on coarser fluctuation variables; only terms independent of w have been canceled. The reconstruction uses the inputs $g_{j,i} w_i$, with their fixed ratios, and contains every inverse square root of the constrained Hessians. There exists a limiting potential V^∞_j on the same product such that

$$\Delta_{j,k} = \sup_{e^\theta \in B_r,\, w \in \Omega_{p_j}} |V^k_j(\theta, w) - V^\infty_j(\theta, w)| \longrightarrow 0, \qquad \sup_{e^\theta \in B_r} \|k^k_j(\theta, \cdot) - k^\infty_j(\theta, \cdot)\|_{\mathrm{TV}} \leq e^{2\Delta_{j,k}} - 1.$$

The reconstructions $\mathscr{C}_{\mathrm{raw}\, d_j^k}$ converge uniformly on this product. The limiting density and the limiting reconstruction are Borel and continuous in θ on the smaller coordinate chart, and all normalizers are positive. The formula defines a version of the conditional law at every field in B_r, including fields of zero probability. Restrictions at coarser levels are functions of the field at level $j-1$, and they cancel from this conditional law wherever it is used. The constants have the fixed-resolution dependence of Theorem 15.6. No total variation statement is made for the images of these kernels under reconstruction maps that depend on k.

Proof. Here $t_j = g_{j-1}/\sqrt{M} = M^{(J-1)/2} g_j$ is the largest coupling of the intermediate scales, and $g_{j,i} = t_j M^{(i-J+1)/2}$, $0 \le i < J$. Thus the cutoff domain, its radii, and all ratios of couplings are fixed once j, L, γ, and the hierarchy are fixed.

We apply Theorem 12.13 with preceding depth d_j^k. Its telescoping identity for the classical action contributes $|w|^2/2$ and the classical remainder. Its triangular determinant contributes the factors $g_{j,i}^{3f_i}$, the zero-fluctuation terms $(1/2)\log\det K_i$, and the differences of these terms that depend on coarser fluctuation variables. Its Haar disintegration densities contribute their values at the identity and all nonconstant differences. The unnormalized fiber is therefore exactly

$$C_j^k(c)\, \mathbf{1}_{\Omega_{p_j}}(w)\, e^{-V_j^k(\theta,w)}\, dw,$$

where $C_j^k(c) > 0$ collects the factors that depend only on the field c, including the value of the input effective interaction at zero fluctuation, and V_j^k is the displayed potential. By Theorem 14.6, the indicator of D_r at level j and all intermediate domain indicators equal one on the whole product, at every field in B_r. Dividing this fiber by its own integral gives the formula for the kernel.

For the convergence, we first compare the same input effective interaction R at two preceding depths, using the common gauge transformation of Step 4 in the proof of Theorem 15.6. Both images lie in $B_{3\rho/4}$ on a common complex product. The difference of the reconstructions tends uniformly to zero, and the derivative bounds for R on $B_{3\rho/4}$ are uniform over $\mathcal{A}_E$. Next we replace R_j^k by R_j^∞ on this image. By the value bound of Lemma 15.5, this changes the potential by at most $D_{\Lambda_j}\rho^2 \mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_j^k - R_j^\infty)$, where D_{Λ_j} is the number of scalar link coordinates at level j. We apply these two comparisons at w and at $w = 0$. The classical and Haar disintegration terms converge by Theorem 11.2. Thus the potentials are uniformly Cauchy on the closed product of fields and fluctuation variables, which gives $\Delta_{j,k} \to 0$.

To define the limiting potential, we fix any sufficiently late depth d and use its gauge transformation Ω_d as a comparison gauge. It puts the image of the limiting reconstruction in $B_{3\rho/4}$, so R_j^∞ can be evaluated holomorphically there. Two such choices agree on real data, by gauge invariance within B_ρ, and hence as holomorphic functions, by the

coordinatewise identity argument of Step 4. The convergence of the reconstructions themselves follows from Theorem 11.2 and does not involve this interaction.

By Lemma 15.1(1), applied to Lebesgue measure on Ω_{p_j}, the total variation distance is at most $e^{2\Delta_{j,k}} - 1$, uniformly in the field. The integrals are positive, since the product has positive Lebesgue measure. On every closed smaller coordinate chart the limiting potential is continuous and bounded, so its exponential has a positive integral which depends continuously on θ. This proves that the normalized density is Borel and continuous in θ, and that the limiting reconstruction is continuous. In particular the density defines a version of the conditional law even at fields of zero probability.

Finally, once the field at level $j-1$ is fixed, a restriction at a coarser level has the form $a(c) \in \{0,1\}$, because all further averaging maps are deterministic. At a field used by the conditioned measure we have $a(c) = 1$, and it cancels between the fiber and its normalizer. For a general nonnegative factor depending only on c the same cancellation holds wherever the factor is positive. This proves the last assertion. □

Lemma 15.10. *Fix $k \geq 1$ and the conditioned Wilson measure ν^k, with meshes $a_j = HB^{-j}$ and preceding depths $d_j^k = J(k-j)$. Fix a Borel map S_0, independent of k, from D_r on the coarse lattice Λ_{n_0} to $\{\theta : \|\theta\|_\infty < r\}$ such that $e^{S_0(U)}$ is gauge equivalent to U; such a map exists and is constructed in the proof. Let $\theta_0 = S_0(V^{Jk})$, where V^{Jk} is the coarse field of $U \sim \nu^k$. Given $\theta_0, w_1, \dots, w_{j-1}$, let w_j have the law $k_j^k(\theta_{j-1}, \cdot)$, and put*

$$U_0 = e^{\theta_0}, \qquad U_j = e^{\theta_j}, \quad \theta_j = \Phi_{d_j^k, j}\big(\theta_{j-1}, (g_{j,i} w_{j,i})_i\big), \qquad T_M^J U_j = U_{j-1} \quad (1 \leq j \leq k).$$

Here $\Phi_{d,j}$ is either the map ϕ_d of Section 15.3, built with the gauge transformations of Theorem 13.2, or the logarithmic coordinate representation $\widehat{\Phi}_{d,\Lambda_j}$ of the reconstruction map of Theorem 15.12 below; in both cases the gauge transformation depends only on the field at level $j-1$ and equals the identity at the vertices of $\Lambda_{n_{j-1}}$. Then the following hold.

1. *The gauge orbits $([U_0], \dots, [U_k])$ have the law of the gauge orbits $([V^{Jk}], [V^{J(k-1)}], \dots, [V^0])$ under ν^k.*
2. *If the field at level $j-1$ is replaced by another gauge-equivalent representative in B_r, the kernels correspond under a triangular change of fluctuation coordinates with orthogonal diagonal blocks, which preserves the balls of the cutoff domain and the normalized density.*
3. *Restrictions at coarser levels that are functions of the field at level $j-1$ do not change the conditional law at level j.*

The map S_0 need not be constant on gauge orbits.

Suppose in addition that, on the products used in the construction,

$$\|\Phi_{d,j}(\theta, q)\|_\infty \leq a_{\mathrm{cap}} \|\theta\|_\infty + C_{\mathrm{rec},J} \max_i \|q_i\|_\infty, \qquad a_{\mathrm{cap}} = C_{\mathrm{CP}}/B, \qquad a_{\mathrm{cap}} \sqrt{B} < 1,$$

where $C_{\mathrm{CP}} \geq 1$ is fixed before J. Put $b_j = \|\theta_j\|_\infty$. Then on every sample, uniformly in k, j, and d_j^k,

$$b_j \leq a_{\mathrm{cap}} b_{j-1} + C_{\mathrm{rec},J} t_j p_j, \qquad b_j \leq r a_{\mathrm{cap}}^j + C_{\mathrm{cap},J} g_3 \sqrt{a_j}\, p_j,$$

for any $C_{\mathrm{cap},J} \geq M^{(J-1)/2} C_{\mathrm{rec},J}/(1 - a_{\mathrm{cap}}\sqrt{B})$. For $2 \leq l \leq k$,

$$\sum_{j=l}^{k} b_{j-1} \leq C_J \{ r a_{\mathrm{cap}}^{l-1} + g_3 \sqrt{a_{l-1}}\,(p_l + 1) \};$$

for $l = 1$ one adds the term $b_0 < r$. These constants have the dependence described in item (2) of Definition 4.14, and they may depend on $(1 - a_{\mathrm{cap}}\sqrt{B})^{-1}$; the physical parameters and the mesh factors are displayed explicitly.

Proof. We first construct S_0. The gauge group of the coarse lattice is a finite product of compact matrix groups and has a countable dense subset $(h_m)_{m \geq 1}$. For $U \in D_r$ the set of gauge transformations carrying U into the open set B_r is nonempty and open, so some h_m does so; we choose the least such m and set $S_0(U) = \mathrm{Log}(U^{h_m})$. The sets $\{U : U^{h_m} \in B_r\}$ are open, and removing from each of them the finitely many earlier ones gives Borel sets on which the choice is constant. Thus S_0 is Borel and independent of k, and it carries every field in D_r into B_r.

At fixed k, the density of ν^k disintegrates, by the fiber formula of Theorem 14.6, into its coarse marginal and the normalized kernels of Theorem 15.9. To verify this without choosing an abstract version of the conditional law, we multiply the unnormalized fiber by a bounded test function of the coarse field and a bounded test function of the fluctuation variables, and integrate. By Fubini's theorem and the exact fiber normalizer, we obtain the proposed conditional integral. We repeat this finite calculation from the coarse side to the fine side. At each repetition, all remaining restrictions at coarser levels are factors depending only on the coarser field, and they cancel. Integrating the resulting iterated product against the coarse marginal constructs the finite random hierarchy of the statement.

For changes between coarse representatives in B_r, we use part (3) of Theorem 13.4. The enlarged-domain reconstruction hypothesis inherited from Theorem 15.6 places both intermediate reconstructions in the required comparison domains, with margins. The transition is triangular in the intermediate scales and has orthogonal color rotations and block permutations on its diagonal, so it preserves every ball, the Gaussian term $|w|^2/2$, and Lebesgue measure, with absolute Jacobian one. The representative change after reconstruction is given by Theorem 13.2(4). For the initial coarse field, which lies in D_r but possibly outside B_r, the passage to the representative $e^{S_0(U)}$ uses the gauge invariance of the input density and of the restriction event in parts (1)–(3) of Theorem 13.4, not the chart theorem of Theorem 12.13. The Haar disintegration density and the gauge-invariant extension of the input effective interaction transform by the same identity, so the

normalized conditional density is preserved. This proves (2). Once the field at level $j-1$ is fixed, the gauge transformation in Φ does not depend on the fluctuation variables and equals the identity at every vertex of $\Lambda_{n_{j-1}}$. By gauge covariance of the block averaging map we have

$$T_M^J\big(\mathscr{C}_{\mathrm{raw}\,d}(c,q)^{\Omega(c)}\big) = \big(T_M^J \mathscr{C}_{\mathrm{raw}\,d}(c,q)\big)^{\Omega|_{\Lambda_{n_{j-1}}}} = c,$$

which proves the relation $T_M^J U_j = U_{j-1}$ at every step. The same computation applies to the reconstruction maps of Theorem 15.12, which have these properties by construction. We conclude that every function of the tuple that is invariant under gauge transformations at each level has the same expectation as under ν^k, which is (1). Assertion (3) is the last part of Theorem 15.9.

On the cutoff domain $\max_i \|g_{j,i} w_{j,i}\|_\infty \le t_j p_j$, and the assumed bound on Φ implies the first recurrence. We write $a = a_{\mathrm{cap}}$, $\xi = a\sqrt{B} < 1$, and $c_B = M^{(J-1)/2}$. Since $b_0 < r$ and $t_i = c_B g_3 \sqrt{a_i} = c_B g_3 \sqrt{a_j} B^{(j-i)/2}$, iteration gives

$$\begin{aligned} b_j &\le r a^j + C_{\mathrm{rec},J} \sum_{i=1}^{j} a^{j-i} t_i p_i = r a^j + c_B C_{\mathrm{rec},J} g_3 \sqrt{a_j} \sum_{i=1}^{j} \xi^{j-i} p_i \\ &\le r a^j + \frac{c_B C_{\mathrm{rec},J}}{1-\xi} g_3 \sqrt{a_j}\, p_j. \end{aligned} \tag{15.20}$$

In the last inequality we used $p_i \le p_j$, which holds since $p_j = p_1 + (j-1)c_p$ with $c_p = A_{\mathrm{w}} \log B/2 > 0$. This gives the second bound on b_j, on every sample. Only a constant depending on J is enlarged here; C_{CP} and a_{cap} stay fixed.

For $l \ge 2$, let $x = B^{-1/2}$. Using $\sqrt{a_h} = \sqrt{a_{l-1}}\, x^{h-l+1}$, $p_h = p_{l-1} + (h-l+1)c_p$, and the sums $\sum_{h\ge 0} x^h = (1-x)^{-1}$ and $\sum_{h\ge 0} h x^h = x(1-x)^{-2}$, we obtain

$$\begin{aligned} \sum_{j=l}^{k} b_{j-1} &\le \frac{r a^{l-1}}{1-a} + C_{\mathrm{cap},J} g_3 \sqrt{a_{l-1}} \Big(\frac{p_{l-1}}{1-x} + \frac{c_p x}{(1-x)^2} \Big) \\ &\le C_J \big\{ r a^{l-1} + g_3 \sqrt{a_{l-1}}\,(p_l + 1) \big\}, \end{aligned} \tag{15.21}$$

where $C_J \ge \max\{(1-a)^{-1}, C_{\mathrm{cap},J}[(1-x)^{-1} + c_p x (1-x)^{-2}]\}$. For $l = 1$ we separate $b_0 < r$ and apply this calculation from $j = 2$. □

Lemma 15.11. *In the hierarchy of Theorem 15.6, fix n_0, $L, \gamma > 0$, and the Borel map S_0 of Lemma 15.10, independent of k. Let $\nu^k_{0,\mathrm{full}}$ be the marginal of ν^k on the coarse lattice, that is, the law of V^{Jk}. Then $\nu^k_{0,\mathrm{full}} = \widehat{\nu}^k_0$, and the laws $\eta^k_0 = (S_0)_* \nu^k_{0,\mathrm{full}}$ and $\eta^\infty_0 = (S_0)_* \widehat{\nu}^\infty_0$ of the coarse logarithm satisfy*

$$\|\eta^k_0 - \eta^\infty_0\|_{\mathrm{TV}} \le \|\widehat{\nu}^k_0 - \widehat{\nu}^\infty_0\|_{\mathrm{TV}} \longrightarrow 0.$$

The limiting stopped measure has a positive normalizer. The map S_0 need only be Borel. The convergence has the dependence of Theorem 15.6 at the fixed coarse side.

Proof. We integrate the density of ν^k down to the coarse lattice, using Theorem 14.6. All k restrictions on the fluctuation variables and the indicator of D_r on the coarse lattice have been included, and no restriction at a coarser level remains. The normalized density is exactly that of $\widehat{\nu}_0^k$. Applying Theorem 15.6 with $j = 0$, we obtain its total variation limit and the positive limiting normalizer. For every Borel set A,

$$|\eta_0^k(A) - \eta_0^\infty(A)| = |\widehat{\nu}_0^k(S_0^{-1}A) - \widehat{\nu}_0^\infty(S_0^{-1}A)| \le \|\widehat{\nu}_0^k - \widehat{\nu}_0^\infty\|_{\mathrm{TV}}.$$

Taking the supremum over A, as in Lemma 5.5, completes the proof; no continuity of S_0 is needed. □

15.5 A fixed family of reconstruction maps

The gauge transformations Ω_d of Theorem 13.2 are auxiliary: they change only the representative in which the input effective interaction is evaluated, and the conditional measures do not depend on them. However, Theorem 13.2 asserts nothing about their convergence as the preceding depth tends to infinity, so the reconstructed fields need not converge. To fix this, we use that at a fixed lattice pair the gauge transformations form a bounded family of holomorphic functions of finitely many variables, so they have a convergent subsequence. We choose one subsequential limit and use it at every preceding depth beyond a deterministic threshold. The exact averaging identities and the conditional densities are preserved, because the new gauge transformation is the identity at the vertices of the coarse lattice and this interaction is gauge invariant. This is not a gauge fixing on the space of gauge orbits. The threshold must be large enough to preserve certain bounds, and we keep track of the order in which the constants are chosen:

$$\begin{aligned} C_{\mathrm{CP}} \text{ and the spatial parameters } &\longrightarrow J \longrightarrow \text{ joint coefficient bounds on larger domains} \\ &\longrightarrow \beta_J,\ r_{\mathrm{eff}},\ r \longrightarrow Q_{\mathrm{act}},\ \text{coupling ceiling, thresholds } d_0(\Lambda). \end{aligned} \tag{15.22}$$

The constants β_J and r_{eff} appear in Lemma 15.15. The thresholds can be increased at the last step without changing any earlier constant. The choice of the limiting gauge depends on the lattice pair and on the domains, and not on the coupling.

Theorem 15.12. *Fix nested complex domains $\mathscr{D}_{\mathrm{in}} \Subset \mathscr{D}_{\mathrm{mid}} \Subset \mathscr{D}_{\mathrm{out}}$ of coarse-field and input variables, with radius ratios less than one, such that all real products of coarse fields and inputs used in the construction lie in $\mathscr{D}_{\mathrm{in}}$ with a margin. The domains and the coefficient ceilings depend only on M, J, and the larger construction domains, and not on the lattice side or the preceding depth.*

1. *On each fixed lattice pair Λ of one RG step, choose once a holomorphic subsequential limit $\Omega_{\infty,\Lambda}$, on the middle domain of coarse fields, of the gauge transformations $\Omega_{d,\Lambda}$ of*

Theorem 13.2 as $d \to \infty$. It is periodic, takes values in $\mathrm{SU}(2)$ at real arguments, equals the identity at $\theta = 0$ and at the vertices of the coarse lattice, is equivariant under global color rotations, and has a bounded holomorphic inverse on that domain. Let $\mathscr{C}_{\mathrm{raw}\infty,\Lambda}$ be the limit of the reconstructions $\mathscr{C}_{\mathrm{raw}d,\Lambda}$ given by Theorem 15.6, and put

$$\Phi_{\infty,\Lambda}(c,q) = \mathrm{Log}\big[\mathscr{C}_{\mathrm{raw}\infty,\Lambda}(c,q)^{\Omega_{\infty,\Lambda}(c)}\big].$$

Then the whole sequence $\mathrm{Log}[\mathscr{C}_{\mathrm{raw}}{}_{d,\Lambda}^{\Omega_{\infty,\Lambda}}]$ converges to $\Phi_{\infty,\Lambda}$ on $\mathscr{D}_{\mathrm{in}}$ in every fixed derivative and every fixed spatial difference, and in the weighted analytic coefficient norm, including all output-fixed row sums and all volume-normalized column sums. The modulus of convergence may depend on Λ.

2. *Fix first tolerances, independent of J, for the finitely many quantities bounded in (3) below, and a tolerance depending on J for the joint coefficient norm on $\mathscr{D}_{\mathrm{in}}$. There exist finite deterministic thresholds $d_0(\Lambda)$, which also enforce the image conditions into B_r at real coarse fields in B_r and into B_ρ on the complex product, such that*

$$\widehat{\Omega}_{d,\Lambda}(c) = \begin{cases} \Omega_{d,\Lambda}(c), & d < d_0(\Lambda), \\ \Omega_{\infty,\Lambda}(c), & d \geq d_0(\Lambda), \end{cases}$$

and

$$\widehat{\mathscr{R}}_{d,\Lambda}(c,q) = \mathscr{C}_{\mathrm{raw}d,\Lambda}(c,q)^{\widehat{\Omega}_{d,\Lambda}(c)}, \qquad \widehat{\Phi}_{d,\Lambda} = \mathrm{Log}\,\widehat{\mathscr{R}}_{d,\Lambda},$$

define maps $\widehat{\Phi}_{d,\Lambda}$ that satisfy the same strict domain conditions on the whole products and have common joint coefficient bounds, with all row and column sums, uniformly in Λ and d. The thresholds depend only on the lattice pair, the deterministic domains, and the tolerances; they do not depend on the coupling, on samples, on sources, on an observation scale, on a position, or on the total number of RG steps. We call $\widehat{\mathscr{R}}_{d,\Lambda}$ the reconstruction map and $\widehat{\Phi}_{d,\Lambda}$ its logarithmic coordinate representation.

3. *Write $\widehat{\Phi}_{d,\Lambda}(c,0) = B^{-1}\overline{A}_{d,\Lambda}(c)$, and let $\nabla_{1/B}$ denote the first differences at spacing $1/B$, in units of the coarse lattice. The field $\overline{A}_{d,\Lambda}$ is a new representative of the gauge orbit of the classical background field; it is not claimed to equal the field of Lemma 11.9. Set*

$$G_{d,\Lambda}(\theta) = \big(\overline{A}_{d,\Lambda}(\theta), \nabla_{1/B}\overline{A}_{d,\Lambda}(\theta)\big),$$

and let $\mathscr{D}_\theta = \{\|\theta\|_\infty \leq r_\theta\}$ be a closed polydisc of coarse fields contained in the coarse-field factor of $\mathscr{D}_{\mathrm{in}}$ and in the ball $\|\theta\|_\infty < r_{\mathrm{cen}}$ of Lemma 11.9. There exists $C_{\mathrm{CP}} \geq 1$, independent of J, Λ, d, and r_θ, with the following properties. For every $\theta \in \mathscr{D}_\theta$ we have $\|G_{d,\Lambda}(\theta)\|_\infty \leq C_{\mathrm{CP}}\|\theta\|_\infty$. The output-fixed row sum and every input-fixed column sum of $D_\theta G_{d,\Lambda}(0)$ are at most C_{CP}. For every $\theta \in \mathscr{D}_\theta$ and $1 \leq s \leq 3$, the output-fixed row sum and every input-fixed column sum of $D_\theta^s G_{d,\Lambda}(\theta)$ are at most $s!\, C_{\mathrm{CP}}^{s+1}$. These sums are those of Definition 4.6, with the spatial weight at the rate a_{cen} of Lemma 11.9, which is fixed before J,

and with the column volume factor B^{-3}. In particular the linear coefficient of $c \mapsto \widehat{\Phi}_{d,\Lambda}(c,0)$ at $c = I$ has row and column sums at most C_{CP}/B. The full joint constants may depend on J. The constant C_{CP} is enlarged before J is chosen, and J is then chosen so that

$$a_{\mathrm{cap}} = C_{\mathrm{CP}}/B, \qquad q_{\mathrm{anc}} = C_{\mathrm{CP}}^2/B < 1,$$

with a margin; one may require $q_{\mathrm{anc}} \le 1/4$. The tolerances preserve these conditions.

4. *Let $\widehat{L}_{d,\Lambda}$ be the derivative at $c = I$ of $c \mapsto \widehat{\Phi}_{d,\Lambda}(c,0)$. In this item and in Step 4 of the proof, let H denote the mesh of the coarse lattice of the pair Λ (not the mesh L/n_0 of level zero), and let $a = H/B$ be the mesh of its fine lattice. Then for every coarse logarithm θ, every orientation i, and every color,*

$$a^2 \sum_x (\widehat{L}_{d,\Lambda}\theta)_i(x) = H^2 \sum_u \theta_i(u),$$

where x runs over the vertices of the fine lattice and u over those of the coarse lattice. In words, for each coarse link and color, the linearized zero-fluctuation reconstruction has the same componentwise integral as the piecewise constant embedding of the coarse potential.

5. *The reconstruction maps preserve the exact averaging identity $T_M^J e^{\widehat{\Phi}_{d,\Lambda}(c,q)} = c$, the gauge orbit of the zero-fluctuation reconstruction, the cutoff domains, the Haar disintegration densities, and the conditional fluctuation kernels.*

The constants have the dependence described in item (2) of Definition 4.14; among them, only the finitely many bounds in (3) are chosen before J. No convergence or uniqueness of the sequence $\Omega_{d,\Lambda}$ itself is asserted.

Proof. The proof has five steps: we choose the limiting gauge transformation, prove convergence of the whole sequence in the fixed limiting gauge, choose the thresholds, prove the identity (4), and verify the preservation statements.

Step 1: a limiting gauge transformation at a fixed lattice pair. On a fixed lattice pair Λ there are finitely many coarse-field coordinates and finitely many matrix entries at the vertices. We take the three domains inside the common product of Lemma 15.4, with strict nested margins. Their sums of radii are less than r_J, the denominator of the rational majorant is at least η_{im}, and all intermediate classical, logarithm, and Haar disintegration domain conditions hold. By Theorem 13.2, the gauge transformations have holomorphic logarithms κ_d in the identity chart, uniformly bounded on the outer domain. By Cauchy's formula, every Taylor coefficient is bounded there. We enumerate the coefficients of all matrix entries and choose nested subsequences along which the first coefficient, the second, and so on converge; along the diagonal subsequence, all coefficients converge. Such subsequences exist, since each coefficient lies in a fixed closed disc of $\mathbb{C}$.

On every strictly smaller polydisc the Cauchy bounds make the tail of the coefficient series uniformly summable: in coordinate dimension D there are $\binom{m+D-1}{D-1}$ monomials of

degree m, and the ratio of radii is bounded by a number less than one. Hence the diagonal series converges uniformly on compact subsets of the middle domain, and so do its fixed derivatives after a further reduction of the domain. Its sum κ_∞ is holomorphic there, and we set $\Omega_{\infty,\Lambda} = \exp \kappa_\infty$. The exponential series gives convergence of the corresponding gauge transformations. The bounded inverse entries have the same subsequential limit, and passing to the limit in $\Omega_d \Omega_d^{-1} = I$, we see that the limiting inverse is holomorphic and bounded. Periodicity, the identity at zero and at the coarse vertices, equivariance under global color rotations, and the values in $\mathrm{SU}(2)$ at real arguments are closed conditions and pass to the limit; for the last one, a limit of unitary matrices of determinant one is unitary with determinant one. We choose one such subsequence for each Λ.

By Theorem 11.2, the reconstructions $\mathscr{C}_{\mathrm{raw}\,d,\Lambda}$ converge along the whole sequence of depths. Along the chosen subsequence both the gauge transformations and the reconstructions converge, so their gauge-transformed logarithms converge to $\Phi_{\infty,\Lambda}$. The logarithm stays on its branch: the bound on the images has a strict gap to the boundary of the branch, and the same bound holds in the limit. Passing to the limit coefficient by coefficient in each nonnegative weighted sum and applying Fatou's lemma, we obtain for $\Phi_{\infty,\Lambda}$ the joint coefficient bounds of the unmodified maps, including its column sums; these bounds may depend on J. In the same way, we obtain separately the bounds of Lemma 11.9(2) for the pair $G_{\infty,\Lambda}$ formed by the field $B\Phi_{\infty,\Lambda}(\cdot, 0)$ and its first differences $\nabla_{1/B}$ in units of the coarse lattice. These are the value bound and the row and column sums of its first three derivatives in the coarse field at every point of $\mathscr{D}_\theta$. Indeed, Lemma 11.9(2) holds at every point of the ball $\|\theta\|_\infty < r_{\mathrm{cen}}$, and at a fixed lattice pair these derivatives are finite arrays whose entries converge along the chosen subsequence. Although Lemma 11.9 gives bounds of all orders that are independent of J, only the finitely many bounds listed in (3) are kept with a constant independent of J in the construction below.

Step 2: the whole sequence in the fixed limiting gauge. We define

$$\Psi_d(c, q) = \mathrm{Log}\big[\mathscr{C}_{\mathrm{raw}\,d,\Lambda}(c, q)^{\Omega_{\infty,\Lambda}(c)}\big]. \tag{15.23}$$

For all sufficiently large d this map is defined on a neighborhood of the inner product contained in the larger analytic domain, and it converges locally uniformly and holomorphically to $\Phi_{\infty,\Lambda}$, with every fixed derivative, because the gauge transformation in (15.23) does not depend on d. We now show that it also converges in the coefficient norm.

All operations needed below preserve nonnegative coefficient bounds with fixed indices; this is the calculus of nonnegative coefficient bounds of Lemma 5.3. For a product of coefficient tensors, the union of their networks connects the external indices, so the exponential weight of the product is at most the product of the weights. An output-fixed sum uses the row sums of all factors; an input-fixed sum uses the column sums of the factors on the path from that input to the output, and the row sums of the

others. The intermediate volume factors cancel, and only the ratio of the volumes of the external output and of the fixed input remains. Expanding derivatives of compositions, with factorials divided out, sums the partitions as in the composition of nonnegative power series. Matrix products contribute only a factor depending on the fixed matrix dimension. The series

$$e^X = \sum_{m\ge 0} X^m/m!, \qquad \log(I+Y) = \sum_{m\ge 1} (-1)^{m+1} Y^m/m$$

give the same conclusion for the exponential and the logarithm on products strictly inside their domains of convergence; the second series is used only where $\|Y\| < 1$ with a fixed margin.

To apply these facts uniformly before any threshold is imposed, we recover a link of the reconstruction from the gauge-transformed link by

$$(\mathscr{C}_{\mathrm{raw}\,d})_e = \Omega_d(x)^{-1} e^{\phi_{d,e}} \Omega_d(y), \qquad e = (x,y). \tag{15.24}$$

The gauge transformation Ω_d, its inverse, and the map ϕ_d have the common bounds of Theorem 13.2 on a larger product domain. The input product is strictly inside (15.5), so its denominator is positive and its intermediate margins hold. The limiting gauge transformation has the same bounds, by Fatou's lemma. Using (15.24), then multiplying by the limiting gauge transformation and applying the logarithm series, we obtain a joint bound, depending on J, for (15.23) on an intermediate product domain. The construction domains are chosen inside this product at the outset, with these margins. This preliminary bound need not carry the small factor B^{-1} of the zero-fluctuation reconstruction. Its constants and radii are independent of Λ, of d, and of the working radius chosen later. At fixed Λ each fixed coefficient tensor of (15.23) converges, and Lemma 15.5 controls the tail in the degree on $\mathscr{D}_{\mathrm{in}}$. Then the whole sequence converges in the coefficient norm, including every volume-normalized column sum. Each fixed spatial difference is a fixed finite difference matrix at this lattice size, so the same argument applies to it. The modulus may depend on Λ. This proves (1).

Step 3: finitely many derivatives, then thresholds. Let $C_0 \ge 1$ be a common constant for the quantities in (3) of the unmodified maps, that is, for the pair G_d formed by $B\phi_d(\cdot,0)$ and its first differences $\nabla_{1/B}$. These quantities are the value bound on $\mathscr{D}_\theta$, the row and column sums of $D_\theta G_d(0)$, and the row and column sums of $D_\theta^s G_d(\theta)$ for $1 \le s \le 3$ and every $\theta \in \mathscr{D}_\theta$. Since the unmodified zero-fluctuation map is $B^{-1}\overline{A}_{d,J}$ of Lemma 11.9 (Theorem 13.2), and Lemma 11.9(2) holds at every point of the ball $\|\theta\|_\infty < r_{\mathrm{cen}}$, the constant C_0 is independent of J, Λ, and d. We prescribe errors at most one in this finite list of scaled quantities, smaller if necessary to keep a chosen strict condition. We enlarge C_{CP} to cover C_0 and these errors. Then C_{CP} serves directly as the constant in the value bound and as the bound for the row and column sums of the linear coefficient tensor,

and it can be chosen so that the bounds of orders $1 \le s \le 3$ have the form $s!\, C_{\mathrm{CP}}^{s+1}$. This enlargement uses no analytic radius depending on J and no modulus of convergence. We choose J using this enlarged constant, with $C_{\mathrm{CP}}^2/B \le 1/4$ and the earlier conditions of Theorem 13.5 and (15.4). The construction of Steps 1 and 2 is then carried out for this J.

We also prescribe one error, depending on J, in the full joint coefficient norm on the inner product. By the convergence just proved, for each fixed Λ there exists a finite $d_0(\Lambda)$ such that, for every $d \ge d_0(\Lambda)$, the map (15.23) differs from $\Phi_{\infty,\Lambda}$ by at most this error, and the quantities in (3) for $B\Psi_d(\cdot, 0)$ and its first differences differ from those of $G_{\infty,\Lambda}$ by at most the prescribed errors, uniformly in $\theta \in \mathscr{D}_\theta$. At a fixed lattice pair these are finitely many entries of finitely many arrays, and they converge uniformly on the closed set $\mathscr{D}_\theta$ by Step 2, since $\mathscr{D}_\theta$ lies in the inner domain. We include in this finite list of requirements the image conditions on the real and complex products and every intermediate logarithm, classical, and Haar disintegration margin. The limiting images have strict margins, inherited from the common bounds of the unmodified maps, and the convergence on these product domains allows us to keep half of each margin. All image requirements concern the inputs q_i, on fixed products that contain every product $\{\max_i \|g_i w_i\|_\infty \le t p(t)\}$ used in the construction, so they do not involve the coupling. For the image into B_r we take the whole product $\{\|\theta\|_\infty \le r\} \times \{\max_i \|q_i\|_\infty \le Q_{\mathrm{act}}\}$ of (15.6), including $r + Q_{\mathrm{act}} < r_J$ and the positive denominator. On this product, the limiting image satisfies the strict bound inherited from the majorant of the unmodified maps, and the convergence in the fixed gauge keeps half of its margin above the threshold. The image into B_ρ is treated in the same way on a smaller product domain inside (15.5). The intermediate domain conditions belong to the reconstruction $\mathscr{C}_{\mathrm{raw}\,d,\Lambda}$, which is unchanged. These requirements use Q_{act} itself, not the varying radius $t p(t)$.

The piecewise family of (2) now has the asserted bounds: below the threshold we use the bounds of the unmodified maps, and above it the bounds of the limit plus the prescribed errors. The maximum of the two is independent of Λ and d, even if the thresholds diverge with the lattice size. Each threshold is a deterministic property of finitely many classical maps, domains, and tolerances.

In (3), $\overline{A}_{d,\Lambda} = B\widehat{\Phi}_{d,\Lambda}(\cdot, 0)$ is a representative of the gauge orbit of the classical background field. Its preserved bounds give $a_{\mathrm{cap}} = C_{\mathrm{CP}}/B$ and, under the choice of J in (3), $a_{\mathrm{cap}}\sqrt{B} \le 1/2$. The full joint constants may depend on J.

Step 4: preservation of componentwise integrals. We prove the identity in (4) directly, by differentiating one averaging step at I. For an array X of logarithms on the links of the fine lattice, we write $X(\sigma)$ for the signed sum of X along a path σ, and $X_i(x)$ for the value on the link from x to $x + e_i$. Differentiating the exponent and the reference path in

Definition 4.3, we obtain

$$\begin{aligned}(DT_M(I)X)_i(v) &= M^{-3}\sum_{x\in \mathsf{B}_M(v)}\sum_{s=0}^{M-1} X_i(x+se_i)+h_X(v)-h_X(v+Me_i),\\ h_X(v) &= M^{-3}\sum_{x\in \mathsf{B}_M(v)} X(\sigma_{v,x}).\end{aligned} \tag{15.25}$$

Here the derivative of the reference transport cancels the derivative of the reference transport subtracted inside the logarithm, and the paths $\sigma_{v+Me_i,x+Me_i}$ are translates of $\sigma_{v,x}$. Summing over the periodic coarse vertices v removes the last two terms. For each s the blocks $\mathsf{B}_M(v)$ partition the fine vertices, and translation by se_i permutes them. Thus every oriented fine link is counted exactly M times in the double sum, and

$$\sum_v (DT_M(I)X)_i(v) = M^{-2}\sum_x X_i(x). \tag{15.26}$$

Multiplying by the square of the coarse mesh converts this into the equality of the integrals of the two piecewise constant potentials, logarithm divided by mesh. Applying (15.26) J times gives the factor B^{-2} for T_M^J.

Every reconstruction map satisfies the exact averaging identity, since its gauge transformation is the identity at the coarse vertices. At zero fluctuation this reads $T_M^J e^{\widehat{\Phi}_{d,\Lambda}(\theta,0)} = e^{\theta}$, and its derivative at $\theta = 0$ gives $D(T_M^J)(I)\widehat{L}_{d,\Lambda}\theta = \theta$. With the coarse mesh H and the fine mesh $a = H/B$, (15.26) yields, for each orientation and color,

$$a^2\sum_x (\widehat{L}_{d,\Lambda}\theta)_i(x) = H^2\sum_u \theta_i(u). \tag{15.27}$$

If $\theta = Hv$ for a coarse potential v in physical units, the two sides are exactly the integrals of the fine linearized reconstruction $a^{-1}\widehat{L}_{d,\Lambda}\theta$ and of the piecewise constant embedding of v. Taking v supported on one oriented coarse link and one color proves (4).

Step 5: preservation of the conditional measures. At a fixed coarse field, the reconstruction map is a fixed fine gauge transformation applied after the unchanged reconstruction $\mathscr{C}_{\mathrm{raw}\,d,\Lambda}$. It fixes the coarse vertices, preserves the product Haar measure and the gauge orbit of the classical background field, and changes neither the fluctuation variables nor the cutoff domain. The Haar disintegration density, the triangular determinant, and the fluctuation exponent of Theorem 12.13 are those of $\mathscr{C}_{\mathrm{raw}\,d,\Lambda}$. The input effective interaction takes the same value at the two representatives, by gauge invariance within B_ρ, since both representatives lie in its domain. Thus the fiber and its normalizer are unchanged, and so is the conditional fluctuation kernel. This proves (5). □

15.6 Convergence of finite-scale reconstructions

We now use the reconstruction maps of Theorem 15.12 in every hierarchy. For the RG step from level j to level $j-1$ let Λ_j be its lattice pair, and use the preceding depth

$d_j^k = J(k-j)$. With the coarse logarithm θ_0 and the fluctuation variables $w_1, \dots, w_l$ of Lemma 15.10, the finite-scale reconstruction is defined by

$$F_0^k = \theta_0, \qquad F_j^k = \widehat{\Phi}_{d_j^k, \Lambda_j}(F_{j-1}^k, (g_{j,i} w_{j,i})_i) \qquad (1 \le j \le l).$$

Theorem 15.13. *Use the reconstruction maps of Theorem 15.12 at the preceding depths $d_j^k = J(k-j)$ in every hierarchy.*

1. *For every finite k, the replacement of Ω_d by $\widehat{\Omega}_d$ is a gauge transformation that depends only on the coarse field and equals the identity at the coarse vertices, applied after the same reconstruction $\mathscr{C}_{\mathrm{raw}\, d}$. At each coarse field in B_r it preserves the small-field event, every ball of the cutoff domain, the coordinates of the reconstruction, the effective classical action, the Haar disintegration density, the triangular determinant, the gauge-invariant extension of the input effective interaction, the normalizer, and the conditional fluctuation kernel. It preserves the exact averaging identities at every level, and the gauge invariance within B_ρ after the triangular change of fluctuation coordinates that accompanies a change of the coarse representative.*
2. *Fix $l < \infty$, $L, \gamma > 0$, and the Borel map S_0 of Lemma 15.10. As $k \to \infty$, the joint law P_l^k of $(\theta_0, w_1, \dots, w_l)$ converges in total variation. The law of the finite-scale reconstruction $(F_0^k, \dots, F_l^k)$ converges weakly and in bounded-Lipschitz distance. Since these reconstructions have a common compact range, it also converges in W_1 for any norm on the finite-dimensional space of logarithmic fields. The limiting laws are compatible: they are the finite iterations of one limiting coarse-level law, the kernels k_j^∞, and the maps Φ_{∞,Λ_j}, and the limit for l is a marginal of the limit for $l+1$. All these objects are Borel.*

No total variation statement is made for the laws of the reconstructed fields. The constants and moduli have the dependence of Theorem 15.6 at fixed l. The construction requires neither a limit of fields in a space of distributions nor a modulus that is uniform in l.

Remark 15.14. The restriction to weak convergence for the reconstructed fields is necessary. The reconstruction maps depend on k, and pushforwards by maps that move with k do not preserve total variation convergence. For example, if $x_k \to x$ with $x_k \neq x$, then $\delta_{x_k} \to \delta_x$ weakly, while $\|\delta_{x_k} - \delta_x\|_{\mathrm{TV}} = 1$. The coordinates $(\theta_0, w_1, \dots, w_l)$, on the other hand, live on fixed products, and there total variation convergence holds.

Proof. At a fixed coarse field, the replacement changes no coordinate of the reconstruction, no fluctuation variable, no ball, and no Jacobian. The indicators of D_r are gauge invariant, and the new representative satisfies the strict domain conditions of Theorem 15.12. Gauge covariance preserves the averaging identity, and gauge invariance within B_ρ preserves the effective classical action and the input effective interaction. By Theorem 14.6, every factor of the fiber, the normalizer, and the conditional fluctuation kernel are therefore preserved.

For a change of the coarse representative, we write $C' = C^{\widetilde{h}}$ for the reconstructions, after the triangular change of fluctuation coordinates. The convention (4.1) gives

$$(C')^{\widehat{\Omega}(c')} = \big(C^{\widehat{\Omega}(c)}\big)^{\widehat{\Omega}(c')\widetilde{h}\widehat{\Omega}(c)^{-1}}. \tag{15.28}$$

The change of coordinates preserves every ball and has absolute Jacobian one, by Theorem 13.4(3), on the comparison domains of the enlarged-domain reconstruction hypothesis. Both representatives lie in the domain of this interaction, so its values at them agree. This proves the gauge invariance within B_ρ without any equivariance of the limiting gauge transformation under local gauge transformations, and completes the proof of (1).

By Lemma 15.11, $\eta_0^k \to \eta_0^\infty$ in total variation. Fix $l < \infty$ and define

$$X_l = \{\|\theta_0\|_\infty \le r\} \times \prod_{j=1}^{l} \Omega_{p_j}.$$

The domain of each reconstruction map strictly contains its closed product. By Lemma 15.10 and Theorem 15.12, the reconstructions F_j^k are defined on X_l and have a common compact range. For k large, each of the finitely many depths d_j^k, $j \le l$, exceeds its threshold $d_0(\Lambda_j)$. The gauge transformation is then the fixed limiting one, and Theorem 15.12(1) implies uniform convergence of each map. Let $u_{j,k} = \|F_j^k - F_j^\infty\|_\infty$, let $v_{j,k}$ be the supremum distance between $\widehat{\Phi}_{d_j^k,\Lambda_j}$ and Φ_{∞,Λ_j} on the smaller product domain, and let ω_{Φ_j} be the modulus of continuity of Φ_{∞,Λ_j} in its first argument there. Adding and subtracting $\Phi_{\infty,\Lambda_j}(F_{j-1}^k, \cdot)$, we obtain

$$u_{j,k} \le v_{j,k} + \omega_{\Phi_j}(u_{j-1,k}), \qquad u_{0,k} = 0, \qquad v_{j,k} \longrightarrow 0. \tag{15.29}$$

By induction on j, $F_j^k \to F_j^\infty$ uniformly on X_l for every $j \le l$.

By Theorem 15.9, the limiting density is continuous on the compact product of fields and fluctuation variables, and its continuous positive normalizer has a positive minimum. Hence the limiting kernel is uniformly continuous in the field, in $L^1(dw)$ and therefore in total variation; let ω_{k_j} be its modulus. For points $h = (\theta_0, w_1, \dots, w_{j-1})$ of the coordinate space, define

$$K_j^k(h, dw) = k_j^k(F_{j-1}^k(h), dw), \qquad K_j^\infty(h, dw) = k_j^\infty(F_{j-1}^\infty(h), dw).$$

The two kernels are evaluated at different reconstructed fields, so the comparison contains a term for this discrepancy. By Theorem 15.9,

$$\sup_h \|K_j^k(h, \cdot) - K_j^\infty(h, \cdot)\|_{\mathrm{TV}} \le e^{2\Delta_{j,k}} - 1 + \omega_{k_j}(u_{j-1,k}) \longrightarrow 0. \tag{15.30}$$

Every term of the conditional fluctuation potential is kept here, including the input effective interaction, the Haar disintegration terms, and the differences of the determinant terms.

By Lemma 15.10, $P_l^k = \eta_0^k K_1^k \cdots K_l^k$ is the law of the coordinates. We define $P_l^\infty = \eta_0^\infty K_1^\infty \cdots K_l^\infty$. Lemma 15.1(2) implies that

$$\|P_l^k - P_l^\infty\|_{\mathrm{TV}} \le \|\eta_0^k - \eta_0^\infty\|_{\mathrm{TV}} + \sum_{j=1}^{l} \sup_h \|K_j^k(h,\cdot) - K_j^\infty(h,\cdot)\|_{\mathrm{TV}} \longrightarrow 0. \tag{15.31}$$

We write $F^k = (F_0^k, \dots, F_l^k)$. The ranges lie in a common compact subset of the finite-dimensional space of logarithmic fields, of diameter D_l. For every continuous f on this set, Lemma 15.1(3) gives

$$\left| \int f(F^k)\, dP_l^k - \int f(F^\infty)\, dP_l^\infty \right| \le 2\|f\|_\infty \|P_l^k - P_l^\infty\|_{\mathrm{TV}} + \omega_f(\|F^k - F^\infty\|_\infty), \tag{15.32}$$

which proves weak and bounded-Lipschitz convergence. For a fixed norm, Lemma 15.1(3) also gives

$$W_1\big((F^k)_* P_l^k, (F^\infty)_* P_l^\infty\big) \le \|F^k - F^\infty\|_\infty + D_l \|P_l^k - P_l^\infty\|_{\mathrm{TV}} \longrightarrow 0.$$

The limiting coarse-level law is a Borel pushforward, and the limiting maps and kernels are continuous on their product domains. Integrating the last probability kernel to one proves the compatibility. Only finitely many lattices, thresholds, and moduli were used. □

15.7 Deterministic amplitude bounds for the reconstruction

The bounds of Lemma 15.10 assume a linear bound on the reconstruction maps. We now derive such bounds, in a nonlinear form, from the joint coefficient bounds of Theorem 15.12. The constants are uniform in the mesh of the coarse lattice and in the coupling; this uniformity is used in Sections 17, 23, 31, and 34.

Lemma 15.15. *For the reconstruction maps of Theorem 15.12 write $\widehat{P}_{d,\Lambda}(c) = \widehat{\Phi}_{d,\Lambda}(c,0)$ and $\widehat{L}_{d,\Lambda} = D\widehat{P}_{d,\Lambda}(0)$. Fix the larger joint domains and one common joint coefficient bound, with all row sums and volume-normalized column sums of Definition 4.6, before the working radius and the radius r are chosen. Let a_m be the larger of the row and column norms of the homogeneous part of degree m of $\widehat{P}_{d,\Lambda}$. There exist $A_J, R_J > 0$, uniform in Λ and d, such that*

$$a_1 \le \alpha_* = C_{\mathrm{CP}}/B, \qquad a_m \le A_J R_J^{-m} \quad (m \ge 2).$$

After a fixed reduction of the radius, which absorbs the degree factors produced by fixing an input, choose

$$\beta_J \ge \max\{1, R_J^{-1}, A_J/(\alpha_* R_J^2)\}.$$

Then, uniformly in Λ and d,

$$\widehat{P} \prec \varphi(z) = \frac{\alpha_* z}{1-\beta_J z}, \qquad \widehat{P} - \widehat{L} \prec \frac{\alpha_* \beta_J z^2}{1-\beta_J z}.$$

Here $\prec$ means that each a_m (with $m \geq 2$ in the second relation) is at most the coefficient of z^m of the series on the right, and that a fixed input is bounded by the corresponding derivative of the same series. The full joint series in the coarse field and the inputs, not only these coefficients, has a common domain depending on J, with its column sums, and the bounds (3) and the identity (4) of Theorem 15.12 hold at the same time.

Choose J, using the constant C_{CP}, so that $B\alpha_*^2 = q_{\mathrm{anc}} \leq 1/4$, and only afterwards choose

$$0 < r_{\mathrm{eff}} < \rho, \qquad \frac{\beta_J r_{\mathrm{eff}}}{1-\alpha_*} < \frac{1}{8}, \qquad 0 < r < r_{\mathrm{eff}}/4.$$

On the working ball $\{\|\theta\|_\infty \leq r_{\mathrm{eff}}\}$,

$$\|D\widehat{P}\| \leq a_{\mathrm{map}} = \frac{\alpha_*}{(1-\beta_J r_{\mathrm{eff}})^2} \leq \frac{64}{49}\alpha_*, \qquad a_{\mathrm{map}}\sqrt{B} \leq \frac{32}{49} < 1.$$

The bounds on the inputs and the coupling ceiling can then be chosen so that every image of the reconstruction, and every repeated zero-fluctuation reconstruction, lies in the working domain. Increasing the thresholds $d_0(\Lambda)$ to obtain these smaller image margins changes none of C_{CP}, A_J, R_J, β_J, or the joint bound. These constants have the dependence described in item (2) of Definition 4.14; they are independent of r, of the thresholds, of the coupling, of the side, of the depth, and of the lattice offset, and among them only C_{CP} is independent of J.

The same joint bounds give the following amplitude bound. Let $H > 0$, $a_j = HB^{-j}$, $t_j = c_B g_3 \sqrt{a_j}$ with $c_B = M^{(J-1)/2}$, and $p_j = A_{\mathrm{w}} \log(1/t_j) \geq 1$. Consider any finite chain $\theta_j = \widehat{\Phi}_{d_j,\Lambda_j}(\theta_{j-1}, q_j)$, $1 \leq j \leq k$, of logarithmic representations of reconstruction maps in the working ball, with $b_0 = \|\theta_0\|_\infty \leq r$ and inputs $\max_i \|q_{j,i}\|_\infty \leq t_j p_j$, and put $b_j = \|\theta_j\|_\infty$. There exists a constant $C_{\mathrm{free},J}$, determined by the joint bounds, such that

$$b_j \leq \frac{\alpha_* b_{j-1}}{1-\beta_J b_{j-1}} + C_{\mathrm{free},J} t_j p_j.$$

Choose a coupling ceiling τ, after the working radii, so that these chains stay in the working ball. Then, whenever $t_1 \leq \tau$, uniformly in H, g_3, k, the preceding depths, the sides, and the lattice offset,

$$b_j \leq C_{\mathrm{cap},J} r \alpha_*^j + C_{\mathrm{cap},J} g_3 \sqrt{a_j}\, p_j, \qquad \sum_{j=1}^{k} b_{j-1} \leq C_{\mathrm{cap},J}\Big[\frac{r}{1-\alpha_*} + g_3\sqrt{H}\,(p_1+1)\Big].$$

The constant $C_{\mathrm{cap},J}$ may depend on the joint bounds, A_{w}, M, J, r_{eff}, β_J, and τ, but not on H or on the coupling. These bounds hold on every sample; they are not moment bounds.

Proof. We first build the majorant φ from the joint bounds and choose the radii. We then prove the amplitude bounds in two passes. The first pass uses the ratio a_{map} and bounds the sum of the amplitudes uniformly; the second uses this sum to recover the smaller ratio α_*, which is what makes the forcing summable.

Step 1: the majorant. We fix the common joint coefficient bound of Theorem 15.12 on a larger product domain, before any working radius is chosen, and restrict it to $q = 0$. If its coarse-field radius is R_0 and its bound is A_0, then the norm of degree m is at most $A_0 R_0^{-m}$. The row and every volume-normalized column use the same bound. Fixing an input produces at most a degree factor m, which is absorbed by replacing R_0 with $R_0/2$, since $m2^{-m}$ is bounded; a fixed finite list of such factors is absorbed by a further fixed reduction. This gives $A_J, R_J > 0$ as in the statement for every $m \geq 2$. The linear coefficient has the separate bound $a_1 \leq C_{\mathrm{CP}}/B = \alpha_*$ from Theorem 15.12(3). Only this last bound is needed uniformly before J is fixed.

We choose β_J at least the displayed maximum; it may be increased to cover the inverse radius of the fixed joint product as well. For $m \geq 2$,

$$\alpha_* \beta_J^{m-1} \geq \frac{A_J}{R_J^2} \beta_J^{m-2} = A_J R_J^{-m} (\beta_J R_J)^{m-2} \geq A_J R_J^{-m}. \tag{15.33}$$

These are the coefficients of $\varphi(z) = \alpha_* z/(1 - \beta_J z)$, whose first coefficient is treated separately. Subtracting the linear term gives the second majorant. In a nonnegative coefficient series, a derivative with respect to a fixed input marks that input and differentiates the same series. The same calculation therefore proves the statement for fixed inputs, with the volume normalization of the column of that input. The full joint series and the identities of Theorem 15.12 are those already proved there; restricting to $q = 0$ does not replace them.

Step 2: the working radii. We first choose J with $C_{\mathrm{CP}}^2/B \leq 1/4$. In particular $\alpha_* < 1$ and $\alpha_* \sqrt{B} \leq 1/2$. All constants defining β_J are now fixed. We choose r_{eff} as small as necessary inside the coarse-field radius of the common product domain, with the displayed inequality, and then $0 < r < r_{\mathrm{eff}}/4$. Such choices exist since β_J is finite. Differentiating the nonnegative series, we have on this working ball

$$\|D\widehat{P}\| \leq \varphi'(r_{\mathrm{eff}}) = \frac{\alpha_*}{(1 - \beta_J r_{\mathrm{eff}})^2}.$$

The working inequality implies $\beta_J r_{\mathrm{eff}} < (1 - \alpha_*)/8 < 1/8$. The last display is therefore at most $(64/49)\alpha_*$, and its product with $\sqrt{B}$ is at most $32/49$. Since $\widehat{P}(0) = 0$, the zero-fluctuation image of the working ball lies in the strictly smaller ball of radius $a_{\mathrm{map}} r_{\mathrm{eff}}$.

For the remaining choices, we note that the common joint series gives a continuous nonnegative majorant $G_J(u,v)$, with $G_J(u,0)=0$, for $\widehat{\Phi}(\theta,q)-\widehat{P}(\theta)$ on the working ball $\|\theta\|_\infty \le r_{\mathrm{eff}}$. We choose a fixed $v_*>0$ so small that

$$G_J(r_{\mathrm{eff}},v_*) < (1-a_{\mathrm{map}})r_{\mathrm{eff}}/4,$$

and, after a further reduction, the image condition into B_r and every intermediate domain margin hold. For example, at a coarse field in B_r the zero-fluctuation reconstruction is at most $a_{\mathrm{map}}r < r/2$, and we choose the bound on the inputs so that their contribution is less than $r/2 - a_{\mathrm{map}}r$. This number is positive, since $a_{\mathrm{map}} \le 32/(49\sqrt{B}) < 1/2$ for $B \ge 3$. The coupling ceiling is then reduced so that $tp(t)$ is below that bound for every smaller coupling. These choices of fixed domains and ceilings do not depend on the coupling.

If necessary, we increase each threshold $d_0(\Lambda)$ to impose these more restrictive image conditions, by the same convergence in the fixed gauge. For depths below the enlarged threshold we use the unmodified family, whose bounds satisfy the chosen requirements. For depths above it we keep the prescribed tolerances for the joint norm and for the quantities in Theorem 15.12(3), and add only these image requirements. Thus increasing a threshold changes none of the earlier coefficient constants. The order of the choices is the joint bound, then β_J, then r_{eff} and r, and then the bounds on the inputs and the coupling ceiling, as in (15.22). This proves the first part of the lemma.

Step 3: a uniform bound for the inputs and a first recursion. All products in the rest of the proof are closed subproducts of the common product of Lemma 15.4; in particular their sums of radii are less than r_J and the denominators of the majorants are positive. Fix $v_0>0$ such that the product with coarse-field radius r_{eff} and input radius $2v_0$ lies in the common joint coefficient domain, with a margin. Differentiating the nonnegative joint series in one input, and using the factor two in the radius, we find that every output-fixed absolute row sum of the derivative with respect to all fluctuation inputs is bounded by one constant $C_{\mathrm{free},J}<\infty$, uniformly in the lattice pair, the preceding depth, and the lattice offset. Integrating $D_q\widehat{\Phi}(\theta,sq)q$ over $0\le s\le 1$ and using its absolute row sum, we obtain

$$\|\widehat{\Phi}_{d,\Lambda}(\theta,q)-\widehat{\Phi}_{d,\Lambda}(\theta,0)\|_\infty \le C_{\mathrm{free},J}\max_i\|q_i\|_\infty, \qquad \|\theta\|_\infty\le r_{\mathrm{eff}},\quad \max_i\|q_i\|_\infty\le v_0. \tag{15.34}$$

The number of output links is never summed in this estimate. The inverse square roots of the constrained Hessians remain inside $\widehat{\Phi}$, whose inputs are exactly $q_i=g_iw_i$. Combining (15.34) with the majorant of $\widehat{P}$, which gives $\|\widehat{P}(\theta)\|_\infty\le\varphi(\|\theta\|_\infty)$, we obtain

$$b_j \le \varphi(b_{j-1})+f_j, \qquad f_j=C_{\mathrm{free},J}t_jp_j, \qquad \varphi(b)=\frac{\alpha_* b}{1-\beta_J b}. \tag{15.35}$$

Let $a=a_{\mathrm{map}}$, $x=B^{-1/2}$, and $\kappa_{\mathrm{w}}=A_{\mathrm{w}}\log B/2$. We choose the common ceiling $\tau>0$, after the working radii, so that

$$\tau\le e^{-1}, \qquad A_{\mathrm{w}}\log(1/\tau)\ge 1, \qquad \tau p(\tau)\le v_0, \qquad C_{\mathrm{free},J}\tau p(\tau)\le (1-a)r_{\mathrm{eff}}/4. \tag{15.36}$$

We also keep every previously imposed image and domain condition, by decreasing τ if necessary. For $0 < t \le \tau$ both $tp(t)$ and $t(p(t)+1)$ are increasing functions of t, since their derivatives are $A_{\mathrm{w}}(\log(1/t)-1)$ and $A_{\mathrm{w}}(\log(1/t)-1)+1$. Thus these conditions hold for every t_j whenever $t_1 \le \tau$. Since $\varphi(b) \le ab$ on the working ball, (15.35) implies

$$b_j \le a b_{j-1} + f_j.$$

It also keeps the chain in the working ball. Starting from $b_0 \le r < r_{\mathrm{eff}}/4$, if $b_{j-1} \le r_{\mathrm{eff}}/2$, then (15.36) gives $b_j \le a r_{\mathrm{eff}}/2 + (1-a) r_{\mathrm{eff}}/4 < r_{\mathrm{eff}}/2$. By induction, every evaluation in (15.35) takes place in the same working ball.

The identities $t_j = t_1 x^{j-1}$ and $p_j = p_1 + \kappa_{\mathrm{w}}(j-1)$ give

$$\sum_{j\ge 1} t_j p_j = t_1 \Big\{ \frac{p_1}{1-x} + \frac{\kappa_{\mathrm{w}} x}{(1-x)^2} \Big\} \le D_J t_1 (p_1+1), \qquad D_J = \frac{1}{1-x} + \frac{\kappa_{\mathrm{w}} x}{(1-x)^2}. \tag{15.37}$$

For a finite chain, the infinite sum is an upper bound for the forcing. Iterating the linear recursion and summing its nonnegative terms, we obtain

$$\sum_{h=0}^{k-1} b_h \le \frac{r + C_{\mathrm{free},J} D_J t_1 (p_1+1)}{1-a} \le S_* = \frac{r_{\mathrm{eff}}/4 + C_{\mathrm{free},J} D_J \tau (p(\tau)+1)}{1-a}. \tag{15.38}$$

This bound is independent of H, g_3, k, the lattice pairs, and their preceding depths. In particular S_* contains neither p_1 nor H as a varying parameter.

Step 4: the sharper ratio. Set

$$K_\beta = \frac{1}{1-\beta_J r_{\mathrm{eff}}} \le \frac{8}{7}, \qquad \zeta_h = \frac{\alpha_*}{1-\beta_J b_h}, \qquad C_{\mathrm{prod}} = \exp(K_\beta \beta_J S_*).$$

For $0 \le y \le \beta_J r_{\mathrm{eff}}$ we have $-\log(1-y) = \int_0^y (1-s)^{-1} ds \le K_\beta y$. Since $b_h \le r_{\mathrm{eff}}/2$, every finite product satisfies

$$\prod_{h=u}^{v} \zeta_h \le \alpha_*^{v-u+1} \exp\Big(K_\beta \beta_J \sum_{h=u}^{v} b_h \Big) \le C_{\mathrm{prod}} \alpha_*^{v-u+1}, \tag{15.39}$$

where we used (15.38); for an empty product we use $1 \le C_{\mathrm{prod}}$. Since $\varphi(b_h) = \zeta_h b_h$, successive substitution in $b_j \le \zeta_{j-1} b_{j-1} + f_j$ gives

$$\begin{aligned} b_j &\le b_0 \prod_{h=0}^{j-1} \zeta_h + \sum_{i=1}^{j} f_i \prod_{h=i}^{j-1} \zeta_h \le C_{\mathrm{prod}} r \alpha_*^j + C_{\mathrm{prod}} C_{\mathrm{free},J} \sum_{i=1}^{j} \alpha_*^{j-i} t_i p_i \\ &\le C_{\mathrm{prod}} r \alpha_*^j + \frac{C_{\mathrm{prod}} C_{\mathrm{free},J}}{1 - \alpha_* \sqrt{B}}\, t_j p_j. \end{aligned} \tag{15.40}$$

In the last inequality we used $t_i = t_j B^{(j-i)/2}$, $p_i \le p_j$, and $\alpha_* \sqrt{B} \le 1/2$. Substituting $t_j = c_B g_3 \sqrt{a_j}$, we obtain the pointwise bound of the statement, with the ratio α_* rather than a.

Summing (15.40) over $h = 1, \dots, k-1$, treating $b_0 \le r$ separately, and using (15.37), we obtain

$$\begin{aligned} \sum_{h=0}^{k-1} b_h &\le \frac{C_{\mathrm{prod}} r}{1-\alpha_*} + \frac{C_{\mathrm{prod}} C_{\mathrm{free},J} D_J}{1-\alpha_* \sqrt{B}}\, t_1 (p_1 + 1) \\ &= \frac{C_{\mathrm{prod}} r}{1-\alpha_*} + \frac{C_{\mathrm{prod}} C_{\mathrm{free},J} D_J c_B x}{1-\alpha_* \sqrt{B}}\, g_3 \sqrt{H}\, (p_1 + 1). \end{aligned} \tag{15.41}$$

For the last two displays, we may take any

$$C_{\mathrm{cap},J} \ge C_{\mathrm{prod}} \max\Big\{1, \frac{C_{\mathrm{free},J} c_B}{1-\alpha_* \sqrt{B}}, \frac{C_{\mathrm{free},J} D_J c_B x}{1-\alpha_* \sqrt{B}}\Big\}. \tag{15.42}$$

It may also be enlarged to cover the constant $C_{\mathrm{cap},J}$ of Lemma 15.10. This constant depends only on the joint bounds, the working radii, and the ceiling. Thus it is uniform in H and g_3 subject to the single condition $t_1 \le \tau$, and in the length of the chain, the sides, the lattice offset, and the preceding depths. The constant C_{CP} is not enlarged in this proof. □

15.8 Uniformity on compact intervals of couplings

In this section the coupling varies in a compact interval $I = [\gamma_-, \gamma_+]$ with $0 < \gamma_- \le \gamma_+ < \infty$. The lattice of level j has side $n_j = nB^j$ for a fixed coarse side $n \in 4\mathbb{N}$, and $a_j = (L/n) B^{-j}$, $g_j^2 = \gamma / n_j$, $t_j = M^{(J-1)/2} g_j$, and $d_j^k = J(k-j)$. On a fixed lattice pair Λ the largest coupling of the intermediate scales is $t = c_\Lambda \sqrt{\gamma}$ for a constant $c_\Lambda > 0$, with the fixed ratios λ_i. Constants with a subscript I may depend on both endpoints of I, on n, L, M, J, the fixed parameter collection Θ of Theorem 23.2, the analytic parameters and exponents, moment orders, and fixed lists of times and observables; constants for a fixed lattice pair may also depend on that pair. None of them depends on the value of $\gamma \in I$, on the preceding depth, or on a finer mesh. This is the dependence described in item (7) of Definition 4.14; these constants are neither the constants of item (3) nor constants chosen before J. Since the cutoff radius $p(t_j)$ depends on γ, we use the rescaled fluctuation variables $v_j = w_j / p(t_j)$, which live on the fixed product Ω_1 of unit balls.

Theorem 15.16. *Fix the parameters and products of Theorem 15.6, with its coupling ceiling g_*, a coarse side $n \in 4\mathbb{N}$, and $I = [\gamma_-, \gamma_+]$ with $0 < \gamma_- \le \gamma_+ < \infty$. Assume that the image, product, and coupling conditions of Theorem 15.6 hold for every $\gamma \in I$. Then the following hold.*

1. *On every fixed lattice pair Λ, at the same radius and exponent,*

$$\lim_{d,d'\to\infty} \sup_{\gamma\in I} \sup_{R\in\mathcal{A}_E} \mathcal{B}_{\rho,a_{\mathrm{sp}}}\big(\widehat{\mathcal{M}}_{d,t}R - \widehat{\mathcal{M}}_{d',t}R\big) = 0. \tag{15.43}$$

   The contraction factor $\vartheta < 1$ of Theorem 15.6 is the same for all $\gamma \in I$. At each finite d the transformation is jointly continuous in (γ, R) in this norm. After the substitution $w = p(t)v$, the classical data and the reconstruction maps converge uniformly in $\gamma \in I$ on every fixed smaller product domain, with every fixed derivative and every fixed spatial difference.
2. *For every fixed j, the effective interactions R_j^k and the stopped measures $\widehat{\nu}_j^k$ converge uniformly in $\gamma \in I$, in $\mathcal{B}_{\rho,a_{\mathrm{sp}}}$ and in total variation respectively, and the limits are continuous in γ in these norms.*
3. *For every fixed l, the joint law of the coarse logarithm and of the rescaled fluctuation variables $(v_1, \dots, v_l)$ converges in total variation, uniformly in $\gamma \in I$. The laws of the finite-scale reconstructions converge in bounded-Lipschitz distance and in W_1, for any norm on the finite-dimensional space of logarithmic fields, uniformly in $\gamma \in I$. The limiting laws are continuous in γ in these distances, and they are compatible.*

All moduli have the dependence described above, at fixed l. No rate that is uniform in l, and no statement as $\gamma \to 0$, is asserted.

The hypothesis holds in particular when $I \subset (0, \gamma_0]$ and the hierarchy satisfies the hypotheses of Theorem 15.6 for every $\gamma \le \gamma_0$. The theorem does not by itself guarantee that these hypotheses hold for a given coarse side and an arbitrary upper endpoint γ_+.

Proof. The proof follows the proofs of Theorems 15.6, 15.9, and 15.13. The new point is that every estimate is proved uniformly in $\gamma \in I$ on fixed products; uniform convergence is never deduced from pointwise convergence and compactness of I.

Step 1: rescaling. On a fixed lattice pair, let $t = c_\Lambda\sqrt{\gamma}$, $t_\pm = c_\Lambda\sqrt{\gamma_\pm}$, $p_- = p(t_+) > 0$, and $p_+ = p(t_-) < \infty$. Let D be the finite number of scalar fluctuation variables, and we change variables $w = p(t)v$, $v \in \Omega_1$. The Jacobian $p(t)^D$ cancels from normalized integrals and from logarithms normalized at the identity. For the Gaussian reference the remaining normalizer is

$$Z_p^{\mathrm{unit}} = \int_{\Omega_1} e^{-p^2|v|^2/2}\,dv, \qquad |\Omega_1| e^{-p_+^2 \sup_{\Omega_1}|v|^2/2} \le Z_p^{\mathrm{unit}} \le |\Omega_1|. \tag{15.44}$$

The scalar factor $z_p^{D/3}$ of (15.8) satisfies the exact relation $z_p^{D/3} = p^D Z_p^{\mathrm{unit}}$, so no normalization is discarded. Every input is $q_i = \lambda_i t p(t) v_i$, with fixed $\lambda_i > 0$ and $t \in [t_-, t_+]$. By Lemma 15.4 and the hypothesis, these inputs lie in one closed subproduct of the larger analytic product domain, and we also use its complex enlargement in the coarse field and a slightly larger input product. Their margins were chosen before the coupling.

Step 2: classical data. In Lemma 12.3, the conditional constrained minimizer minimizes $E_d \circ b$, the constrained Hessian is its second derivative in the free variables, and its square root is the analytic branch that is positive at real arguments. These objects do not depend on γ; the coupling enters only through $q_i = g_i w_i$ and the explicit divisors g_i^2 of the action. The finitely many ratios of couplings are fixed powers of M. By Theorem 11.2, the minimizers, the constrained Hessians, their square roots and inverses, the Haar disintegration densities, and the reconstructions converge with every fixed derivative on this one product of inputs. The formulas of Theorem 12.13 are finite compositions of these data, with factors $g_i^{-1} \le (\lambda_i t_-)^{-1}$ and bounded p and p^{-1}. Thus their substitutions converge uniformly in $\gamma \in I$, including every fixed derivative in the coarse field of the classical and Haar disintegration exponent, with all dependences of the determinant terms on coarser fluctuation variables. This proves the last assertion of (1).

Step 3: the input effective interaction. We use the same gauge transformation Ω_d of Theorem 13.2 on the two reconstructions being compared; its derivatives in the coarse field and its inverse are bounded on the common product domain. One image lies in $B_{\rho/2}$, and the uniform convergence of the reconstructions puts the other in $B_{3\rho/4}$ for all sufficiently large pairs of depths, uniformly over the product of Step 1 and over $\gamma \in I$. By Lemma 15.5, every $R \in \mathcal{A}_E$ satisfies

$$\sup_{B_{3\rho/4}} |D^s R| \le C_{s,\Lambda} \rho^{2-s} E. \tag{15.45}$$

Using the chain rule and the integral of DR along the segment between the two images, we find that every fixed derivative of the term with the input effective interaction converges, uniformly in R and in γ. Gauge invariance within B_ρ identifies these evaluations with the values of R_{sat}, and the coordinatewise identity argument of Step 4 in the proof of Theorem 15.6 identifies the holomorphic extensions. No convergence of Ω_d is needed.

Step 4: the partition functions. The integrands on Ω_1 are now uniformly Cauchy, together with each fixed derivative in the coarse field. On the finite set $\mathcal{Q}_\Lambda$ of boxes of the lattice, let $\boldsymbol{U}_{d,t,R}$ be the local interaction decomposition of Lemma 15.8, after the zero-fluctuation terms and the Gaussian factor have been removed. Its reference measure is the product probability

$$d\pi_p^{\mathrm{unit}}(v) = (Z_p^{\mathrm{unit}})^{-1} e^{-p^2|v|^2/2} \mathbf{1}_{\Omega_1}(v)\, dv.$$

The estimates of Lemma 15.8 for the supports, the support-counting factors, and the radii give $\|\boldsymbol{U}_{d,t,R}\|_{\mathscr{S}_8} \le \eta_0/2$ on the same enlarged product of coarse fields, uniformly in $\gamma \in I$, d, and R. These smallness conditions hold throughout I by hypothesis; the bounds involve only the fixed domains, their radius ratios, and bounded p, t, t^{-1}, and E. Theorem 12.7 applies to this family of coefficients in the coarse field, allows scalar

coefficients, and has constants independent of the reference probability and of the number of fluctuation variables. It gives a family $\boldsymbol{\mathcal{L}}$ with

$$-\log \Xi_{d,t,R} = \sum_{Y} \mathcal{L}_Y, \qquad \|\boldsymbol{\mathcal{L}}\|_{\mathscr{S}_2} \le C \|\boldsymbol{U}_{d,t,R}\|_{\mathscr{S}_8}.$$

Every support is nonempty, so on the complex product

$$\Big|\sum_{Y} \mathcal{L}_Y\Big| \le \sum_{Y} \sum_{\nu} \rho^{|\nu|} |\mathcal{L}_{Y,\nu}| \le |\mathcal{Q}_\Lambda| \|\boldsymbol{\mathcal{L}}\|_{\mathscr{S}_2} \le C |\mathcal{Q}_\Lambda| \eta_0/2.$$

The branch of the logarithm vanishes at zero interaction and agrees with the real logarithm on real data. This proves that the normalized complex partition functions do not vanish and satisfy

$$|\log \Xi_{d,t,R}| \le C_{\Lambda,I,E}, \qquad |\Xi_{d,t,R}| \ge e^{-C_{\Lambda,I,E}}. \tag{15.46}$$

Comparing the ratio of two close partition functions on a disc about one, we find that their logarithms normalized at the identity, and their fixed coefficient tensors, are uniformly Cauchy. The uniform lower bound (15.46) is not inferred from positivity of the normalizers at real arguments.

Step 5: the transformations. Fix $\rho < \rho_1 < 2\rho$ so close to ρ that the enlarged product with coarse-field radius ρ_1 still lies in the larger analytic product domain. Using the same composition bounds and bounds for local interaction decompositions, followed by the conversion used for (15.17), we obtain

$$\sup_{\gamma \in I,\, d,\, R \in \mathcal{A}_E} \mathcal{B}_{\rho_1, a_{\mathrm{sp}}}\big(\widehat{\mathcal{M}}_{d,t} R\big) \le C_{\Lambda,I,E}. \tag{15.47}$$

Indeed, the argument of the input effective interaction stays below its input radius ρ, the fixed connected box sets still satisfy $a_{\mathrm{sp}} t \le 2|Y|$, and the conversion factor is $9\rho_1^{-2}$; none of these facts depends on t. The finitely many small depths are included in the bound, on their own product domains. We split the difference of two outputs at a Taylor degree h. Its tail is at most $2C_{\Lambda,I,E}(\rho/\rho_1)^{h-1}$, by Lemma 15.5. We choose h first, and then d, d' so large that the finitely many remaining tensors are close, by Step 4. This proves (15.43) in the coefficient norm at the unchanged ρ and a_{sp}.

At a finite depth d the rescaled integrand and Z_p^{unit} depend continuously on $t > 0$. The same logarithm and tail argument proves continuity in the norm for fixed R. The contraction of Theorem 15.6, applied at a fixed parameter to two inputs, implies continuity in R. Its conditions on t, $p(t)$, and E hold for every $\gamma \in I$ by hypothesis, so the factor ϑ is unchanged. This proves (1).

Step 6: effective interactions and stopped measures. For fixed j and m we take the supremum over I in (15.18). By (1),

$$\sup_{\gamma\in I} \mathcal{B}_{\rho,a_{\mathrm{sp}}}(R_j^k - R_j^{k'}) \le 2E\vartheta^m + \sum_{h=j+1}^{j+m} \vartheta^{h-j-1}\varepsilon_{h,I}(k,k'), \qquad \varepsilon_{h,I}(k,k') \longrightarrow 0, \tag{15.48}$$

where $\varepsilon_{h,I}$ is the supremum over $\gamma \in I$ of the quantity ε_h of (15.18). We choose m first and then k, k'. By the completeness of the coefficient space, proved in Step 6 of the proof of Theorem 15.6, we obtain the uniform limit $R_j^\infty(\gamma) \in \mathcal{A}_E$. Each finite effective interaction is continuous in γ, since it is a finite composition of transformations that are continuous by (1), starting from the zero interaction on the finest lattice. The uniform limit is then continuous as well.

On the fixed domain D_r at level j, the difference of the classical terms in (15.19) is divided by $g_j^2 \ge \gamma_-/n_j$. Using the value bound of Lemma 15.5, we obtain

$$\delta_{j,k,I} = \sup_{\gamma\in I}\sup_{D_r}\Big|\frac{E_{J(k-j),\mathrm{sat}} - E_{\infty,\mathrm{sat}}}{g_j^2} + R_{j,\mathrm{sat}}^k - R_{j,\mathrm{sat}}^\infty\Big| \longrightarrow 0. \tag{15.49}$$

At this fixed volume all these exponents are bounded uniformly in $\gamma \in I$. This common domain contains an open neighborhood of the identity of positive Haar measure, so the normalizers have a positive lower bound uniform in γ. By Lemma 15.1(1), the total variation distance is at most $e^{2\delta_{j,k,I}} - 1$, which proves the uniform convergence of the stopped measures. The same bounds and the fixed domain prove continuity in γ in total variation, both at finite k and in the limit. In particular, with the fixed Borel map S_0 of Lemmas 15.10 and 15.11, the coarse-level laws η_0^k and η_0^∞ converge in total variation uniformly in γ and depend continuously on γ. No continuity of S_0 is needed. This proves (2).

Step 7: kernels and finite-scale reconstructions. For the potential of Theorem 15.9, with all its terms, we write

$$\widetilde{V}_j^k(\gamma,\theta,v) = V_j^k(\gamma,\theta,p_j(\gamma)v), \qquad v \in \Omega_1.$$

By Steps 2 and 3 and (15.49), we have

$$\Delta_{j,k,I} = \sup_{\gamma,\theta,v}|\widetilde{V}_j^k - \widetilde{V}_j^\infty| \longrightarrow 0, \tag{15.50}$$

where all suprema are over closed smaller product domains. Each finite potential is jointly continuous in (γ,θ,v), and so is the uniform limit, which is bounded there. The integral of $e^{-\widetilde{V}_j^\infty}$ over Ω_1 is at least $|\Omega_1|\exp(-\sup|\widetilde{V}_j^\infty|) > 0$. Thus the limiting normalized kernel on the unit product is jointly continuous in (γ,θ) in total variation, with one modulus

$\omega_{j,I}$ in the field. By Lemma 15.1(1), the finite kernel differs from it in total variation by at most $e^{2\Delta_{j,k,I}} - 1$, uniformly in the field and in γ.

The thresholds $d_0(\Lambda_j)$ of Theorem 15.12 do not depend on the coupling. For a fixed l, all gauge transformations are therefore the fixed limiting ones once k is large. After the substitution $q_i = g_{j,i}(\gamma)p_j(\gamma)v_i$, the reconstruction maps converge uniformly on the common compact product of γ and the coordinates, and their first derivatives in the coarse field are uniformly bounded. Let F_j^k be the finite-scale reconstruction, and let $u_{j,k,I} = \sup_{\gamma,h} |F_j^k(\gamma, h) - F_j^\infty(\gamma, h)|$. Then

$$u_{0,k,I} = 0, \qquad u_{j,k,I} \le v_{j,k,I} + C_{j,I} u_{j-1,k,I}, \qquad v_{j,k,I} \longrightarrow 0, \tag{15.51}$$

where $v_{j,k,I}$ is the uniform distance between the maps and $C_{j,I}$ bounds the first derivative of the limiting map. Since there are finitely many $j \le l$, all $u_{j,k,I}$ tend to zero. Evaluated along the reconstruction, the kernels differ by at most $e^{2\Delta_{j,k,I}} - 1 + \omega_{j,I}(u_{j-1,k,I})$. Using the disintegration of Lemma 15.10 and Lemma 15.1(2), we obtain

$$\sup_{\gamma \in I} \|P_l^k(\gamma) - P_l^\infty(\gamma)\|_{\mathrm{TV}} \le \sup_{\gamma \in I} \|\eta_0^k - \eta_0^\infty\|_{\mathrm{TV}} + \sum_{j=1}^{l} \left\{ e^{2\Delta_{j,k,I}} - 1 + \omega_{j,I}(u_{j-1,k,I}) \right\} \longrightarrow 0. \tag{15.52}$$

This bound accounts for the whole finite-scale reconstruction, including the dependence of later fields on earlier fluctuation variables. The logarithmic fields have a common compact range, by the amplitude bounds. Lemma 15.1(3), as in (15.32), implies uniform convergence in bounded-Lipschitz distance, and its coupling bound gives uniform convergence in W_1, with error at most $\|F^k - F^\infty\|_\infty + D_l \|P_l^k - P_l^\infty\|_{\mathrm{TV}}$. The continuity in γ of the coarse-level laws and of the kernels in total variation, and the continuity of the limiting reconstruction maps, prove the continuity of the limiting laws. Compatibility is the disintegration identity. This proves (3). □

PART V

Heat estimates and backward reconstruction

SECTION 16

Heat-kernel estimates, interpolation, and concentration

This section proves the analytic and probabilistic estimates through which the conditional fluctuation kernels of Sections 13 and 15 control the reconstructed field in norms of negative regularity. The main result is Theorem 16.6. It concerns one renormalization group step, from a coarse field c to the lattice of mesh a, and the lattice potential $A = a^{-1}\Phi$, where Φ is the logarithm of the reconstructed fine field in a gauge that depends only on c. Conditionally on c, the fluctuation $F = A - \mathbb{E}[A \mid c]$ of A about its conditional expectation satisfies, for $0 < \alpha < 3/2$ and every $p \geq 1$,

$$\Big(\mathbb{E}\Big[\Big(\sup_{0<s\leq T_0} s^{\alpha/2}\|P_s F\|_\infty\Big)^p \;\Big|\; c\Big]\Big)^{1/p} \leq C_p g_3 a^{\alpha-1/2}\sqrt{\log(2+L/a)},$$

where P_s is the continuum heat semigroup applied to F, viewed as a function that is constant on lattice cells. The bound is uniform in c and in the number of averaging steps that precede the step. For $\alpha > 1/2$ it tends to zero with the mesh and is summable over a geometric sequence of meshes. It controls only the fluctuation about the conditional expectation; the conditional expectation itself is estimated in Lemma 17.1.

The auxiliary results are deterministic heat and interpolation estimates and probabilistic maximal inequalities. We prove bounds for the heat kernel on the periodic lattice and on the torus (Lemma 16.1), and we construct a smooth cardinal interpolation between lattices whose meshes have an integer ratio, which preserves the integral of every column exactly (Lemma 16.3). We also prove an elementary chaining lemma (Lemma 16.4), estimates for time convolutions (Lemma 16.8), and the convergence of the discrete heat evolution of a fixed bounded finite-dimensional family of smooth fields to the continuum heat evolution (Lemma 16.9). All heat estimates are stated on a fixed finite time interval and keep the constant mode.

The scale in the main estimate. The factor $g_3 a^{\alpha-1/2}$ has a simple origin. Let $g^2 = g_3^2 a$ be the coupling at mesh a. The Jacobian of the map from the normalized fluctuation variables w to the lattice potential A has counting ℓ^2 operator norm at most $C_J g/a = C_J g_3 a^{-1/2}$. At a time $s \geq a^2$, the heat kernel averages over about $(\sqrt{s}/a)^3$ cells, and a linear function of w with this averaging has Lipschitz constant smaller by the factor $a^{3/2}s^{-3/4}$. When $\alpha < 3/2$, the product $s^{\alpha/2}a^{3/2}s^{-3/4}$ is largest at $s \asymp a^2$, where it equals a^α. By the concentration

inequality for the conditional fluctuation kernel, the fluctuations at each point have size $g_3 a^{\alpha-1/2}$, and the maximum over space and time costs the factor $\sqrt{\log(2+L/a)}$.

Three linear operations. Three linear operations on lattice arrays occur in this and the following sections.

Operation	Input and output	Use
Continuum heat semigroup P_s applied to the cell embedding	An array on the lattice of mesh a, extended as a constant on each half-open cell; a smooth function on $\mathbb{T}_L^3$	Negative-regularity norms of reconstructed fields (Theorem 16.6, Section 17)
Discrete heat semigroup P_t^a	An array on the lattice of mesh a; an array on the same lattice	Heat bounds for the lattice flow (Lemmas 16.1 and 16.9)
Cardinal interpolation $I_{a_0 \to a}$	An array on the lattice of mesh a_0; an array on the finer lattice of mesh $a = a_0/m$	Comparison of fields from different scales on a common lattice; values and difference arrays are interpolated separately (Lemmas 16.3 and 16.9)

Two points that need care. First, the conditional fluctuation kernel is supported on a product of balls, but it is not a product measure: the normalized fluctuation variables interact, and they are not Gaussian. We use only that its potential V satisfies $D_w^2 V \geq I/2$ on the convex support. This implies a logarithmic Sobolev inequality and Gaussian concentration for Lipschitz functions, with constants independent of the dimension. Second, the column sums of the reconstruction Jacobian must be normalized by the cell volume of the lattice on which each fluctuation variable lives. A uniform bound on the row sums alone does not imply the ℓ^2 operator bound used in the concentration argument, and the column bound with the correct input volume produces the factor $a^{3/2}$ above.

Inputs, uses, and attribution. The conventions for meshes, heat semigroups, analytic norms, and flow norms are those of Section 4. The probabilistic input is the concentration theorem on convex products of balls, Theorem 5.4. It rests on the variance inequality of Brascamp and Lieb [33], the logarithmic Sobolev inequality of Gross [103], and the curvature criterion of Bakry and Émery [8], with the boundary of the product treated in Section 5. The conditional fluctuation kernel and the bounds on the reconstruction and its derivatives come from Theorems 13.2 and 13.8; the reconstruction maps and the preservation of the kernels under them come from Theorems 15.12 and 15.13. The concentration theorem is used in Section 17; the heat bounds, the interpolation, and

the chaining lemma are used in Sections 17, 24, 26, 27, 29, 31, and 34; the convolution estimates in Section 24; and the consistency lemma in Section 25.

The heat-kernel bounds are standard; we prove them by Fourier analysis because the normalizations matter. The maximal inequalities use chaining in the sense of Dudley [79]. For general tail bounds by generic chaining, see Dirksen [74, Theorems 3.2 and 3.5]; the second of these theorems treats increments with mixed sub-Gaussian and exponential tails. Those results are stated for semimetrics satisfying the triangle inequality. Our version assumes only the covering and continuity properties that we use, and we include its short proof. Only the verification that the conditional fluctuation kernel and the reconstruction satisfy the hypotheses of these general estimates, uniformly in the coarse field and in the depth, depends on the construction.

Notation. Throughout this section, $L > 0$ is the side length of the torus $\mathbb{T}_L^3$. For a mesh $a = L/n$ with an integer $n \geq 4$, we write $\Gamma_a = (a\mathbb{Z}/L\mathbb{Z})^3$ for the vertex set of Λ_n in physical units, and we use the measure $a^3 \sum_{x \in \Gamma_a}$ in all norms L_a^r. Arrays on positive links are identified with arrays on vertices by attaching the link $(x, x + ae_i)$ to its starting vertex x; the direction i and the color form a fixed finite set of components, and all operators below act componentwise. For a direction i, we write $D_{a,i}^+ f(x) = (f(x + ae_i) - f(x))/a$ and $D_{a,i}^- f(x) = (f(x) - f(x - ae_i))/a$ for the physical forward and backward differences, $\Delta_a = \sum_i D_{a,i}^- D_{a,i}^+$, and $P_t^a = e^{t\Delta_a}$; this semigroup keeps the constant mode. For an integer $q \geq 0$, we write D_a^q for any ordered product of q physical forward or backward differences (the identity if $q = 0$). When the particular product matters, we write D_a^ϵ, and ∂^ϵ for the corresponding product of partial derivatives; bounds stated for D_a^q hold uniformly over the finitely many products of order q. The continuum heat semigroup is $P_t = e^{t\Delta}$ on $\mathbb{T}_L^3$, with kernel $p_t(x - y)$. The cell embedding of an array f on Γ_a is the function on $\mathbb{T}_L^3$ equal to f_y on the half-open cell $Q_y = y + [0, a)^3$. In this section, the letter q denotes an order of differentiation or an exponent; it is unrelated to the plaquette energy. Constants C may change from line to line, and depend only on the parameters listed in the statement being proved.

16.1 Heat-kernel bounds

The following lemma collects the bounds on the discrete and continuum heat kernels used in the rest of the paper. Its last assertion is a maximal inequality for sub-Gaussian processes. We state it here because it is applied to processes built from the heat kernel; it is a special case of Lemma 16.4. For a set I, a nonnegative symmetric function d on $I \times I$, and $v > 0$, we write $N(I, d, v)$ for the smallest cardinality of a set $\mathcal{N} \subset I$ such that every $i \in I$ has some $i' \in \mathcal{N}$ with $d(i, i') \leq v$.

Lemma 16.1. *Fix $L, T > 0$. Let $a = L/n$ with an integer $n \geq 4$, and let $p_t^a(x,y)$ be the density of P_t^a with respect to the measure $a^3 \sum_y$. Then $p_0^a(x,y) = a^{-3}\mathbf{1}_{x=y}$, $p_t^a \geq 0$, and $a^3 \sum_y p_t^a(x,y) = 1$. For every integer $q \geq 0$, every product D_a^ϵ of q physical forward or backward differences acting on the variable y, every $x \in \Gamma_a$, and every $0 \leq t \leq T$,*

$$\begin{aligned} \|D_a^\epsilon p_t^a(x,\cdot)\|_{L_a^1} &\leq C_q (t + a^2)^{-q/2}, \\ \|D_a^\epsilon p_t^a(x,\cdot)\|_{L_a^2} &\leq C_q (t + a^2)^{-3/4 - q/2}, \\ \|D_a^\epsilon p_t^a(x,\cdot)\|_{\infty} &\leq C_q (t + a^2)^{-(3+q)/2}. \end{aligned} \tag{16.1}$$

The continuum heat kernel p_t is smooth for $t > 0$ and satisfies the same three bounds with $a = 0$, for $0 < t \leq T$, with D_a^ϵ replaced by a product of q partial derivatives. The constants depend only on q, the fixed sets of directions and colors, and T/L^2.

For $y \in \Gamma_a$, $0 < t \leq T$, and $x \in \mathbb{T}_L^3$ let

$$\omega_y(t,x) = \int_{Q_y} p_t(x - z)\, dz.$$

Then

$$\|\omega(t,x)\|_{\ell^2} \leq C \min\{1, a^{3/2} t^{-3/4}\} \qquad (0 < t \leq T),$$

and

$$\|\omega(t,x) - \omega(t,x')\|_{\ell^2} \leq C a^{3/2} t^{-3/4} \min\{1, \operatorname{dist}(x,x')/\sqrt{t}\} \qquad (a^2 \leq t \leq T).$$

More generally, for every multi-index ν and every integer $r \geq 0$, the array of cell integrals of $\partial^\nu \partial_t^r p_t(x - \cdot)$ has ℓ^2 norm at most $C_{\nu,r} a^{3/2} t^{-3/4 - |\nu|/2 - r}$ for $0 < t \leq T$. Thus every additional spatial derivative costs a factor $t^{-1/2}$ and every time derivative a factor t^{-1}, and the corresponding increment bounds follow; for example, with $v = \min\{s,t\}$,

$$\|\omega(t,x) - \omega(s,x)\|_{\ell^2} \leq C a^{3/2} v^{-3/4} \min\{1, |t-s|/v\} \qquad (0 < s, t \leq T).$$

For $0 < t \leq a^2$ we use instead that $\|P_t f\|_\infty \leq \max_y |f_y|$ for the cell embedding of an array f.

Finally, let $(X_i)_{i \in I}$ be a centered real process and let d be a nonnegative symmetric function on $I \times I$ with $\sup d \leq \sigma$. Suppose that

$$\mathbb{E} e^{z X_i} \leq e^{z^2 \sigma^2/2}, \qquad \mathbb{E} e^{z(X_i - X_j)} \leq e^{z^2 d(i,j)^2/2} \qquad (z \in \mathbb{R},\ i, j \in I),$$

that $N(I, d, \eta\sigma) \leq A \eta^{-v}$ for every $0 < \eta < 1$, where $A \geq 1$ and $v \geq 0$, and that the process has a version which is continuous with respect to d and whose supremum equals its supremum over a countable d-dense subset of I (this holds automatically if I is finite). Then there is a universal constant C such that, for $u \geq 0$,

$$\mathbb{P}\Big\{ \sup_{i \in I} |X_i| > C\sigma \big[\sqrt{\log(2A)} + \sqrt{v} + \sqrt{u} \big] \Big\} \leq 2 e^{-u},$$

$$\mathbb{E} \sup_{i \in I} |X_i| \leq C\sigma \big[\sqrt{\log(2A)} + \sqrt{v} \big].$$

No Gaussian or independence assumption is made.

Remark 16.2. The finite horizon T cannot be removed, because the semigroups keep the constant mode. For instance, as $t \to \infty$ the density $p_t^q(x, \cdot)$ tends to the constant L^{-3}, whose L_a^2 norm is $L^{-3/2}$, while $(t + a^2)^{-3/4} \to 0$. In the same way, for $E_\theta = I$ and $a = a_0$ in Lemma 16.3 below, the undifferentiated row of W_t tends to the constant row n^{-3}, whose counting ℓ^2 norm is $n^{-3/2}$. The bound $Ca_0^{3/2}(t + a_0^2)^{-3/4}$ therefore cannot hold with a fixed constant on an unbounded time interval. For this reason, all row and covering estimates in this section are stated for times in $[0, T]$, and their constants depend on T/L^2.

Proof of Lemma 16.1. We use Euclidean norms on the fixed spaces of directions and colors; changing between equivalent norms costs a fixed factor. All heat times below lie in $[0, T]$, and they are positive for the continuum kernel and the cell integrals.

The discrete kernel and its L^1 bounds. We begin with unit spacing on $\mathbb{Z}$. Let S_+ and S_- be the two shifts. The kernel r_s of

$$e^{s(S_+ + S_- - 2I)} = e^{-2s} \sum_{k,l \ge 0} \frac{s^{k+l}}{k!\, l!} S_+^k S_-^l$$

is nonnegative and has sum one; the series converges in operator norm on bounded arrays. Its Fourier multiplier on $[-\pi, \pi]$ is $e^{-4s \sin^2(\theta/2)}$. Let ∇^ϵ be a product of r unit forward or backward differences in this coordinate, and set $h_s = \nabla^\epsilon r_s$. Up to a sign, the multiplier of h_s is

$$m_s(\theta) = e^{-il\theta}(e^{i\theta} - 1)^r e^{-4s \sin^2(\theta/2)}, \qquad 0 \le l \le r,$$

where l is the number of backward differences. For $s \le 1$, we have $\sum_j |h_s(j)| \le 2^r$ by the difference stencil. For $s \ge 1$, the inequalities $|e^{i\theta} - 1| \le |\theta|$ and $\sin^2(\theta/2) \ge \theta^2/\pi^2$ on $[-\pi, \pi]$ imply

$$\int_{-\pi}^{\pi} |m_s|^2 \, d\theta \le C_r s^{-r-1/2}, \qquad \int_{-\pi}^{\pi} |m_s'|^2 \, d\theta \le C_r s^{-r+1/2}. \tag{16.2}$$

Here and below, the finitely many sign patterns are included in C_r. To verify the second bound, note that m_s' is a sum of terms bounded by

$$C_r\big(|\theta|^r + \mathbf{1}_{r \ge 1}|\theta|^{r-1} + s|\theta|^{r+1}\big)e^{-cs\theta^2};$$

the first term is absent when $l = 0$, and only the last term is present when $r = 0$. Squaring, integrating, and substituting $v = \sqrt{s}\,\theta$, we obtain (16.2), since $\int_{\mathbb{R}} |v|^m e^{-cv^2} \, dv < \infty$ for every $m \ge 0$. For this finiteness, we split $[0, \infty)$ into the intervals $[k, k+1]$, $k \ge 0$; on each of them, $|v|^m e^{-cv^2} \le (k+1)^m e^{-ck^2}$, and these bounds form a summable sequence. The

negative half-line is treated by symmetry. The Fourier coefficients of m_s' are $ijh_s(j)$. By Parseval's identity, we have

$$\sum_j |h_s(j)|^2 \le C_r s^{-r-1/2}, \qquad \sum_j j^2 |h_s(j)|^2 \le C_r s^{-r+1/2}.$$

These identities may be applied first to the absolutely convergent kernel series, or obtained by approximation with trigonometric polynomials in L^2. For $s \ge 1$, we have $\sum_{j\in\mathbb{Z}}(1 + j^2/s)^{-1} \le C\sqrt{s}$; to see this, we separate $|j| \le \sqrt{s}$ from $|j| > \sqrt{s}$ and use $s\sum_{j>\sqrt{s}} j^{-2} \le C\sqrt{s}$. Then the weighted Cauchy–Schwarz inequality implies

$$\sum_j |h_s(j)| \le \Big(\sum_j (1 + j^2/s)^{-1}\Big)^{1/2} \Big(\sum_j (1 + j^2/s)|h_s(j)|^2\Big)^{1/2} \le C_r s^{-r/2}. \tag{16.3}$$

The kernel on $\mathbb{Z}^3$ is the product of three copies of r_s. A product of q differences puts r_i differences on coordinate i, with $r_1 + r_2 + r_3 = q$, and the absolute counting L^1 norm of the differentiated kernel is the product of the three one-dimensional norms. By (16.3), it is at most $C_q(1 + s)^{-q/2}$ for every $s \ge 0$. Periodizing with period n does not increase this norm, by the triangle inequality, and it preserves positivity and mass. At spacing a, the time is $s = t/a^2$, the density carries the factor a^{-3}, and a product of q physical differences carries the factor a^{-q}. We obtain

$$a^3 \sum_y |D_a^\epsilon p_t^a(x, y)| \le C_q a^{-q}(1 + t/a^2)^{-q/2} = C_q(t + a^2)^{-q/2}.$$

The periodized kernel solves the finite heat equation with initial density $a^{-3}\mathbf{1}_{x=y}$, and by uniqueness for this finite linear system it equals p_t^a. This proves the L^1 bound and the assertions on positivity and mass, including at $t = 0$.

The L^2 and supremum bounds. Fix one representative of each $k \in (\mathbb{Z}/n\mathbb{Z})^3$ with $|k_i| \le n/2$. Then

$$p_t^a(x, y) = L^{-3} \sum_k e^{-t\lambda_a(k)} e^{2\pi i k\cdot(x-y)/L}, \qquad \lambda_a(k) = 4a^{-2} \sum_i \sin^2(\pi k_i/n). \tag{16.4}$$

Indeed, these exponentials are eigenfunctions of Δ_a, and their orthogonality on Γ_a yields the required initial density at $t = 0$. For these representatives,

$$c|k|^2/L^2 \le \lambda_a(k) \le C|k|^2/L^2,$$

and the multiplier of D_a^ϵ has absolute value at most $C_q(|k|/L)^q$. If $0 \le t \le a^2$, we obtain the supremum bound $2^q a^{-3-q}$ and the L^2_a bound $2^q a^{-3/2-q}$ from the difference stencil and the mass identity; since $t + a^2 \le 2a^2$, these are the asserted bounds. If $t \ge a^2$, we extend the sum over nonzero frequencies to $\mathbb{Z}^3 \setminus \{0\}$. For every $r \ge 0$ and $c > 0$,

$$L^{-3} \sum_{k\ne 0} (|k|/L)^r e^{-ct|k|^2/L^2} \le C_{r,c} t^{-(3+r)/2}. \tag{16.5}$$

To check this estimate, we set $u = t/L^2$ and group the frequencies with $j \le |k| < j+1$. There are at most $C(j+1)^2$ of them, since the disjoint unit cubes centered at these points lie in an annulus of fixed extra width. For $u \le 1$, the sum of $(j+1)^{r+2}e^{-cuj^2}$ over $j \ge 1$ is at most $C_{r,c}u^{-(r+3)/2}$: on the interval $[j, j+1]$, we may replace j^2 by $x^2/4$ and $(j+1)^{r+2}$ by $C_r x^{r+2}$, and then integrate. For $u \ge 1$, we have $e^{-cuj^2} \le e^{-cu/2}e^{-cj^2/2}$ for $j \ge 1$, and $e^{-cu/2} \le C_{r,c}u^{-(r+3)/2}$. Rescaling gives (16.5).

The triangle inequality in (16.4), together with (16.5) for $r = q$, implies the supremum bound. By orthogonality on Γ_a, the square of the L^2_a norm equals L^{-3} times the sum over k of the squared multipliers times $e^{-2t\lambda_a(k)}$, and (16.5) with $r = 2q$ bounds it. For $q = 0$, the frequency $k = 0$ contributes L^{-3} both to the supremum and to the square of the L^2_a norm. On the horizon, we have $L^{-3} \le (T/L^2)^{3/2}t^{-3/2}$, and this contribution is at most $C(T/L^2)t^{-3/2}$ in both cases; every difference of positive order annihilates it. Since $t + a^2 \le 2t$ in this range, these are the asserted bounds, with constants depending only on q and T/L^2.

The continuum kernel and the cell integrals. The continuum kernel is the periodization of

$$G_t(z) = (4\pi t)^{-3/2}e^{-|z|^2/(4t)},$$

which has mass one. For each multi-index ν, the derivative $\partial^\nu G_t$ equals $t^{-(3+|\nu|)/2}$ times a fixed polynomial in $z/\sqrt{t}$ times $e^{-|z|^2/(4t)}$. A change of variables yields $\|\partial^\nu G_t\|_1 \le C_\nu t^{-|\nu|/2}$, and periodization does not increase the absolute L^1 norm. The periodic Fourier coefficients are $L^{-3}e^{-4\pi^2 t|k|^2/L^2}$, obtained by integrating the periodized Gaussian over one period. The other two bounds follow from (16.5), with the term $k = 0$ treated as before. For $t > 0$, all these series and their derivatives converge absolutely; multiplying Fourier coefficients then verifies the heat equation and the semigroup property.

By positivity and mass, we have $\sum_y \omega_y(t,x) = 1$, and hence $\|\omega(t,x)\|_2 \le 1$. Using the Cauchy–Schwarz inequality on each cell, we find

$$\sum_y \Big| \int_{Q_y} \partial^\nu \partial_t^r p_t(x-z)\, dz \Big|^2 \le a^3 \|\partial^\nu \Delta^r p_t\|_2^2 \le C_{\nu,r} a^3 t^{-3/2-|\nu|-2r}, \tag{16.6}$$

where we used the heat equation $\partial_t p_t = \Delta p_t$ and, in the last inequality, the continuum L^2 bound with $q = |\nu| + 2r$. The case $\nu = 0$, $r = 0$ is the second bound on $\|\omega(t,x)\|_2$. Integrating one spatial derivative along a shortest segment in $\mathbb{T}^3_L$ from x to x', we bound the difference of the two cell arrays by $Ca^{3/2}t^{-5/4}\operatorname{dist}(x,x')$. The value bound, used twice, bounds it by $Ca^{3/2}t^{-3/4}$, and the minimum of the two is the increment bound. In the same way, (16.6) controls every fixed spatial and time derivative. For the time increment, we integrate the time derivative over $[v, v + |t-s|]$ when $|t-s| \le v$, and we use the two value bounds otherwise. The same reasoning, applied to a differentiated array of cell integrals, yields its increment bounds, with the additional factors displayed

in (16.6). Finally, for $t \le a^2$, positivity and unit mass imply $\|P_t f\|_\infty \le \max_y |f_y|$ for every cell embedding f; this needs no regularity across cell boundaries.

The chaining assertion is a special case of Lemma 16.4; we deduce it at the end of Section 16.3. □

16.2 Cardinal interpolation and volume-normalized columns

We next define the cardinal interpolation used to compare arrays on different lattices.

Fix an even nonnegative function $b \in C_c^\infty([-1,1])$ that is positive on $(-1,1)$; all its derivatives vanish at ± 1. Set

$$\zeta(v) = \frac{b(v)}{\sum_{m\in\mathbb{Z}} b(v-m)} \quad (v \in \mathbb{R}), \qquad \zeta_3(u) = \prod_{i=1}^{3} \zeta(u_i) \quad (u \in \mathbb{R}^3).$$

Let $a_0 = L/n$ with $n \ge 4$, let $m \ge 1$ be an integer, and let $a = a_0/m$. For $x \in \Gamma_{a_0}$ let

$$\psi_x(z) = \sum_{l\in\mathbb{Z}^3} \zeta_3((z - x + Ll)/a_0) \qquad (z \in \mathbb{T}_L^3)$$

be the periodization of the translated function $\zeta_3((\cdot - x)/a_0)$. The cardinal interpolation of an array f on Γ_{a_0} is the array on Γ_a defined componentwise by

$$(I_{a_0\to a} f)_i(y) = \sum_{x\in\Gamma_{a_0}} \psi_x(y) f_i(x) \qquad (y \in \Gamma_a), \tag{16.7}$$

where, as above, each positive link is attached to its starting vertex. The continuous interpolant is $I_{a_0} f(z) = \sum_x \psi_x(z) f(x)$ for $z \in \mathbb{T}_L^3$. In (16.7) we also write $\zeta_3((y-x)/a_0)$ for $\psi_x(y)$.

For a matrix K from scalar variables ξ attached to the cells of the lattice of mesh a_0 to arrays on the lattice of mesh a, we use the row sums $\sup_y \sum_\xi |K(y,\xi)|$ and the volume-normalized column sums $\sup_\xi (a^3/a_0^3) \sum_y |K(y,\xi)|$, as in Definition 4.6. Throughout, a column is normalized by the cell volume a_0^3 of its input.

Lemma 16.3. *Fix $L, T > 0$ and the function b. Let $a_0 = L/n$ with $n \ge 4$, let $m \ge 1$ be an integer, and let $a = a_0/m$. All times below lie in $[0,T]$.*

1. *The map $I_{a_0\to a}$ is local within distance $\sqrt{3}a_0$, commutes with constant color rotations, preserves constants, satisfies $(I_{a_0\to a} f)(x) = f(x)$ for $x \in \Gamma_{a_0}$, and $I_{a\to a}$ is the identity. For every integer $q \ge 0$,*

$$\|D_a^q I_{a_0\to a} f\|_\infty \le C_q a_0^{-q} \|f\|_\infty, \qquad a^3 \sum_y \psi_x(y) = a_0^3,$$

$$a^3 \sum_y \operatorname{dist}(y,x) \psi_x(y) \le C a_0^4, \qquad \|D_a^q P_t^a I_{a_0\to a} f\|_\infty \le C_q (t + a_0^2)^{-q/2} \|f\|_\infty.$$

The continuous interpolant $I_{a_0} f$ satisfies the corresponding derivative bounds, and $\int_{\mathbb{T}^3_L} \psi_x(z)\, dz = a_0^3$.

2. *Let E_θ be a deterministic matrix, depending on a parameter θ, from scalar variables ξ attached to the cells of the lattice of mesh a_0, at most v_J of them per cell, to arrays on that lattice. Suppose that, uniformly in θ, its row sums and volume-normalized column sums are at most C_J, that is,*

$$\sup_x \sum_\xi |E_\theta(x,\xi)| \le C_J, \qquad \sup_\xi a_0^3 \sum_x |E_\theta(x,\xi)| \le C_J a_0^3, \tag{16.8}$$

and that its columns decay exponentially at scale a_0, with fixed rate and amplitude. Set $W_t = P_t^a I_{a_0 \to a} E_\theta$. Then for every integer $q \ge 0$,

$$\sup_{x,\theta} \|D_a^q W_t(x,\cdot)\|_{\ell^2} \le C_{J,q} a_0^{3/2} (t + a_0^2)^{-3/4 - q/2},$$
$$\|D_a^q W_t\|_{\ell^2 \to L^2_a} \le C_{J,q} a_0^{3/2} (t + a_0^2)^{-q/2},$$

where ℓ^2 refers to the variables ξ. For $q \in \{0,1\}$, put $A_q(t) = a_0^{3/2}(t+a_0^2)^{-3/4-q/2}$ and $v = \min\{s,t\}$. Then

$$\|D_a^q W_t(x,\cdot) - D_a^q W_s(x,\cdot)\|_{\ell^2} \le C_{J,q} A_q(v) \min\{1, |t-s|/(v+a_0^2)\},$$
$$\|D_a^q W_t(x,\cdot) - D_a^q W_t(y,\cdot)\|_{\ell^2} \le C_{J,q} A_q(t) \min\{1, \mathrm{dist}(x,y)/\sqrt{t+a_0^2}\}.$$

At fixed θ, for $q \in \{0,1\}$ and $0 < \eta < 1$, the set $\Gamma_a \times [0,T]$ with the distance $a_0^q \|D_a^q W_t(x,\cdot) - D_a^q W_s(y,\cdot)\|_{\ell^2}$ between (x,t) and (y,s) has an η-net with at most

$$C_{J,q} (1 + L/(\eta a_0))^3 (1 + T/(\eta a_0^2))$$

points. For the normalized rows $D_a^q W_t(x,\cdot)/A_q(t)$ the same holds, up to a factor which is a fixed power of $1 + T/a_0^2$.

3. *Let u be an array on the lattice of mesh a_1 with $a_1/a \in \mathbb{N}$. Then, componentwise,*

$$a^3 \sum_{y \in \Gamma_a} I_{a_1 \to a} u(y) = a_1^3 \sum_{x \in \Gamma_{a_1}} u(x).$$

Hence, if arrays originating on lattices of different meshes are interpolated separately from their own lattices to a common finer lattice before they are added or subtracted, every componentwise integral is preserved exactly; in particular every prescribed zero integral is preserved.

All the estimates are uniform in the ratio $m = a_0/a$, in n, and in θ, at fixed J and fixed coefficient constants. The constants depend only on b, q, T/L^2, v_J, C_J, and the decay constants of the columns. The hypotheses of the second part hold, with a constant C_J depending only on J, the fixed construction domains, and the order of differentiation, for the normalized Jacobian of the reconstruction and for each of its mixed derivatives of fixed order in the coarse field and the fluctuation variables, uniformly in the coarse field and in the depth; see Lemma 16.5.

Proof. All matrices in this proof are written in counting coordinates, and all times lie in $[0, T]$; we apply Lemma 16.1 with the same L and T. The parameter θ is fixed during the construction of each net, and the constants are uniform in θ; the covering assertion is not an entropy estimate for the family indexed by θ.

The basis functions and their masses. Let $d_b(u) = \sum_{m\in\mathbb{Z}} b(u-m)$. Since only finitely many terms are nonzero near any point, d_b is smooth and one-periodic. It is strictly positive, since some integer has distance at most $1/2$ from u, and its minimum over one period is positive. The function $\zeta = b/d_b$ is smooth, nonnegative, even, and supported in $[-1,1]$; all its derivatives vanish at ± 1, and

$$\zeta(k) = \mathbf{1}_{k=0} \quad (k \in \mathbb{Z}), \qquad \sum_{k\in\mathbb{Z}} \zeta(u-k) = 1. \tag{16.9}$$

The first identity holds because $b(k) = 0$ for integers $k \neq 0$ and $d_b(0) = b(0)$; the second follows by replacing every $d_b(u-k)$ by $d_b(u)$. The periodization in ψ_x accounts for every periodic seam. These functions sum to one as x ranges over Γ_{a_0}, they are supported within torus distance $\sqrt{3}a_0$ of x, and $\psi_x(x') = \mathbf{1}_{x=x'}$ for $x' \in \Gamma_{a_0}$. The map preserves constants and samples, and it is the identity when $a = a_0$. Since it acts by the same scalar coefficients on each direction and color, it commutes with every constant color rotation.

Since at any point of $\mathbb{T}^3_L$ at most a fixed number of the functions ψ_x are nonzero, we have

$$\|\partial^\epsilon I_{a_0} f\|_\infty \le C_q a_0^{-q} \|f\|_\infty$$

for every product ∂^ϵ of q partial derivatives. For a smooth periodic function h, each physical forward or backward difference is an average of the corresponding derivative,

$$D^{\pm}_{a,i} h(z) = \int_0^1 \partial_i h(z \pm r a e_i)\, dr. \tag{16.10}$$

Applying this identity repeatedly, we write a product of q differences as an average of the corresponding derivative of order q. The preceding bound therefore implies the bound on $D^q_a I_{a_0\to a} f$, uniformly in m.

For the mass, we write an integer l as $l = mk + r$ with $0 \le r < m$. By (16.9), we have

$$\sum_{l\in\mathbb{Z}} \zeta(l/m) = \sum_{r=0}^{m-1} \sum_{k\in\mathbb{Z}} \zeta(k + r/m) = m.$$

Taking the product over the three coordinates and regrouping the periodization, we obtain

$$a^3 \sum_{y\in\Gamma_a} \psi_x(y) = a^3 m^3 = a_0^3. \tag{16.11}$$

Since $\psi_x \ge 0$ is supported within distance $\sqrt{3}a_0$ of x, the first moment is at most $\sqrt{3}a_0^4$. Integrating the second identity in (16.9) over $[0,1]$, we find $\int_{\mathbb{R}} \zeta(u)\, du = 1$, and the

product over the coordinates gives $\int_{\mathbb{T}_L^3} \psi_x(z)\,dz = a_0^3$. These arguments also prove the assertions on the continuous interpolant.

Heat smoothing. If $t \le a_0^2$, we commute the differences with the discrete heat semigroup and use that P_t^a contracts the supremum norm, together with the bound on $D_a^q I_{a_0 \to a} f$; this gives $C_q a_0^{-q} \|f\|_\infty$. If $t \ge a_0^2$, we move the differences onto the heat kernel and use its L_a^1 bound from Lemma 16.1, together with $\|I_{a_0 \to a} f\|_\infty \le \|f\|_\infty$; since $a \le a_0$, we obtain $C_q t^{-q/2} \|f\|_\infty$. Both bounds are at most $C_q (t + a_0^2)^{-q/2} \|f\|_\infty$. The same argument, with continuous derivatives and the continuum heat kernel, proves the corresponding continuous estimate.

Row sums and volume-normalized column sums. We write ξ for the scalar input variables. The finitely many variables per cell and the color components are included in C_J. The estimates below use only (16.8), and they apply to every matrix obeying (16.8). The interpolation, whose range is $\sqrt{3} a_0$, preserves the exponential decay of the columns, but this decay is not needed for the numerical bounds.

Let $K = I_{a_0 \to a} E_\theta$. For every product of q differences,

$$\sup_y \sum_\xi |D_a^q K(y, \xi)| \le C_{J,q} a_0^{-q}, \qquad \sup_\xi a^3 \sum_y |D_a^q K(y, \xi)| \le C_{J,q} a_0^{3-q}. \tag{16.12}$$

For the first bound, we expand K over the coarse vertices. By (16.10) and the bounded overlap of the differentiated continuous basis functions, we have $\sum_x |D_a^q \psi_x(y)| \le C_q a_0^{-q}$, and the row bound in (16.8) implies the claim. For the second bound, each differentiated basis function has magnitude at most $C_q a_0^{-q}$ and support within distance $C_q a_0$ of its vertex, which contains at most $C_q (a_0/a)^3$ fine vertices. This also holds if the support wraps around the torus, by summing over its lifts. We conclude that $a^3 \sum_y |D_a^q \psi_x(y)| \le C_q a_0^{3-q}$, and summing over x with the column bound in (16.8) gives the second bound.

For $t \le a_0^2$, the heat semigroup is a contraction on absolute row sums and on volume-normalized column sums, and (16.12) holds for $D_a^q W_t$. In particular, the ℓ^2 norm of a row of $D_a^q W_t$ is at most its absolute row sum $C_{J,q} a_0^{-q} = C_{J,q} A_q(0)$. For $t \ge a_0^2$, we use the undifferentiated K in the heat convolution and move all differences to the heat kernel. The L_a^1 bound and the supremum bound of Lemma 16.1 yield, respectively,

$$\sup_x \sum_\xi |D_a^q W_t(x, \xi)| \le C_{J,q} t^{-q/2}, \qquad \sup_{x,\xi} |D_a^q W_t(x, \xi)| \le C_{J,q} a_0^3 t^{-(3+q)/2}. \tag{16.13}$$

The square of the ℓ^2 norm of a row is at most the product of these two quantities, that is, at most $C_{J,q} a_0^3 t^{-3/2-q}$. Together with the bound for $t \le a_0^2$, this proves the row bound with $t + a_0^2$ on the whole interval.

For the operator norm, we use Schur's test with the volume weights of the output lattice,

$$a^3 \sum_x \Big| \sum_\xi H(x,\xi) u_\xi \Big|^2 \le \Big(\sup_x \sum_\xi |H(x,\xi)| \Big) \Big(\sup_\xi a^3 \sum_x |H(x,\xi)| \Big) \sum_\xi |u_\xi|^2, \tag{16.14}$$

which follows from the Cauchy–Schwarz inequality in each row and an interchange of two finite sums. For $t \le a_0^2$, we use (16.12). For $t \ge a_0^2$, the first factor is bounded by (16.13), and the second is at most $C_{J,q} a_0^3 t^{-q/2}$, by the L^1_a bound on the heat kernel and the undifferentiated column bound for K. Taking the square root gives $C_{J,q} a_0^{3/2} (t + a_0^2)^{-q/2}$. The volume in this computation is the input cell volume a_0^3; refining the output lattice does not change it.

Increments and nets. Let $R_q(t,x)$ denote the row $D_a^q W_t(x,\cdot)$. The bounds already proved hold for every order of differentiation. Since $\partial_t W_t = \Delta_a W_t$, they imply

$$\|\partial_t R_q(t,x)\|_{\ell^2} \le C_{J,q} \frac{A_q(t)}{t + a_0^2}, \qquad \|D^{\pm}_{a,i} R_q(t,x)\|_{\ell^2} \le C_{J,q} \frac{A_q(t)}{\sqrt{t + a_0^2}}.$$

Since A_q is decreasing, integrating the first bound between s and t gives $C_{J,q} |t - s| A_q(v)/(v + a_0^2)$; the sum of the two row norms is at most $C_{J,q} A_q(v)$, and the minimum of the two bounds is the time increment. For the spatial increment, we join two fine vertices by a shortest periodic path along coordinate directions, of total physical length at most $\sqrt{3}\,\mathrm{dist}(x,y)$. Summing the second bound along this path gives the distance times the displayed derivative bound; the sum of the two value bounds is the alternative without the distance.

For the distance $d_q((x,t),(y,s)) = a_0^q \|R_q(t,x) - R_q(s,y)\|_{\ell^2}$, these estimates imply

$$d_q((x,t),(y,s)) \le C_{J,q} \Big(\frac{\mathrm{dist}(x,y)}{a_0} + \frac{|t-s|}{a_0^2} \Big).$$

We choose spatial points at physical separation at most $c_{J,q} \eta a_0$ and times at separation at most $c_{J,q} \eta a_0^2$. If a exceeds the proposed spatial separation, we use all vertices, whose number is then smaller than the bound below; otherwise, we round a continuum cubic covering to fine vertices, which at most doubles its radius. The resulting net has at most $C_{J,q}(1 + L/(\eta a_0))^3 (1 + T/(\eta a_0^2))$ points, independently of the number of fine vertices. For the normalized rows $R_q(t,x)/A_q(t)$, differentiation in time produces the additional term $A_q'(t)/A_q(t) = -(3/4 + q/2)/(t + a_0^2)$. The same estimates give a spatial Lipschitz bound $C_{J,q}/a_0$ and a time Lipschitz bound $C_{J,q}/a_0^2$ for the normalized rows, and the same net works. Alternatively, using only the global bounds costs powers of $a_0^{-q}/A_q(T) = (1 + T/a_0^2)^{3/4 + q/2}$.

Column integrals. Let u be an array on the lattice of mesh a_1 with $a_1/a \in \mathbb{N}$. Interchanging finite sums and using (16.11) with a_1 in place of a_0, we obtain

$$a^3 \sum_y I_{a_1 \to a} u(y) = \sum_x u(x)\, a^3 \sum_y \psi_x(y) = a_1^3 \sum_x u(x).$$

Applying this identity to each array on its own lattice before adding or subtracting arrays from different lattices preserves every signed componentwise integral exactly. This is an identity for arrays of components, not for lattice cochains or holonomies. All the constants above depend only on b, the order of differentiation, T/L^2, and the coefficient constants. □

16.3 Supremum bounds from covering numbers

The maximal inequalities of this paper are obtained by elementary chaining. We consider a process indexed by a set $\mathcal{T}$ with a nonnegative symmetric function d that controls the tails of the increments. We do not assume that d satisfies the triangle inequality; the proof uses only the covering numbers of d and the continuity of the process with respect to d. As in Section 16.1, for $v > 0$, a v-net is a set $\mathcal{N} \subset \mathcal{T}$ such that every $z \in \mathcal{T}$ has some $z' \in \mathcal{N}$ with $d(z, z') \le v$, and $N(\mathcal{T}, d, v)$ is the smallest cardinality of a v-net. A process $(F_z)_{z \in \mathcal{T}}$ is continuous with respect to d if $F_{z_k} \to F_z$ whenever $d(z_k, z) \to 0$.

Lemma 16.4. *Let $\mathcal{T}$ be a nonempty set and $d : \mathcal{T} \times \mathcal{T} \to [0, \infty)$ a symmetric function. Let $(F_z)_{z \in \mathcal{T}}$ be a real process which has a version that is continuous with respect to d and whose supremum equals its supremum over a countable d-dense subset of $\mathcal{T}$. Let $z_0 \in \mathcal{T}$, $s, b \ge 0$, $D < \infty$, $A \ge 1$, and $q_{\mathrm{ent}} \ge 0$, and assume that*

$$\sup_{z, z' \in \mathcal{T}} d(z, z') \le D, \qquad N(\mathcal{T}, d, v) \le A v^{-q_{\mathrm{ent}}} \quad (0 < v \le 1),$$

and that for every $u > 0$ and all $z, z' \in \mathcal{T}$,

$$\mathbb{P}\{|F_{z_0}| > s\sqrt{u} + bu\} \le 2e^{-u}, \qquad \mathbb{P}\{|F_z - F_{z'}| > d(z, z')(s\sqrt{u} + bu)\} \le 2e^{-u}.$$

Put $D_1 = \max\{1, D\}$ and $H = \log(2A) + q_{\mathrm{ent}}$. There is a universal constant C such that, for $u \ge 0$ and $1 \le p < \infty$,

$$\mathbb{P}\Big\{\sup_z |F_z| > C D_1 \big[s(\sqrt{H} + \sqrt{u}) + b(H + u)\big]\Big\} \le 2e^{-u},$$

$$\Big\|\sup_z |F_z|\Big\|_{L^p} \le C D_1 \big[s(\sqrt{H} + \sqrt{p}) + b(H + p)\big].$$

No Gaussian or independence assumption is made; in particular the lemma applies to centered processes.

Further, let $Y_1, \dots, Y_N$, $N \geq 1$, be real random variables with $\mathbb{P}\{|Y_i| > s\sqrt{u} + bu\} \leq 2e^{-u}$ for every $u > 0$, and let $M \geq 0$ be a random variable with $M \leq \max_{i \leq N} |Y_i| + e$ almost surely, for a deterministic $e \geq 0$. Then, for $u \geq 0$ and $1 \leq p < \infty$,

$$\mathbb{P}\big\{M > e + s\sqrt{\log(2N) + u} + b(\log(2N) + u)\big\} \leq e^{-u},$$
$$\|M\|_{L^p} \leq e + C\big\{s\big[\sqrt{\log(2N)} + \sqrt{p}\big] + b\big[\log(2N) + p\big]\big\}.$$

Every assertion holds under a fixed conditional probability kernel, with the same constants, if all the hypotheses hold for each fixed value of the conditioning variable. The constant C does not depend on the dimension, the meshes, the radii, the couplings, or the conditioning value. A bound which is uniform in the conditioning value requires that the parameters $s, b, D, A, q_{\mathrm{ent}}$ (and e) be bounded uniformly in that value.

Proof. We first normalize. Dividing d by D_1 gives a function of supremum at most one. At the radii 2^{-k}, $k \geq 1$, it has nets $\mathcal{T}_k$ with at most $A2^{kq_{\mathrm{ent}}}$ points: if $D_1 2^{-k} \leq 1$, we use the given net for d at radius $D_1 2^{-k}$, and otherwise we use the net at radius one. In the normalized function, the increment parameters become at most $D_1 s$ and $D_1 b$, while the parameters of the point z_0 are unchanged and are at most $D_1 s$ and $D_1 b$. If a net of minimal cardinality does not exist at some radius, we enlarge the radius by a factor two; the universal constant absorbs this factor. It therefore suffices to consider $D_1 = 1$ and nets $\mathcal{T}_k$ of radius at most 2^{1-k}.

We choose the nets and the connections deterministically. We connect every point of $\mathcal{T}_1$ to z_0, and each point of $\mathcal{T}_k$, $k \geq 2$, to one point of $\mathcal{T}_{k-1}$ within distance 2^{2-k}; such a point exists because $\mathcal{T}_{k-1}$ is a net of radius 2^{2-k} for all of $\mathcal{T}$. There are at most $A2^{kq_{\mathrm{ent}}}$ connections at level k. Set

$$h_0 = u + \log 8, \qquad h_k = u + \log(2A) + kq_{\mathrm{ent}} \log 2 + (k+3)\log 2 \quad (k \geq 1).$$

The point z_0 violates the bound $s\sqrt{h_0} + bh_0$ with probability at most $e^{-u}/4$. By a union bound over the connections at level k, the probability that one of them violates its bound is at most $e^{-u} 2^{-k-3}$. The sum of these probabilities is less than $2e^{-u}$.

On the complementary event, we follow the connections from a point of $\mathcal{T}_k$ back to z_0. The value of the process at every net point is then bounded by the bound at z_0, plus the bound for its connection at level one, plus

$$\sum_{k \geq 2} 2^{2-k}(s\sqrt{h_k} + bh_k).$$

Since the sums of 2^{-k}, $k2^{-k}$, and $\sqrt{k}2^{-k}$ converge, and $\sqrt{x+y} \leq \sqrt{x} + \sqrt{y}$, this expression is at most

$$C\big\{s\big[\sqrt{\log(2A) + q_{\mathrm{ent}}} + \sqrt{u}\big] + b\big[\log(2A) + q_{\mathrm{ent}} + u\big]\big\}.$$

Every $z \in \mathcal{T}$ is the limit, with respect to d, of net points $z_k \in \mathcal{T}_k$, since $d(z, z_k) \le 2^{1-k}$. On the event where the given version is continuous, we have $F_{z_k} \to F_z$, and the bound extends to every point. The supremum equals a countable supremum and is therefore measurable. Restoring D_1 proves the tail bound. If $s = b = 0$, the same countable argument applies: the value at z_0 and every increment along a connection vanish almost surely. This also covers points at distance zero.

For the moments, we use that a nonnegative random variable X with $\mathbb{P}\{X > \alpha_0 + c\sqrt{u} + d_0 u\} \le 2e^{-u}$ for all $u \ge 0$ satisfies $\|X\|_{L^p} \le \alpha_0 + C(c\sqrt{p} + d_0 p) + C(c + d_0)$. To see this, let E be an exponential random variable with $\mathbb{P}(E > v) = e^{-v}$. Since $\min\{1, 2e^{-u}\} = \mathbb{P}(E + \log 2 > u)$, the variable X is stochastically dominated by $\alpha_0 + c\sqrt{E + \log 2} + d_0(E + \log 2)$. Minkowski's inequality and

$$\mathbb{E}E^r = \int_0^\infty t^r e^{-t}\, dt \le 2(2r/e)^r \qquad (r > 0)$$

imply the claim; the last inequality follows by maximizing $t^r e^{-t/2}$ and integrating the remaining factor $e^{-t/2}$, and we apply it with $r = p/2$ and $r = p$. In our case, $\alpha_0 = CD_1(s\sqrt{H} + bH)$, $c = CD_1 s$, and $d_0 = CD_1 b$, and $H \ge \log 2$ absorbs the term $C(c + d_0)$. This proves the L^p bound, including the bound on the expectation at $p = 1$.

For the finite family, we apply the tail bound for each Y_i with $u + \log(2N)$ in place of u and sum the N probabilities of failure; then we add the deterministic error e. The same comparison with an exponential random variable yields the moment bound.

Every step above is an inequality under one fixed probability measure, and we may therefore apply it separately under each conditional kernel. In the applications, the supremum is over rational times and a finite spatial grid, or over a set on which the process is continuous; its measurability is part of the hypotheses. The nets are constructed for the fixed value of the conditioning variable and require no random choice. Bounds on the parameters that are uniform in the conditioning value give bounds that are uniform in that value. □

Proof of the chaining assertion in Lemma 16.1. If $\sigma > 0$, we apply Lemma 16.4 to the function d/σ, with $s = \sqrt{2}\sigma$, $b = 0$, $D = 1$, $q_{\mathrm{ent}} = v$, the given A, and an arbitrary point $i_0 \in I$. The moment generating function bounds imply the required tails. Indeed, for a variable Y with $\mathbb{E}e^{zY} \le e^{z^2 r^2/2}$ for all real z, minimizing $e^{-zx}\mathbb{E}e^{zY}$ at $z = \pm x/r^2$ gives $\mathbb{P}\{|Y| > x\} \le 2e^{-x^2/(2r^2)}$, which is the required tail with $u = x^2/(2r^2)$. Since the one-point variance proxy is at most σ at every point, the choice of i_0 is arbitrary. The hypothesis on nets concerns radii $\eta < 1$; at radius one, a single point is a net, since $d/\sigma \le 1$. The lemma then gives the displayed tail and expectation bounds, where we use $\sqrt{\log(2A) + v} \le \sqrt{\log(2A)} + \sqrt{v}$. If $\sigma = 0$, every value of the process on the countable dense set vanishes almost surely by its moment generating function bound, and the claim follows from the continuity of the version. □

16.4 Concentration of conditionally centered reconstructions

One renormalization group step. Fix an odd integer $M \geq 3$, an integer $J \geq 1$, $B = M^J$, and the parameters of Theorems 13.8 and 15.13: the analytic radii, the cutoff amplitude A_{w}, the bound E_* on the effective interaction, and the larger construction domains. Fix $L > 0$ and the continuum coupling $g_3 > 0$. Let $a = L/n$ be a mesh such that $n/B \geq 4$ is an integer. We consider the renormalization group step from the lattice of mesh Ba, which we call the coarse lattice, to the lattice of mesh a, preceded by $d \geq 0$ averaging steps; we call d the depth. Its intermediate scales are indexed by $0 \leq i \leq J-1$. The intermediate scale i has mesh $a_i = M^i a$ and coupling $g_i = g_3\sqrt{a_i} = M^{i/2}g$, where $g = g_3\sqrt{a}$, so that $g^2 = g_3^2 a$. The largest coupling of the step is $t = g_{J-1} = M^{(J-1)/2}g$. The normalized fluctuation variables $w = (w_{i,e})$ take values in the fluctuation cutoff domain $\Omega_p = \prod_{i,e}\{w_{i,e} \in \mathbb{R}^3 : |w_{i,e}| \leq p_i\}$, whose radii satisfy $p_i \leq p(t) = A_{\mathrm{w}} \log(1/t)$. We write $q_i = g_i w_i$ for the corresponding coupling-scaled fluctuation inputs, which range over a product of balls of radius at most $Q = \max_i g_i p_i \leq t p(t)$.

The conditional fluctuation kernel. Let R_{supp} be a support radius, either $R_{\mathrm{supp}} = r$ or $R_{\mathrm{supp}} = \rho$ as described below, and let $c \in B_{R_{\mathrm{supp}}}$ be a coarse field, with $\theta = \operatorname{Log} c$. Its conditional fluctuation kernel is

$$\begin{aligned} V_{d,c}^{[R_{\mathrm{supp}}]}(w) &= \tfrac{1}{2}|w|^2 + H_{d,J}(\theta, w) + R_{\mathrm{in}}^{[R_{\mathrm{supp}}]}(e^{\varphi_\theta(w)}) - R_{\mathrm{in}}^{[R_{\mathrm{supp}}]}(e^{\varphi_\theta(0)}), \\ Z_{d,c}^{[R_{\mathrm{supp}}]} &= \int_{\Omega_p^{[R_{\mathrm{supp}}]}} e^{-V_{d,c}^{[R_{\mathrm{supp}}]}(w)}\, dw, \\ d\mu_{d,c}^{[R_{\mathrm{supp}}]}(w) &= \frac{\mathbf{1}_{\Omega_p^{[R_{\mathrm{supp}}]}}(w) e^{-V_{d,c}^{[R_{\mathrm{supp}}]}(w)}}{Z_{d,c}^{[R_{\mathrm{supp}}]}}\, dw. \end{aligned} \tag{16.15}$$

Here $\varphi_\theta(w) = \Phi_{d,J}(\theta, (g_i w_i)_i)$ is the reconstruction of Theorem 13.2, at which the effective interaction is evaluated, and $R_{\mathrm{in}}^{[R_{\mathrm{supp}}]}$ is the effective interaction produced by the d preceding averaging steps. The function $H_{d,J}(\theta, w)$ collects the remaining terms of the conditional fluctuation potential: the part of the effective classical action beyond its quadratic approximation, the Haar disintegration densities, and the logarithms of the Jacobian determinants of the conditional Hessian normalizations. The density in (16.15) is exactly the kernel $k(c, dw)$ of Theorem 13.8 (compare (4.8)). The subtraction of $R_{\mathrm{in}}^{[R_{\mathrm{supp}}]}(e^{\varphi_\theta(0)})$ depends only on c and cancels in the normalized kernel. The domain $\Omega_p^{[R_{\mathrm{supp}}]}$ does not depend on c. Since the potential is smooth on the compact closed product and the exponential is positive, $0 < Z_{d,c}^{[R_{\mathrm{supp}}]} < \infty$. When no confusion can arise, we write $\mu_{d,c}$, V_c, and Ω_p.

For $R_{\mathrm{supp}} = r$, the coarse field ranges over the small-link domain B_r, and $\mu_{d,c}$ is the conditional law, given the coarse field, of the fluctuation variables of the step under the

conditioned Wilson measure. Indeed, once the coarse field is fixed, the restrictions at coarser scales are fixed factors and cancel in the normalized kernel (Theorem 13.8). For $R_{\mathrm{supp}} = \rho$, we assume that a separate instance of Theorem 13.8 with support radius ρ is given. It has its own incoming effective interaction $R_{\mathrm{in}}^{[\rho]}$, its own fluctuation cutoff domain, normalized kernel, and change-of-gauge identity, and the image conditions of Theorem 13.2 hold for all coarse fields in B_ρ, including the margins of Lemma 16.5 below. This instance is a different conditional measure; it is not obtained by evaluating the auxiliary integral of Section 14 at coarse fields in $B_\rho \setminus B_r$, and we make no statement about that integral there. In Section 17, only the case $R_{\mathrm{supp}} = r$ is used.

The reconstruction. Let $\Phi(c, q)$ be the logarithm of a reconstruction of the fine field, in a gauge transformation that depends only on the coarse field c. We require the following properties on the whole product of coarse fields $c \in B_{R_{\mathrm{supp}}}$ and coupling-scaled fluctuation inputs of radius at most Q. The image of the reconstruction lies in the domain prescribed by Theorem 13.2. Its derivatives in q satisfy the absolute row bounds and the volume-normalized column bounds of that theorem, with each variable of the intermediate scale i normalized by its own cell volume a_i^3. The map $\Phi_{d,J}$ of Theorem 13.2 and the logarithmic form $\widehat{\Phi}_d$ of the reconstruction maps $\widehat{\mathscr{R}}$ of Theorem 15.12 have these properties; see Lemma 16.5. We set

$$A(w) = a^{-1}\Phi(c, (g_i w_i)_i),$$

the lattice potential of the reconstructed field, and we view it as a cell function: the component of A on a positive link $(y, y + ae_i)$ is extended as a constant on the cell Q_y.

The domain conditions. The next lemma collects the conditions under which the whole product of fluctuation variables lies in the domain where the coefficient bounds of Theorem 13.2 and the Hessian bound of Theorem 13.8 hold. It fixes the order of choices: the larger construction domains and coefficient constants first, then the support radius, and the coupling bound g_* last; J is fixed throughout.

Lemma 16.5. *Let $K_* \geq 2$, ρ, s_J, r_J, C_J, and the coefficientwise majorant series*

$$\mathfrak{M}_J(u, v) = B^{-1}Z(u) + \frac{C_J v}{1 - C_J(u + v)}$$

for the absolute row sums of the reconstruction, be as in Theorem 13.2. Thus Z has nonnegative coefficients and no constant term, and

$$4K_*\rho < r_J, \qquad C_J 4K_*(\rho + s_J) < 1, \qquad \mathfrak{M}_J(4K_*\rho, 4K_* s_J) < \rho/2.$$

For the reconstruction and conditional-potential assertions, fix a support radius $0 < R_{\mathrm{supp}} \leq \rho$ and a conditional-kernel instance on $B_{R_{\mathrm{supp}}}$. Assume that this ball of coarse fields satisfies the

coordinate-domain conditions of that instance, and that its product with the coupling-scaled fluctuation inputs lies in the domain of the chosen reconstruction, with the fixed radius ratios; for the reconstruction maps of Theorem 15.12, assume that this product lies in their common inner domain. In the application below $R_{\mathrm{supp}} = r$, or $R_{\mathrm{supp}} = \rho$ with the separately hypothesized instance and its own domains. For this fixed ball and instance, choose $Q_\circ$ with $0 < Q_\circ \le s_J$ and $Q_\circ < (r_J - \rho)/2$, inside every further domain of coarse fields and coupling-scaled fluctuation inputs used by the reconstruction, and set $\eta_\circ = 1 - C_J(\rho + s_J)$. Then the following statements hold.

1. *We have $\eta_\circ > 0$ and*

$$0 < R \le \rho, \quad 0 \le Q \le Q_\circ \quad \Longrightarrow \quad R + Q < r_J, \quad 1 - C_J(R+Q) \ge \eta_\circ. \tag{16.16}$$

2. *For $0 \le u \le \rho$ and $0 \le v \le Q_\circ$,*

$$\partial_v \mathfrak{M}_J(u,v) = \frac{C_J(1 - C_J u)}{[1 - C_J(u+v)]^2} \le C_J \eta_\circ^{-2}.$$

   On the fixed product of coarse fields $c \in B_{R_{\mathrm{supp}}}$ and coupling-scaled fluctuation inputs of radius at most $Q_\circ$, the normalized Jacobian $g^{-1} D_w \Phi(c, (g_i w_i)_i)$, with each fluctuation variable attached to a cell of the lattice of mesh a, and each of its mixed derivatives of fixed order in the coarse field and the fluctuation variables, satisfy (16.8) *with $a_0 = a$ and a constant depending only on J, the fixed construction domains, the order of differentiation, and $\eta_\circ$.*

3. *For $0 < R \le \rho$ put $Q_{\mathrm{gate}}(R) = \min\{Q_\circ, R\eta_\circ/(8C_J)\}$. If $0 \le Q \le Q_{\mathrm{gate}}(R)$, then $\mathfrak{M}_J(R,Q) < 3R/16 < R/2$.*

4. *Fix $0 < R \le \rho$. There is $g_* > 0$, depending only on the fixed construction data and on R, such that for all $0 < t \le g_*$,*

$$\begin{aligned} tp(t) &\le Q_{\mathrm{gate}}(R), \qquad 1 - Ctp(t) > 0, \\ \frac{C[tp(t) + t^2(1 + E_*)]}{[1 - Ctp(t)]^3} &\le \frac{1}{2}, \end{aligned} \tag{16.17}$$

   where $p(t) = A_{\mathrm{w}} \log(1/t)$ and C is the constant in the Hessian bound of Theorem 13.8 (not the row constant C_J).

In particular, for the fixed support radius and instance specified above, let g_* be as in the fourth part with $R = R_{\mathrm{supp}}$, let $0 < t \le g_*$, and let the radii of the fluctuation cutoff domain satisfy $p_i \le p(t)$. Then for every coarse field in $B_{R_{\mathrm{supp}}}$ the whole product of fluctuation variables, and not only the point $w = 0$, is mapped into the product of the first part; the image condition $\mathfrak{M}_J(R,Q) < R/2$ of Theorem 13.2 holds with $Q = \max_i g_i p_i$; and the conditional fluctuation potential satisfies $D_w^2 V_c \ge I/2$ on the closed product.

Proof. Since $K_* \geq 2$, we have $C_J(\rho + s_J) < 1/(4K_*) < 1$, and hence $\eta_\circ > 0$. If $0 < R \leq \rho$ and $0 \leq Q \leq Q_\circ$, then $R + Q \leq \rho + Q_\circ < \rho + (r_J - \rho)/2 < r_J$ and $1 - C_J(R + Q) \geq 1 - C_J(\rho + s_J) = \eta_\circ$. This proves (16.16). The choice of $Q_\circ$ is possible because $r_J - \rho > 0$, and it can be made strictly inside every further domain used by the map, since these domains are open and have fixed radius ratios. For the reconstruction maps of Theorem 15.12, the required room comes from the hypothesis that the fixed product of coarse fields and coupling-scaled fluctuation inputs lies in their common inner domain with fixed radius ratios. We use their coefficient bound for mixed derivatives at fixed J and their uniform interior-domain conditions, rather than a majorant uniform in J.

Every product in (16.16) is contained in the product with radii $4K_*\rho$ and $4K_*s_J$. By Theorem 13.2, the image of this larger product lies in $B_{\rho/2}$, with interior margins for the intermediate classical, logarithm, and Haar disintegration conditions; subsets inherit these margins. On this product, the formula for $\partial_v \mathfrak{M}_J$ follows by differentiation, and the bound follows from $1 - C_J u \leq 1$ and $1 - C_J(u + v) \geq \eta_\circ$. The derivatives of the column majorants with respect to one fixed input give the volume-normalized column sums, with the same lower bound $\eta_\circ$ on the denominator. Each further derivative of fixed order costs only a factorial, the order, and inverse powers of $\eta_\circ$; it does not depend on the number of lattice points. These are derivatives of the absolute coefficient series, not consequences of a bound on the values of a holomorphic function. It remains to convert the normalizations. A fluctuation variable of the intermediate scale i lives on the lattice of mesh $a_i = M^i a$, and its column is normalized by a_i^3. Attaching it to a cell of the lattice of mesh a changes the normalization by the factor $M^{3i} \leq B^3$, and replacing q_i by $g_i w_i$ and dividing by g multiplies the derivative by $g_i/g = M^{i/2}$. At most a number of variables depending only on J is attached to each cell. These conversions only enlarge C_J by a factor depending on J, and they yield (16.8) for the normalized Jacobian and its mixed derivatives of fixed order. This proves the second part.

For the third part, the coefficients of Z are nonnegative and $Z(0) = 0$. Comparing term by term and using $(R/(4K_*\rho))^k \leq R/(4K_*\rho)$ for every degree $k \geq 1$, we find $Z(R) \leq (R/(4K_*\rho))Z(4K_*\rho)$ for $0 < R \leq \rho$. Since $B^{-1}Z(4K_*\rho) \leq \mathfrak{M}_J(4K_*\rho, 4K_*s_J) < \rho/2$, we obtain

$$B^{-1}Z(R) \leq \frac{R}{4K_*\rho} B^{-1}Z(4K_*\rho) < \frac{R}{8K_*} \leq \frac{R}{16}.$$

If $Q \leq Q_{\mathrm{gate}}(R)$, then by (16.16),

$$\mathfrak{M}_J(R, Q) \leq B^{-1}Z(R) + C_J Q/\eta_\circ < \frac{R}{16} + \frac{R}{8} = \frac{3R}{16} < \frac{R}{2}.$$

For the fourth part, let $x = \log(1/t)$. Then $tp(t) = A_{\mathrm{w}} x e^{-x} \to 0$ as $t \downarrow 0$, since $e^x \geq x^3/6$ for $x > 0$, and $t^2(1 + E_*) \to 0$. By the definition of a limit, the three conditions in (16.17) hold for all t in an interval $(0, g_*]$, not only for one value of t. This is a single

reduction of the upper bound on the coupling, which uses only the fixed construction data and R; it introduces no dependence on the lattice side, the depth, or the coarse field.

Finally, let $R = R_{\mathrm{supp}}$, let $t \le g_*$, and let $p_i \le p(t)$. Since $g_i \le t$, we have $Q = \max_i g_i p_i \le t p(t) \le Q_{\mathrm{gate}}(R) \le Q_\circ$. Hence, for every coarse field in $B_{R_{\mathrm{supp}}}$, the whole product of fluctuation variables lies in the fixed product on which the reconstruction and the conditional potential of the chosen instance are defined, and in the product of the first part. The third part gives $\mathfrak{M}_J(R, Q) < R/2$. Shrinking Q does not enlarge the domain of coarse fields; the ball $B_{R_{\mathrm{supp}}}$ and its conditional kernel are given by the hypothesis. In particular, the majorant of Theorem 13.2 is never evaluated beyond this product or across its pole, and both the image condition and the domain conditions under which it is stated hold. The last condition in (16.17) is the hypothesis of the Hessian bound in Theorem 13.8, which implies $D_w^2 V_c \ge I/2$ on the closed product. □

Theorem 16.6. *Fix M, J, and the parameters of Theorems 13.8 and 15.13, and fix $L, T_0 > 0$. Let $R_{\mathrm{supp}} = r$, or $R_{\mathrm{supp}} = \rho$ under the additional hypothesis on the separate instance described above, and let g_* be as in Lemma 16.5 with $R = R_{\mathrm{supp}}$. Let $a = L/n$ be a mesh with $n/B \ge 4$, let $d \ge 0$, let $g^2 = g_3^2 a$, and assume that $t = M^{(J-1)/2} g \le g_*$. Let $c \in B_{R_{\mathrm{supp}}}$, let $\mu_{d,c}$ be the conditional fluctuation kernel* (16.15)*, and let Φ be a reconstruction with the properties described above; the reconstruction maps of Theorem 15.12 are an example. Put $A(w) = a^{-1}\Phi(c, (g_i w_i)_i)$, viewed as a cell function, and*

$$F = A - \mathbb{E}_{\mu_{d,c}} A, \qquad \|F\|_{-\alpha;T_0} = \sup_{0<s\le T_0} s^{\alpha/2} \|P_s F\|_\infty,$$

where P_s is the continuum heat semigroup acting componentwise. Then for every $0 < \alpha < 3/2$ and $u \ge 0$,

$$\mu_{d,c}\Big\{ \|F\|_{-\alpha;T_0} > C g_3 a^{\alpha-1/2} \sqrt{\log(2 + L/a) + u} \Big\} \le C e^{-u}.$$

For every $p \ge 1$ and $\lambda \ge 0$, with $\tau_a = C g_3 a^{\alpha-1/2}$,

$$\big(\mathbb{E}_{\mu_{d,c}} \|F\|_{-\alpha;T_0}^p\big)^{1/p} \le C_p g_3 a^{\alpha-1/2} \sqrt{\log(2 + L/a)},$$
$$\mathbb{E}_{\mu_{d,c}} e^{\lambda \|F\|_{-\alpha;T_0}} \le \exp\Big\{ C\lambda\tau_a \sqrt{\log(2 + L/a)} + C\lambda^2 \tau_a^2 \Big\}.$$

In particular, if $1/2 < \alpha < 3/2$ and $a \downarrow 0$ with g_3 fixed (equivalently, with L and $\gamma = g_3^2 L$ fixed), then for each fixed p the conditional L^p norms of $\|F\|_{-\alpha;T_0}$ tend to zero, for each fixed λ the exponential moments $\mathbb{E}_{\mu_{d,c}} e^{\lambda\|F\|_{-\alpha;T_0}}$ tend to one, and the bounds on $\mathbb{E}_{\mu_{d,c}} \|F\|_{-\alpha;T_0}$ are summable along every geometric sequence of meshes; these statements are uniform in c and d.

For every deterministic real $\varphi \in L^2(\mathbb{T}_L^3)$, paired componentwise with A,

$$\mathrm{Var}_{\mu_{d,c}} \langle A, \varphi \rangle \le C_J g_3^2 a^2 \|\varphi\|_2^2, \qquad \log \mathbb{E}_{\mu_{d,c}} e^{z\langle F, \varphi\rangle} \le C_J z^2 g_3^2 a^2 \|\varphi\|_2^2 \qquad (z \in \mathbb{R}).$$

For finitely many real $\varphi_1, \dots, \varphi_m \in L^2(\mathbb{T}_L^3)$ and every compact set $\mathcal{K} \subset \mathbb{C}^m$,

$$\sup_{z \in \mathcal{K}} \Big| \mathbb{E}_{\mu_{d,c}} \exp\Big(\sum_{j=1}^{m} z_j \langle F, \varphi_j \rangle \Big) - 1 \Big| \longrightarrow 0$$

as $a \downarrow 0$ with g_3 fixed.

If $c \in D_{R_{\mathrm{supp}}}$, choose a gauge transformation k on the vertices of the coarse lattice with $c^k \in B_{R_{\mathrm{supp}}}$, and transport the conditional fluctuation kernel by the corresponding change of coordinates. Then all the above estimates hold for the reconstruction evaluated at c^k, uniformly in c and in the choice of k.

The constants depend only on M, J, the fixed construction domains and their margins, the Hessian bound, the row and column constants of the derivatives of Φ, α, L, T_0, and, where displayed, p. They do not depend on n, d, or c, and they do not depend on the coupling below g_*, except through the displayed factors of g_3.

Remark 16.7. Theorem 16.6 bounds the fluctuation F about the conditional expectation under the conditional fluctuation kernel. It gives no bound on $\mathbb{E}_{\mu_{d,c}} A$, which is estimated in Lemma 17.1. The norm $\|\cdot\|_{-\alpha;T_0}$ is not invariant under gauge transformations that vary in space, and the estimates refer to the chosen gauge representative of the reconstruction.

Proof of Theorem 16.6. We fix c and the kernel $\mu = \mu_{d,c}$ for the whole proof; all expectations and probabilities are taken with respect to μ, and nothing in the proof differentiates in c. The constants have the dependence stated in the theorem, and C_J may increase by factors depending on M, J, and the fixed construction domains. The proof has seven steps. We verify the hypotheses of the concentration theorem and bound the Jacobian of $w \mapsto A(w)$. We then bound $P_s F$ at a fixed time by chaining over space, using the cell integrals of the heat kernel, take the supremum over times by a dyadic decomposition, and derive the moments, the exponential moments, and the limits. Finally, we estimate deterministic source pairings and their generating functions, and we transport the conclusions to coarse fields in $D_{R_{\mathrm{supp}}}$.

Step 1: the kernel and its convexity. Let R_{supp} and g_* be as in the statement. We apply Lemma 16.5 to this support radius and to the corresponding instance of the conditional kernel: for $R_{\mathrm{supp}} = r$ the kernel of Theorem 13.8 on B_r, and for $R_{\mathrm{supp}} = \rho$ the separately hypothesized instance on B_ρ, each with its own domains. By that lemma, for every $c \in B_{R_{\mathrm{supp}}}$, the whole product Ω_p is mapped into the fixed product on which the reconstruction and the potential are defined, and the image condition of Theorem 13.2 holds. For the reconstruction of Theorem 13.2, each intermediate classical, logarithm, and Haar disintegration input lies in the enlarged product of that theorem, and its interior margin remains valid. For the reconstruction maps of Theorem 15.12, the same inputs lie in their inner domain, where that theorem preserves the uniform interior-domain

conditions and the normalized conditional kernels. We use only the joint coefficient bound of that family at fixed J. In the case $R_{\mathrm{supp}} = \rho$, the image condition is required on all of B_ρ, including the margins of Lemma 16.5, and not only on B_r; the analytic radius and the coefficient constants of that instance cover B_ρ by hypothesis.

By the last condition in (16.17), Theorem 13.8 gives $D_w^2 V_c \geq I/2$ on the closed convex product, with a C^2 extension to an open neighborhood. Then μ satisfies the hypotheses of Theorem 5.4 with $m = 1/2$; that theorem includes the faces and corners of the product of balls. We use only the following two of its conclusions: for every function H of w in $H^1(\mu)$ and every real Euclidean-Lipschitz function H,

$$\mathrm{Var}_\mu H \leq 2\mathbb{E}_\mu |\nabla_w H|^2, \qquad \log \mathbb{E}_\mu e^{z(H-\mathbb{E}_\mu H)} \leq z^2 \,\mathrm{Lip}_w(H)^2 \quad (z \in \mathbb{R}). \tag{16.18}$$

These inequalities require no independence under μ.

The kernel does not depend on the gauge in which the observable A is computed: another gauge transformation depending only on c changes A but not V_c. The reconstruction maps of Theorem 15.12 are obtained from the same reconstruction before gauge transformation by a gauge transformation depending only on the coarse field. By Theorems 15.12 and 15.13, they preserve the fluctuation cutoff domain, the free logarithmic coordinates, the effective classical action, the Haar disintegration density, the Jacobian determinants of the conditional Hessian normalizations, the incoming effective interaction, the coarse field, and the normalization constant. Hence (16.15) defines the same conditional measure for the reconstruction maps, and its Hessian is that of the same potential.

Step 2: the Jacobian. We write ξ for a scalar fluctuation coordinate, e for a scalar component of the output on a positive link, and $\varphi(w) = \Phi(c, (g_i w_i)_i)$. By the derivative bounds of Theorem 13.2 on the whole product, converted as in the second part of Lemma 16.5, we have

$$\sup_{w,e} \sum_{\xi} |\partial_{w_\xi} \varphi_e(w)| \leq C_J g, \qquad \sup_{w,\xi} \sum_{e} |\partial_{w_\xi} \varphi_e(w)| \leq C_J g. \tag{16.19}$$

We convert the normalizations as in the proof of Lemma 16.5. The column of a variable of the intermediate scale i is normalized by a_i^3, and the column bound of Theorem 13.2 reads $a^3 \sum_e |\partial_{q_\xi} \Phi_e| \leq C_J a_i^3$. The substitution $q_\xi = g_i w_\xi$ contributes the factor $g_i = M^{i/2} g$, and the passage to counting coordinates costs the factor M^{3i}; the row bound is converted with the same bounded ratios of couplings. These factors, and the number of variables per cell, depend only on J, and (16.19) holds with no factor depending on the number of cells or on d. The gauge transformation depends only on c and has no derivative in w, and the derivatives of the conditional Hessian normalizations and of the reconstruction before gauge transformation are included in (16.19). For the reconstruction

maps of Theorem 15.12, that theorem provides the joint coefficient bound, every volume-normalized column, and the image conditions on their common domains, uniformly in the depth and with deterministic thresholds that do not depend on the coupling or on the sample. The same computation applies, with the constant of that family at fixed J.

By Schur's test (16.14) in counting coordinates, we have

$$\sup_{w} \|D_w A(w)\|_{\ell^2 \to \ell^2} \le K_a, \qquad K_a = C_J g / a = C_J g_3 a^{-1/2}, \tag{16.20}$$

where the norm is from the fluctuation variables to the components of A on the links. Since the product is convex, integrating the derivative along the segment from w to w' gives

$$\|A(w) - A(w')\|_{\ell^2} \le K_a \|w - w'\|_2. \tag{16.21}$$

Step 3: a fixed time. Fix one scalar component, given by a direction and a color, and let $X_s(x) = P_s F(x)$. Since F is constant on the half-open cells, we have

$$X_s(x) = \sum_y \omega_y(s,x)\big(A_y(w) - \mathbb{E}_\mu A_y\big), \tag{16.22}$$

by integration of the cell function against the continuum heat kernel. As a function of w, the right side is a linear combination of the components of A. By (16.20), its Lipschitz constant is at most $K_a \|\omega(s,x)\|_2$, and the Lipschitz constant of $X_s(x) - X_s(y)$ is at most $K_a \|\omega(s,x) - \omega(s,y)\|_2$. Both have mean zero, because the subtracted mean is the conditional expectation under μ. By (16.18) and Lemma 16.1 with horizon T_0, their sub-Gaussian parameters, in the normalization $e^{z^2\sigma^2/2}$, can be taken as

$$\sigma_s = C_J K_a \min\{1, a^{3/2} s^{-3/4}\} \tag{16.23}$$

and, when $s \ge a^2$,

$$d_s(x,y) = C_J K_a a^{3/2} s^{-3/4} \min\{1, \operatorname{dist}(x,y)/\sqrt{s}\}. \tag{16.24}$$

The constants include the factor $\sqrt{2}$ that converts (16.18) to this normalization. The function d_s is nonnegative and symmetric, and after enlarging the constants we have $\sup d_s \le \sigma_s$ for $s \ge a^2$.

For $s \ge a^2$, a cubic grid on $\mathbb{T}_L^3$ of spacing at most $c\eta\sqrt{s}$ is an $\eta\sigma_s$-net for d_s, which gives

$$N(\mathbb{T}_L^3, d_s, \eta\sigma_s) \le C(1 + L/\sqrt{s})^3 \eta^{-3} \qquad (0 < \eta < 1).$$

For each w, the function $x \mapsto P_s F(x)$ is smooth for $s > 0$. Its supremum is determined by a countable dense set, and the process is continuous with respect to d_s. We set $\ell_a = \log(2 + L/a)$. Applying the chaining assertion of Lemma 16.1 with $A = C(1 + L/\sqrt{s})^3$ and $v = 3$, we obtain

$$\mathbb{P}_\mu\Big\{ \|P_s F\|_\infty > C K_a a^{3/2} s^{-3/4} \sqrt{\ell_a + u} \Big\} \le C e^{-u}, \qquad \mathbb{E}_\mu \|P_s F\|_\infty \le C K_a a^{3/2} s^{-3/4} \sqrt{\ell_a}. \tag{16.25}$$

Here we used $\log(2 + C(1 + L/\sqrt{s})^3) \le C\ell_a$, which holds because $s \ge a^2$. There are nine scalar components; a union bound over them and the equivalence of norms on the components change only C.

Step 4: the supremum over times. Each scalar cell variable $A_y - \mathbb{E}_\mu A_y$ is centered and K_a-Lipschitz. The exponential bound in (16.18), applied to it and to its negative, yields

$$\mathbb{P}_\mu\{|A_y - \mathbb{E}_\mu A_y| > 2K_a\sqrt{h}\} \le 2e^{-h} \qquad (h \ge 0).$$

There are $9n^3$ scalar cell variables. Choosing $h = u + \log(18n^3)$ and summing, we obtain

$$\mathbb{P}_\mu\Big\{\|F\|_\infty > CK_a\sqrt{\ell_a + u}\Big\} \le Ce^{-u}. \tag{16.26}$$

Since the heat semigroup contracts the supremum norm, we have, for $0 < s \le \min\{a^2, T_0\}$,

$$s^{\alpha/2}\|P_sF\|_\infty \le a^\alpha\|F\|_\infty.$$

Together with (16.26), this implies the required bound at all these times, including the case $T_0 < a^2$.

Suppose now that $T_0 \ge a^2$. Let $s_j = 2^j a^2$ for $0 \le j \le r$, where r is the largest integer with $s_r \le T_0$. By the semigroup property and the contraction of the supremum norm, we have, for $s_j \le s \le \min\{2s_j, T_0\}$,

$$s^{\alpha/2}\|P_sF\|_\infty \le 2^{\alpha/2}s_j^{\alpha/2}\|P_{s_j}F\|_\infty. \tag{16.27}$$

The weighted scale at the time s_j satisfies

$$K_a a^{3/2}s_j^{\alpha/2-3/4} = K_a a^\alpha 2^{-j(3/4-\alpha/2)} \le K_a a^\alpha, \tag{16.28}$$

where we used $\alpha < 3/2$. Further, $r + 1 \le 1 + \log_2(T_0/a^2) \le C_{T_0/L^2}\ell_a$, since $n = L/a \ge 4$. We use (16.25) at every s_j with $u + \log(r + 2)$ in place of u, and (16.26) with the same parameter. The sum of the probabilities of failure is at most Ce^{-u}. Since $\log(r + 2) \le C_{T_0/L^2}\ell_a$, all the thresholds in (16.27) and (16.28) are bounded by

$$CK_a a^\alpha\sqrt{\ell_a + u} = Cg_3 a^{\alpha-1/2}\sqrt{\ell_a + u}.$$

This proves the tail bound for all meshes in the statement. The time supremum is measurable, because the heat field is continuous in (s, x) for $s > 0$ and a countable dense subset of $(0, T_0] \times \mathbb{T}_L^3$ determines it. For each finite lattice, the field is bounded, and the norm is finite.

Step 5: moments, exponential moments, and limits. Let $\tau_a = C g_3 a^{\alpha-1/2}$, with C large enough for the preceding bounds, and let $Z = \|F\|_{-\alpha;T_0}$. Since $\sqrt{\ell_a + u} \le \sqrt{\ell_a} + \sqrt{u}$, the positive part of $Z - C\tau_a\sqrt{\ell_a}$ has tail at most $C\exp[-x^2/(C\tau_a^2)]$ at height x. Multiplying this tail by px^{p-1}, integrating over $x > 0$, and substituting $x = \tau_a v$, we obtain $C_p\tau_a^p$. By the triangle inequality in L^p and $\ell_a \ge \log 2$, we have

$$\mathbb{E}_\mu Z \le C\tau_a\sqrt{\ell_a}, \qquad (\mathbb{E}_\mu Z^p)^{1/p} \le C_p\tau_a\sqrt{\ell_a}.$$

The norm Z is itself a Lipschitz function of w, with constant at most $C\tau_a$. Indeed, by (16.21) and the bound on the cell integrals of the heat kernel, the difference of its values at w and w' is at most

$$CK_a\|w - w'\|_2 \sup_{0<s\le T_0} s^{\alpha/2}\min\{1, a^{3/2}s^{-3/4}\} \le CK_a a^\alpha \|w - w'\|_2,$$

where in the last inequality we used $s^{\alpha/2} \le a^\alpha$ for $s \le a^2$, and that $s^{\alpha/2-3/4}$ is decreasing for $s \ge a^2$. The subtracted conditional mean does not depend on w. Applying (16.18) to Z, we obtain

$$\mathbb{E}_\mu e^{\lambda Z} \le \exp\{\lambda\mathbb{E}_\mu Z + C\lambda^2\tau_a^2\} \le \exp\Big\{C\lambda\tau_a\sqrt{\ell_a} + C\lambda^2\tau_a^2\Big\}.$$

Since the concentration theorem applies to every real Lipschitz function, no smoothness of Z is needed.

All limits and summability statements are at fixed L and g_3, equivalently at fixed L and $\gamma = g_3^2 L$. If $\beta = \alpha - 1/2 > 0$, then $a^\beta\sqrt{\log(2 + L/a)} \to 0$ as $a \downarrow 0$, and every fixed conditional L^p norm therefore tends to zero, uniformly in c and d. The exponential moment is at least one because $Z \ge 0$, and its upper bound tends to one for fixed λ. For a geometric sequence of meshes $a_k = a_*\mathfrak{b}^{-k}$ with a fixed $\mathfrak{b} > 1$, we have

$$a_k^\beta\sqrt{\log(2 + L/a_k)} \le a_*^\beta\mathfrak{b}^{-k\beta}\Big\{\sqrt{\log(2 + L/a_*)} + \sqrt{k\log\mathfrak{b}}\Big\},$$

and both resulting series converge; the ratio of consecutive terms in the second tends to $\mathfrak{b}^{-\beta} < 1$. This proves the summability of the bounds on the expected norms, without any independence between different meshes.

Step 6: deterministic sources and generating functions. For a real test field φ, let $q_y = \int_{Q_y}\varphi(x)\,dx$, with the pairing of directions and colors included. By the Cauchy–Schwarz inequality on each cell, we have

$$\sum_y |q_y|^2 \le a^3\|\varphi\|_2^2. \tag{16.29}$$

Combining this with (16.20), we find that the pairing $H_\varphi = \langle A, \varphi\rangle$ has Lipschitz constant at most

$$K_a a^{3/2}\|\varphi\|_2 = C_J g_3 a\|\varphi\|_2,$$

and its gradient satisfies the same bound pointwise. The two inequalities in (16.18) then imply

$$\operatorname{Var}_\mu H_\varphi \le C_J g_3^2 a^2 \|\varphi\|_2^2, \qquad \log \mathbb{E}_\mu e^{z\langle F,\varphi\rangle} \le C_J z^2 g_3^2 a^2 \|\varphi\|_2^2 \quad (z \in \mathbb{R}).$$

Next, fix finitely many real sources $\varphi_1, \dots, \varphi_m$ and a compact set $\mathcal{K} \subset \mathbb{C}^m$, and let $Y_z = \sum_j z_j \langle F, \varphi_j\rangle$. By the variance bound and the triangle inequality in L^2, we have

$$(\mathbb{E}_\mu |Y_z|^2)^{1/2} \le C_J g_3 a \sum_j |z_j| \|\varphi_j\|_2.$$

Since the real part of Y_z is the pairing of F with the real source $\sum_j \Re(z_j)\varphi_j$, the exponential bound gives

$$\mathbb{E}_\mu e^{2|\Re Y_z|} \le \mathbb{E}_\mu e^{2\Re Y_z} + \mathbb{E}_\mu e^{-2\Re Y_z} \le 2 \exp\Big\{ C_J g_3^2 a^2 \Big(\sum_j |z_j| \|\varphi_j\|_2 \Big)^2 \Big\}.$$

By the identity $e^y - 1 = y \int_0^1 e^{\varrho y}\, d\varrho$ and the Cauchy–Schwarz inequality, uniformly for $z \in \mathcal{K}$,

$$|\mathbb{E}_\mu e^{Y_z} - 1| \le (\mathbb{E}_\mu |Y_z|^2)^{1/2} (\mathbb{E}_\mu e^{2|\Re Y_z|})^{1/2} \longrightarrow 0$$

as $a \downarrow 0$ with g_3 fixed. For each finite lattice, these functions of z are entire. Indeed, the domain of the fluctuation variables is compact and the reconstruction is continuous on a neighborhood of it; hence the exponential of the source pairing has a uniformly convergent power series on every compact set of sources. Complex test fields are handled by including their real and imaginary parts among the real sources.

Step 7: coarse fields in $D_{R_{\mathrm{supp}}}$. Let R_{supp} be as in (16.15). For $c \in D_{R_{\mathrm{supp}}}$, choose a gauge transformation k on the vertices of the coarse lattice with $c' = c^k \in B_{R_{\mathrm{supp}}}$. The change-of-gauge identity of Theorem 15.13, together with the corresponding identity for the reconstruction in Theorem 13.2, uses a triangular change $\mathcal{T}_k$ of the fluctuation variables whose diagonal blocks are orthogonal. It preserves each ball of the fluctuation cutoff domain and has Jacobian of absolute value one, and

$$(\mathcal{T}_k)_* \mu_{d,c}^{[R_{\mathrm{supp}}]} = \mu_{d,c'}^{[R_{\mathrm{supp}}]}.$$

For $R_{\mathrm{supp}} = \rho$, this is the change-of-gauge identity of the separate instance, not an extension of the auxiliary integral. Since $\mathcal{T}_k$ preserves the radii of all the balls, the radius Q and all the domain conditions verified above are the same at c'. The transported representative is therefore exactly the case $c' \in B_{R_{\mathrm{supp}}}$ already treated, and the bounds are uniform in c and in the choice of k. Evaluating the transported reconstruction at c' gives the last assertion of the theorem. □

16.5 Weighted heat convolutions

The Duhamel integrals for the Wilson flow in Section 24 lead to time convolutions of two powers, each regularized by the same positive parameter ϵ; in the applications, $\epsilon = a_0^2$ for a mesh a_0. The following lemma estimates these scalar integrals.

Lemma 16.8. *Let $\epsilon > 0$, $t \ge 0$, $0 \le p < 1$, and $q \ge 0$, and define*

$$I^{\epsilon}_{p,q}(t) = \int_0^t (s+\epsilon)^{-p}(t-s+\epsilon)^{-q}\,ds.$$

For fixed p and q, uniformly in ϵ and t,

$$I^{\epsilon}_{p,q}(t) \le C_{p,q} \begin{cases} (t+\epsilon)^{1-p-q}, & 0 \le q < 1, \\ (t+\epsilon)^{-p}[1+\log(1+t/\epsilon)], & q = 1, \\ \epsilon^{1-q}(t+\epsilon)^{-p}, & q > 1. \end{cases}$$

For $0 \le t \le \epsilon$ we also have $I^{\epsilon}_{p,q}(t) \le t\epsilon^{-p-q}$, and for $p = q = 1/2$ we have $I^{\epsilon}_{1/2,1/2}(t) \le \pi$.

In particular, let $1/2 < \alpha_{\mathrm{fl}} < 2/3$, $p = (\alpha_{\mathrm{fl}}+1)/2$, and $\epsilon = a_0^2$ with $a_0 > 0$. Then

$$I^{a_0^2}_{p,3/4}(t) \le C(t+a_0^2)^{-\alpha_{\mathrm{fl}}/2-1/4}, \qquad I^{a_0^2}_{p,5/4}(t) \le Ca_0^{-1/2}(t+a_0^2)^{-p},$$

$$\sup_{t\ge 0}\Big\{(t+a_0^2)^{\alpha_{\mathrm{fl}}-1/2} I^{a_0^2}_{p,3/4}(t) + (t+a_0^2)^{\alpha_{\mathrm{fl}}} I^{a_0^2}_{p,5/4}(t)\Big\} \le C_{\alpha_{\mathrm{fl}}} a_0^{\alpha_{\mathrm{fl}}-3/2}.$$

The same bound holds if either of the two weights $(t+a_0^2)^{\alpha_{\mathrm{fl}}-1/2}$ and $(t+a_0^2)^{\alpha_{\mathrm{fl}}}$ is replaced by the same power of $t+a^2$, for some $0 < a \le a_0$. For $p = 3\alpha_{\mathrm{fl}}/2$, the integrals with $q = 0$ and $q = 1/2$, which correspond to the value and to one spatial difference of a heat convolution, are bounded by $C(t+\epsilon)^{1-3\alpha_{\mathrm{fl}}/2}$ and $C(t+\epsilon)^{1/2-3\alpha_{\mathrm{fl}}/2}$, respectively. The constants depend only on the displayed exponents.

Proof. All integrands are nonnegative. If $t = 0$, the integral is zero. If $0 < t \le \epsilon$, each factor of the integrand is at most its value with s or $t-s$ replaced by zero, which gives

$$I^{\epsilon}_{p,q}(t) \le t\epsilon^{-p-q}. \tag{16.30}$$

Since $\epsilon \le t+\epsilon \le 2\epsilon$ in this range, this implies the three general bounds, with a constant depending only on p and q; in the case $q = 1$, we use $1+\log(1+t/\epsilon) \ge 1$.

For $t \ge \epsilon$, we split the integral at $t/2$. On the first half, $t-s+\epsilon \ge (t+\epsilon)/2$, which gives

$$\int_0^{t/2} (s+\epsilon)^{-p}(t-s+\epsilon)^{-q}\,ds \le 2^q(t+\epsilon)^{-q}\int_0^{t/2}(s+\epsilon)^{-p}\,ds \le \frac{2^q}{1-p}(t+\epsilon)^{1-p-q}.$$

On the second half, we set $r = t - s$ and use $s + \epsilon \geq (t + \epsilon)/2$; this half is at most

$$2^p (t+\epsilon)^{-p} \int_0^{t/2} (r+\epsilon)^{-q}\, dr.$$

The last integral is at most $(t+\epsilon)^{1-q}/(1-q)$ if $q < 1$, it equals $\log(1 + t/(2\epsilon))$ if $q = 1$, and it is at most $\epsilon^{1-q}/(q-1)$ if $q > 1$. The first half is absorbed in the bounds for the second half: for $q = 1$, it is of order $(t+\epsilon)^{-p}$, and for $q > 1$ we use $(t+\epsilon)^{1-q} \leq \epsilon^{1-q}$. This proves the general estimate for all t and ϵ.

For $p = q = 1/2$ and $t > 0$, we decrease the two positive shifts to zero and obtain

$$I^{\epsilon}_{1/2,1/2}(t) \leq \int_0^t s^{-1/2}(t-s)^{-1/2}\, ds = \int_0^{\pi/2} 2\, d\vartheta = \pi,$$

where we substituted $s = t \sin^2 \vartheta$. At $t = 0$, the bound is trivial.

Now let $\alpha = \alpha_{\mathrm{fl}}$ and $p = (\alpha + 1)/2$. Then $p < 1$, and the cases $q = 3/4$ and $q = 5/4$ of the general estimate yield

$$I^{\epsilon}_{p,3/4}(t) \leq C_\alpha (t+\epsilon)^{-\alpha/2-1/4}, \qquad I^{\epsilon}_{p,5/4}(t) \leq C_\alpha \epsilon^{-1/4} (t+\epsilon)^{-(\alpha+1)/2}.$$

Multiplying by the two weights, we obtain

$$\begin{aligned} (t+\epsilon)^{\alpha-1/2} I^{\epsilon}_{p,3/4}(t) &\leq C_\alpha (t+\epsilon)^{\alpha/2-3/4}, \\ (t+\epsilon)^{\alpha} I^{\epsilon}_{p,5/4}(t) &\leq C_\alpha \epsilon^{-1/4} (t+\epsilon)^{(\alpha-1)/2}. \end{aligned} \tag{16.31}$$

Since both powers of $t + \epsilon$ on the right are negative for α in the stated range, both right sides are at most $C_\alpha \epsilon^{\alpha/2-3/4}$, which equals $C_\alpha a_0^{\alpha-3/2}$ for $\epsilon = a_0^2$. Replacing either weight by the corresponding power of $t + a^2$ decreases it, since $a \leq a_0$ and both powers are positive. The short-time bound (16.30) remains available; in particular, none of these bounds replaces an integral that vanishes at $t = 0$ by a singular expression.

Finally, $p = 3\alpha/2 < 1$, and the cases $q = 0$ and $q = 1/2$ of the general estimate give $(t+\epsilon)^{1-3\alpha/2}$ and $(t+\epsilon)^{1/2-3\alpha/2}$, respectively. All constants in this proof are built from 2^p, 2^q, $(1-p)^{-1}$, $|1-q|^{-1}$ (when $q \neq 1$), and fixed powers of two; they do not depend on any mesh ratio, coupling, lattice side, or depth. □

16.6 Heat consistency for finite-scale reconstructions

The last lemma of this section compares the discrete heat evolution of a sampled smooth field with the continuum heat evolution. It is applied in Section 25 to the cardinal interpolation of a finite-scale reconstruction, that is, of a field reconstructed from a fixed finite number of renormalization group steps. The family of fields is fixed before the mesh tends to zero, and no uniformity is claimed as the number of scales grows. The

comparison concerns the linear heat evolution only; the corresponding statement for the quadratic Picard term is proved in Section 25.

For a smooth periodic function f we write $\|f\|_{C^r}$ for the maximum of the supremum norms of its derivatives of order at most r. For a mesh $a = L/n$ we write $S_a f = f|_{\Gamma_a}$ for the restriction of f to the vertices.

Lemma 16.9. *Fix $L, T, H > 0$ with $L/H \in \mathbb{N}$, a finite collection of meshes $a_1, \dots, a_l$ commensurate with H, and a deterministic bound M_H. Let $\mathscr{F}_H$ be the set of functions $f = \sum_{j=1}^{l} I_{a_j} u^{(j)}$, where each $u^{(j)}$ is an array of link variables on the lattice of mesh a_j with $\|u^{(j)}\|_\infty \le M_H$; it is a bounded finite-dimensional family of smooth periodic functions. Let $a \downarrow 0$ run through meshes $a = L/n$ such that $a_j/a \in \mathbb{N}$ for every j. Then, uniformly in $f \in \mathscr{F}_H$ and $0 \le t \le T$,*

$$\|P_t^a S_a f - S_a P_t f\|_\infty \le C_H a^2,$$

and for every ordered product D_a^ϵ of $q \ge 1$ forward or backward differences, with corresponding product of partial derivatives ∂^ϵ,

$$\|D_a^\epsilon P_t^a S_a f - S_a \partial^\epsilon P_t f\|_\infty \le C_{H,q} a.$$

For a general smooth periodic function f the two right sides may be replaced by $CTa^2\|f\|_{C^4}$ and $C_q\big[a\|f\|_{C^{q+1}} + Ta^2\|f\|_{C^{q+4}}\big]$, respectively. These bounds include $t = 0$, the periodic seams, and the constant mode.

Let $u_a(t) = P_t^a S_a f$ and $u_a^\epsilon(t) = D_a^\epsilon P_t^a S_a f$, and let $I_a u_a(t)$ and $I_a u_a^\epsilon(t)$ be their cardinal interpolations on $\mathbb{T}_L^3$, each array being interpolated separately. Then $I_a u_a \to P_t f$ and $I_a u_a^\epsilon \to \partial^\epsilon P_t f$ uniformly on $[0, T] \times \mathbb{T}_L^3$, and the same convergence holds after multiplying the discrete and the continuum quantities by the weights $(t + a^2)^\delta$ and t^δ, respectively, for any $\delta > 0$. In particular, the separately interpolated value and difference arrays converge in the positive-time weighted heat norms of Definition 4.8.

The constants depend on L, T, q, the meshes $a_1, \dots, a_l$, the function b, and M_H, but not on the finer mesh a, the coupling, the depth, or the number of steps of the whole reconstruction.

Remark 16.10. The convergence in Lemma 16.9 concerns the value array and each difference array, interpolated separately. It is not a statement about the derivatives of the interpolated value field, and such a statement would be false. Indeed, $\zeta'(k) = 0$ for every integer k: at $k = 0$ because ζ is even, at $k = \pm 1$ because all derivatives of ζ vanish there, and elsewhere because ζ vanishes near k. It follows that $\partial_i(I_a u)$ vanishes at every vertex of Γ_a for every array u, and it cannot converge uniformly to $\partial_i f$ even when $u = S_a f$. The proof below uses no identity between D_a^ϵ and derivatives of I_a.

Proof of Lemma 16.9. The fields are deterministic. By Lemma 16.3, for every integer $r \ge 0$, the functions in $\mathscr{F}_H$ satisfy

$$\sup_{f \in \mathscr{F}_H} \|f\|_{C^r} \le C_{b,r} M_H \sum_{j=1}^{l} (1 + a_j^{-r}), \tag{16.32}$$

and we denote the right side by $K_{H,r}$. Since there are only finitely many link variables on the meshes a_j, the family $\mathscr{F}_H$ is bounded and finite-dimensional; no compactness argument is needed for the uniform estimates below.

Taylor's formula with integral remainder in the coordinate i gives, for a smooth periodic function f,

$$\|D^-_{a,i}D^+_{a,i}S_af - S_a\partial_i^2 f\|_\infty \le Ca^2\|\partial_i^4 f\|_\infty.$$

To see the cancellation, we expand $f(x+ae_i)$ and $f(x-ae_i)$ to order three at x; the odd terms cancel, and the two remainders of order four, divided by a^2, are at most $Ca^2\|\partial_i^4 f\|_\infty$. Summing over i, we obtain

$$\|\Delta_a S_a f - S_a\Delta f\|_\infty \le Ca^2\|f\|_{C^4}. \tag{16.33}$$

The Taylor expansions are carried out on the periodic lift of f to $\mathbb{R}^3$, so they apply at every seam with the same constants.

The discrete and the continuum semigroups both commute with their own constant-coefficient derivatives, and both contract the supremum norm; for the continuum semigroup, this follows from its convolution kernel in Lemma 16.1. Differentiating $P^a_{t-s}S_aP_sf$ in s and integrating, we obtain the identity

$$P^a_tS_af - S_aP_tf = \int_0^t P^a_{t-s}(\Delta_aS_a - S_a\Delta)P_sf\,ds. \tag{16.34}$$

The differentiation is legitimate because f is smooth and the discrete space is finite. Since $\|P_sf\|_{C^4} \le \|f\|_{C^4}$, inserting (16.33) into (16.34), we obtain the bound $CTa^2\|f\|_{C^4}$, uniformly on $[0,T]$.

Fix an ordered product of q differences D^ϵ_a and the corresponding product of derivatives ∂^ϵ. Using (16.10) repeatedly, we write $D^\epsilon_aS_af(x)$ as an average of $\partial^\epsilon f$ over shifts of x of total length at most qa. The fundamental theorem of calculus along these shifts then gives

$$\|D^\epsilon_aS_af - S_a\partial^\epsilon f\|_\infty \le C_qa\|f\|_{C^{q+1}}. \tag{16.35}$$

We commute the differences with P^a_t and compare the differentiated initial data:

$$D^\epsilon_aP^a_tS_af - S_a\partial^\epsilon P_tf = P^a_t\big(D^\epsilon_aS_af - S_a\partial^\epsilon f\big) + \big(P^a_tS_a\partial^\epsilon f - S_aP_t\partial^\epsilon f\big).$$

The first term is bounded by (16.35), and the second by the value estimate already proved, applied to $\partial^\epsilon f$, and we obtain $C_q\{a\|f\|_{C^{q+1}} + Ta^2\|f\|_{C^{q+4}}\}$. This argument does not divide an error in the values by a. It includes $t=0$, and both errors vanish identically for constant f. Together with (16.32), this proves the two estimates for the family $\mathscr{F}_H$; since $a \le L$, the term of order a^2 is absorbed into $C_{H,q}a$.

For the interpolation statement, we use the nonnegative partition of unity and its support radius: for every smooth periodic g and every array u,

$$\|I_aS_ag - g\|_\infty \le Ca\|\nabla g\|_\infty, \qquad \|I_au\|_\infty \le \|u\|_\infty. \tag{16.36}$$

We apply the first bound to $g = P_t f$ and $g = \partial^{\epsilon} P_t f$, and the second to the differences between the discrete arrays and the sampled continuum functions. The smooth norms of these continuum functions are bounded uniformly by (16.32) and heat contraction. Then the interpolated value array and each separately interpolated difference array converge uniformly on $[0, T] \times \mathbb{T}_L^3$ to the corresponding continuum functions.

For a positive power δ, the weights $(t + a^2)^{\delta}$ are bounded by $(T + L^2)^{\delta}$ and converge to t^{δ} uniformly on $[0, T]$ as $a \downarrow 0$, by the uniform continuity of $v \mapsto v^{\delta}$ on $[0, T + L^2]$. Multiplying the uniform errors in the values and the differences by the weights of Definition 4.8 therefore preserves the convergence, also when one compares the weighted discrete and the weighted continuum functions themselves. All constants depend only on the meshes a_j, M_H, b, L, T, and q. □

SECTION 17

Backward reconstruction and conditional quadratic moments

This section proves three estimates on the coarse-to-fine reconstruction of the fine field under the conditioned Wilson measure. They are used in Sections 26 and 27 to control the heat evolution of the reconstructed field and its quadratic Picard term, and also in Sections 28 and 31. Throughout, the torus, the coarsest mesh H, the continuum coupling $g_3 > 0$, and a time horizon T_0 are fixed, and all estimates are uniform in the number k of renormalization group steps between the coarsest and the finest lattice.

The purpose of the three estimates. Recall from Section 3.3 that the fine field is reconstructed from the coarsest field one renormalization group step at a time, from coarse to fine. At the jth step, the logarithm θ_j of the reconstructed field on the lattice of mesh a_j is obtained from the logarithm θ_{j-1} on the lattice of mesh $a_{j-1} = Ba_j$ and from the normalized fluctuation variables w_j of that step. Let $A_j = a_j^{-1}\theta_j$ be the lattice potential, and let C_j be the zero-fluctuation reconstruction in the same units, that is, the reconstruction with $w_j = 0$. We write $\overline{P}$, $\overline{Q}$, and $\overline{R}$ for the linear, quadratic, and cubic parts of the zero-fluctuation reconstruction defined in Lemma 17.2, so that $C_j = a_{j-1}^{-1}[\overline{P}\theta_{j-1} + \overline{Q}(\theta_{j-1}, \theta_{j-1}) + \overline{R}(\theta_{j-1})]$. Viewing all terms as functions that are constant on lattice cells, we obtain the exact decomposition

$$A_j - E_{a_{j-1}} A_{j-1} = \big(A_j - \mathbb{E}[A_j \mid \mathcal{F}_{j-1}]\big) + m_j + D_d A_{j-1} + a_{j-1}^{-1}\overline{Q}(\theta_{j-1}, \theta_{j-1}) + a_{j-1}^{-1}\overline{R}(\theta_{j-1}). \tag{17.1}$$

Here $E_{a_{j-1}}$ is the cell embedding on the coarser lattice, and $\mathcal{F}_{j-1}$ is generated by the coarsest field and the fluctuation variables of the first $j-1$ steps. The term $m_j = \mathbb{E}[A_j \mid \mathcal{F}_{j-1}] - C_j$ is the conditional mean correction (in the notation of Sections 26 and 34, $m_j = m_j^{\mathrm{ph}}$), and $D_d A_{j-1}$ is the difference between the linearized reconstruction of A_{j-1} and its cell embedding; the precise definitions are given below. The first term is controlled by Theorem 16.6. Lemma 17.1 gives a deterministic bound on θ_j, the reconstruction amplitude bound, which tends to zero with the mesh. It also bounds m_j and shows that the sum over j of $A_j - C_j$, which is the sum of the first two terms, is small in a negative-regularity norm. Lemma 17.2 shows that each column of the linear operator D_d has zero integral and is localized at the scale a_{j-1}, so that heat smoothing at time t gains the factor $a_{j-1}/\sqrt{t}$. Theorem 17.4 controls the quadratic term. The cubic term is

controlled by the reconstruction amplitude bound on θ_{j-1}.

Inputs and attribution. The deterministic inputs are the reconstruction maps of Theorem 15.12, with the representation of the conditioned Wilson measure in Lemma 15.10, the preservation of the conditional kernels in Theorem 15.13, and the derivative bounds of Lemma 15.15. The zero-fluctuation reconstruction is built from the classical background fields of Bałaban [16], and the averaging is a version of Bałaban's averaging operation [12]. The probabilistic inputs are the bounds on conditional means and covariances of Theorem 13.10, the concentration theorem Theorem 5.4, and the results of Section 16. The concentration theorem rests on the convexity methods of Brascamp and Lieb [33], Gross [103], and Bakry and Émery [8]. The gain from a column of zero integral is the standard cancellation of a localized kernel with vanishing mass, and the maximal inequalities are elementary chaining in the sense of Dudley [79] (see also [74]), in the form of Lemma 16.4.

17.1 Setting

Order of the parameters. We use the constructions of Section 15 with the following order of choices. The constant $C_{\mathrm{CP}} \geq 1$ of Theorem 15.12, which bounds the first three derivatives in the coarse field and the first spatial difference of the zero-fluctuation reconstruction, is fixed before J. Before J is chosen, it may be enlarged to include finitely many further bounds of the same kind, as in the proofs below. Then J is chosen so that $q_{\mathrm{anc}} = C_{\mathrm{CP}}^2/B < 1$, where $B = M^J$; Theorem 15.12 allows $q_{\mathrm{anc}} \leq 1/4$. The larger analytic domains and their coefficient bounds, which may depend on J, are fixed next. Then the radii are chosen as in Lemma 15.15,

$$0 < r < r_{\mathrm{eff}}/4, \qquad \frac{\beta_J r_{\mathrm{eff}}}{1-\alpha_*} < \frac{1}{8}, \qquad \alpha_* = C_{\mathrm{CP}}/B,$$

and the bounds on the coupling-scaled fluctuation inputs and on the coupling are chosen so that every reconstructed field lies in the working domain of that lemma. Finally, the upper bound g_* on the couplings is fixed. It includes the bound of Theorem 16.6 with $R_{\mathrm{supp}} = r$, it ensures that $p_j \geq 1$, and it makes $t_j p_j^3$ as small as required in Theorem 13.10, in the notation introduced next.

The coarse-to-fine reconstruction. Fix $L > 0$, $T_0 > 0$, a coarsest mesh $H = L/n_0$ with $n_0 \in 4\mathbb{N}$, and $g_3 > 0$ such that $t_1 \leq g_*$, in the notation introduced below; here $\gamma = g_3^2 L$. We also fix the Borel choice of gauge of Lemma 15.10, which carries every stopping field in D_r into B_r and does not depend on k, and the reconstruction maps $\widehat{\mathscr{R}}$ of Theorem 15.12. We write $\widehat{\Phi}_{d,j}$ for their logarithmic form at depth d, at the jth step. For $k \geq 1$, let $a_j = HB^{-j}$ and $d_j^k = J(k-j)$ for $0 \leq j \leq k$. For $1 \leq j \leq k$, we define

$$g_j = g_3\sqrt{a_j}, \qquad g_{j,s} = M^{s/2} g_j \quad (0 \leq s < J), \qquad t_j = M^{(J-1)/2} g_j, \qquad p_j = A_{\mathrm{w}} \log(1/t_j).$$

Since $t_j = t_1 B^{-(j-1)/2}$, we have $t_j \le t_1 \le g_*$ at every fluctuation step. Here g_j^2 is the lattice coupling at mesh a_j, $g_{j,s}$ is the coupling at the intermediate scale s of the jth step, and t_j is the largest of these couplings. Further, p_j is the radius of the fluctuation cutoff domain of the jth step, and d_j^k is the number of averaging steps that precede it, counted from the finest lattice. The reconstruction is

$$\theta_j = \widehat{\Phi}_{d_j^k,j}\big(\theta_{j-1}, (g_{j,s} w_{j,s})_{s=0}^{J-1}\big), \qquad \mathcal{F}_j = \sigma(\theta_0, w_1, \dots, w_j) \qquad (1 \le j \le k), \tag{17.2}$$

where θ_0 is the logarithm of the stopping field in the chosen gauge, and $w_j = (w_{j,s})_s$ are the normalized fluctuation variables of the jth step. The meshes and depths are

$$(\theta_0;\, H;\, Jk) \longrightarrow (\theta_1;\, H/B;\, J(k-1)) \longrightarrow \cdots \longrightarrow (\theta_k;\, H/B^k;\, 0).$$

The measure. Let $N = n_0 B^k$, and let $\nu = \nu_{N,n_0,\gamma}$ be the conditioned Wilson measure. By Lemma 15.10, the gauge orbits of the fields $(e^{\theta_0}, \dots, e^{\theta_k})$ have exactly the law of the averaged configurations under ν. The conditional law of w_j given $\mathcal{F}_{j-1}$ is the conditional fluctuation kernel $k(e^{\theta_{j-1}}, dw)$ of Theorem 13.8 at the coarse field $e^{\theta_{j-1}}$, and the reconstruction maps preserve it (Theorem 15.13). This kernel has a density $Z^{-1}\mathbf{1}_\Omega e^{-V}$ on a fixed product Ω of three-dimensional balls of radius p_j, where V is smooth on a neighborhood of the closed product and $D_w^2 V \ge I/2$ there. It is not a product of independent Gaussian measures. All conditional expectations below are taken under ν. The marginal law of θ_{j-1} under ν includes the restrictions at all coarser steps, and it is in general not a stopped measure. Once $\mathcal{F}_{j-1}$ is fixed, these restrictions are fixed factors, and they cancel in the conditional law of w_j.

At each step, the coarse field $e^{\theta_{j-1}}$ lies in B_r, after the change of gauge of Lemma 15.10 if it is given in D_r. By the strict domain inclusions established in Lemma 15.15 and Theorem 15.13, the reconstruction of Theorem 13.2 and the reconstruction maps act on the same product. All segments of coarse fields and of coupling-scaled fluctuation inputs used below lie in the larger domains on which the derivative bounds hold. We use Theorem 16.6 with $R_{\mathrm{supp}} = r$, together with its change-of-gauge assertion.

Norms. Every array is embedded as a componentwise constant function on the half-open cells of its own lattice, each positive link being attached to its starting vertex. We use the heat norm

$$\|f\|_{-\alpha;T_0} = \sup_{0<s\le T_0} s^{\alpha/2} \|P_s f\|_\infty, \tag{17.3}$$

where P_s is the continuum heat semigroup acting componentwise; it keeps the constant mode. Since the heat kernel is positive and has unit mass, we have

$$\|f\|_{-\alpha;T_0} \le T_0^{\alpha/2} \|f\|_\infty \qquad (\alpha > 0). \tag{17.4}$$

Discrete heat semigroups carry their mesh as a superscript, as in Section 16. For linear and quadratic coefficient arrays, we use the row sums and the volume-normalized column

sums of Definition 4.6: a column of an input on a lattice of mesh a_{in} is multiplied by $a_{\mathrm{out}}^3/a_{\mathrm{in}}^3$.

Constants. We vary the depth at fixed L, T_0, H, and g_3, and all limits are taken at these fixed values. Constants have the dependence specified in each result: the lemma on conditional means allows dependence on the upper bound on the coupling, the lemma on column cancellation has the independence stated there, and the theorem on quadratic moments allows dependence on the fixed positive g_3 and the fixed H. No stronger statement, uniform as H varies or as $g_3 \downarrow 0$, is claimed; the bounds of Lemma 15.15 that are uniform in H are not used to improve this dependence. A subscript J indicates a constant that may depend on J; such constants are chosen after J. The applications of Lemmas 16.1 and 16.3 use the horizon $T = T_0$, and their constants therefore depend on T_0/L^2.

17.2 Conditional means along the reconstruction

The first lemma bounds the reconstructed fields and their conditional mean corrections. The stopping-field contribution to the reconstruction amplitude bound is $r(a_j/H)^{\kappa_{\mathrm{term}}}$, where κ_{term} is determined by the contraction factor $a_{\mathrm{cap}} = C_{\mathrm{CP}}/B$ of the linearized reconstruction; the fluctuation contribution is bounded by $C_J g_3 \sqrt{a_j}\, p_j$. The conditional mean correction is at most $C_J g_3^2$ times the size of the coarser field. Indeed, by Theorem 13.10, the conditional mean of the reconstructed link variables differs from the zero-fluctuation reconstruction by $O(t_j^2 \|\theta_{j-1}\|_\infty)$, and t_j^2/a_j is a fixed multiple of g_3^2.

Lemma 17.1. *Assume the setting of Section 17.1, and let the constant $C_{\mathrm{CP}} \geq 1$, fixed before J, satisfy*

$$a_{\mathrm{cap}} = C_{\mathrm{CP}}/B, \qquad a_{\mathrm{cap}}\sqrt{B} < 1, \qquad \kappa_{\mathrm{term}} = -\frac{\log a_{\mathrm{cap}}}{\log B} > \frac{1}{2}.$$

For $1 \leq j \leq k$ set

$$A_j = a_j^{-1}\theta_j, \qquad C_j = a_j^{-1}\widehat{\Phi}_{d_j^k, j}(\theta_{j-1}, 0), \qquad m_j = \mathbb{E}[A_j \mid \mathcal{F}_{j-1}] - C_j,$$

each embedded as a componentwise constant function on the cells of its own lattice. Then, on every sample of the conditioned Wilson measure,

$$b_j = \|\theta_j\|_\infty \leq \overline{b}_j, \qquad \overline{b}_j = r(a_j/H)^{\kappa_{\mathrm{term}}} + C_J g_3 \sqrt{a_j}\, p_j, \qquad \|m_j\|_\infty \leq C_J g_3^2 b_{j-1}.$$

For $2 \leq l \leq k$ let

$$M_l = C_J g_3^2 \bigl\{ r a_{\mathrm{cap}}^{l-1} + g_3 \sqrt{a_{l-1}}\,(p_l + 1) \bigr\}.$$

Then $\sum_{j=l}^{k} \|m_j\|_\infty \le M_l$, *and* $M_l \to 0$ *as* $l \to \infty$, *uniformly in* $k \ge l$. *For every* $1/2 < \alpha < 3/2$ *and* $u \ge 0$,

$$\sum_{j=l}^{k} \mathbb{E}\|A_j - C_j\|_{-\alpha;T_0} \le C_{J,\alpha} g_3 a_l^{\alpha-1/2} \sqrt{\log(2 + L/a_l)} + C_{\alpha,T_0} M_l,$$

and, with probability at least $1 - Ce^{-u}$, *simultaneously for all terms of this finite sum,*

$$\sum_{j=l}^{k} \|A_j - C_j\|_{-\alpha;T_0} \le C_{J,\alpha} g_3 a_l^{\alpha-1/2} \big[\sqrt{\log(2 + L/a_l)} + \sqrt{u}\big] + C_{\alpha,T_0} M_l.$$

These estimates also hold after integration over the law of the stopping field under the conditioned Wilson measure, uniformly in k. *The constants depend on the fixed construction parameters, on* L, T_0, α, H, *and on the upper bound on the coupling, but not on* j, k, *the depth, or the choice of the representative of the stopping field.*

The factors g_3 and the powers of the mesh are displayed explicitly. The exponent κ_{term} is defined by the contraction of the linearized reconstruction and is unrelated to the exponent $\kappa_{\mathrm{fl}} = 1 - 3\alpha_{\mathrm{fl}}/2$ of the flow norms. The lemma controls $A_j - C_j$, the deviation of the reconstructed field from its zero-fluctuation reconstruction; the adjacent difference $A_j - A_{j-1}$ contains in addition the last three terms of (17.1), which are treated in Sections 17.3 and 17.4.

Proof. All constants have the dependence allowed in the statement. A constant with subscript J may include the finitely many ratios of couplings within a step and the factor $(1 - a_{\mathrm{cap}}\sqrt{B})^{-1}$. The proof has four steps: the reconstruction amplitude bound, its summation, the bound on the conditional mean in the gauge of the reconstruction maps, and the bounds on the centered part.

Step 1: the reconstruction amplitude bound. The recurrence and its summation in Steps 1 and 2 are also stated in Lemma 15.10. We repeat the short computation because the distinction between the constant $C_{\mathrm{rec},J}$ of the recurrence and the constant $C_{\mathrm{cap},J}$ of its solution is used again in the proof of Theorem 17.4. We first explain the choice of C_{CP}. Let K_1, K_2, and K_3 be the bounds, independent of J, from Lemma 15.15 for the linear term, the quadratic term, and the cubic remainder of the normalized zero-fluctuation reconstruction $\overline{A}_d$ (see Lemma 17.2) on its fixed inner ball. For a coarse field of norm $R \le 1$, the value of $\overline{A}_d$ is at most $K_1 R + K_2 R^2 + K_3 R^3 \le (K_1 + K_2 + K_3) R$. We include this sum in C_{CP}; the working ball is chosen inside the inner ball, with $R \le 1$, after J is fixed. No constant that depends on all orders of differentiation at fixed J is used to choose J. With this choice, the bound

$$\|\widehat{\Phi}_{d,j}(\theta, q)\|_\infty \le a_{\mathrm{cap}} \|\theta\|_\infty + C_{\mathrm{rec},J} \max_s \|q_s\|_\infty$$

of Lemma 15.10 holds with the same a_{cap}; here $C_{\mathrm{rec},J}$ is the constant of that lemma for the coupling-scaled fluctuation inputs.

Set $\varrho = a_{\mathrm{cap}}\sqrt{B} < 1$. Since $|g_{j,s}w_{j,s}| \le t_j p_j$ on the fluctuation cutoff domain, the last bound implies that, at every point of the support of the conditioned measure,

$$b_j \le a_{\mathrm{cap}} b_{j-1} + C_{\mathrm{rec},J} t_j p_j, \qquad b_0 \le r.$$

Let $c_B = M^{(J-1)/2}$, so that $t_j = c_B g_3 \sqrt{a_j}$, and fix

$$C_{\mathrm{cap},J} \ge \frac{c_B C_{\mathrm{rec},J}}{1-\varrho}. \tag{17.5}$$

Both $C_{\mathrm{rec},J}$ and $C_{\mathrm{cap},J}$ are chosen after J, and neither changes C_{CP}. Since $t_j = t_1 B^{-(j-1)/2}$, we have

$$p_j = p_1 + c_{\mathrm{w}}(j-1), \qquad c_{\mathrm{w}} = \tfrac{1}{2} A_{\mathrm{w}} \log B > 0; \tag{17.6}$$

in particular p_j is increasing in j. Iterating the recurrence, with no exceptional set, and using $a_{\mathrm{cap}}^{j-i}\sqrt{a_i} = \varrho^{j-i}\sqrt{a_j}$ and $p_i \le p_j$ for $i \le j$, we obtain

$$b_j \le r a_{\mathrm{cap}}^{j} + c_B C_{\mathrm{rec},J} g_3 \sqrt{a_j} \sum_{i=1}^{j} \varrho^{j-i} p_i \le r a_{\mathrm{cap}}^{j} + C_{\mathrm{cap},J} g_3 \sqrt{a_j}\, p_j.$$

Since $a_{\mathrm{cap}}^{j} = B^{-\kappa_{\mathrm{term}} j} = (a_j/H)^{\kappa_{\mathrm{term}}}$, this is the asserted bound, with a constant $C_J \ge C_{\mathrm{cap},J}$ that may also dominate the constants of the summation and of the mean below. The condition $\kappa_{\mathrm{term}} > 1/2$ is equivalent to $\varrho < 1$.

Step 2: summation of the amplitude bound. Let $q_B = B^{-1/2}$ and $j = l + h$. By the amplitude bound, (17.6), and $a_{j-1} = a_{l-1} B^{-h}$, we have

$$\sum_{j=l}^{k} b_{j-1} \le \frac{r a_{\mathrm{cap}}^{l-1}}{1-a_{\mathrm{cap}}} + C_{\mathrm{cap},J} g_3 \sqrt{a_{l-1}} \sum_{h \ge 0} q_B^h (p_l + c_{\mathrm{w}} h) \le C_J \{ r a_{\mathrm{cap}}^{l-1} + g_3 \sqrt{a_{l-1}} (p_l + 1) \}.$$

The two series equal $(1-q_B)^{-1}$ and $q_B(1-q_B)^{-2}$. The constant does not depend on k or on the sample.

Step 3: the conditional mean in the gauge of the reconstruction maps. Conditionally on $\mathcal{F}_{j-1}$, the coarse field is fixed, the gauge transformation of the reconstruction maps depends only on it, and the conditional fluctuation kernel is the same as for the reconstruction of Theorem 13.2. Equality of the kernels does not by itself identify the two reconstructed means, because the observable changes; we show that the bound on the mean survives the change of gauge. We write $\phi = \theta_{j-1}$ and $R = \|\phi\|_\infty$. Let $X_e(w)$ be the

logarithm of the reconstruction of Theorem 13.2 on one output link e, and let $x_e = X_e(0)$. By the bound on the reconstructed mean in Theorem 13.10, we have

$$|\mathbb{E}X_e - x_e| \le C_J g_j^2 R,$$

where we used $t_j^2 = c_{B\mathcal{G}}^2 g_j^2$. The variance of X_e is at most $C_J g_j^2$, by Theorem 16.6, applied under the conditional fluctuation kernel at the coarse field $e^\phi \in B_r$, with fine mesh a_j and horizon T_0. Indeed, we apply its variance bound to the test function $a_j^{-3}\mathbf{1}_{Q_e}$ in one color component of X/a_j, whose squared L^2 norm is a_j^{-3}, and multiply by a_j^2. Summing over the three colors, we obtain

$$\mathbb{E}|X_e - x_e|^2 \le C_J g_j^2 + C_J g_j^4 R^2 \le C'_J g_j^2. \tag{17.7}$$

The reconstruction of Theorem 13.2 satisfies the hypotheses of both theorems used here.

At the fixed coarse field, the reconstruction maps differ from this reconstruction by a gauge transformation given by matrices h_x at the vertices. On the link $e = (x, y)$, the logarithm of the reconstruction map is $H_e(X_e)$, where $H_e(X) = \mathrm{Log}(h_x e^X h_y^{-1})$. By the bounds of Theorems 13.2 and 15.12, the two zero-fluctuation reconstructions x_e and $\widehat{x}_e = H_e(x_e)$ have norm at most CR. The identity $e^{\widehat{x}_e} = h_x e^{x_e} h_y^{-1}$ therefore implies $|\mathrm{Log}(h_y^{-1}h_x)| \le CR$. Let $z_e = \mathrm{Log}(h_y^{-1}h_x)$. By conjugation, we have

$$H_e(X) = \mathrm{Ad}(h_x)\,\mathrm{Log}(e^X e^{z_e}).$$

On the fixed small ball of logarithms, the analytic series of the exponential and the logarithm give bounded derivatives of $(X, z) \mapsto \mathrm{Log}(e^X e^z)$ through order three. More precisely, we enlarge this ball within the fixed chart so that $\|e^X e^z - I\| \le q < 1$ in matrix norm. Termwise differentiation of $\mathrm{Log}(I + Z) = \sum_{m\ge1}(-1)^{m+1}Z^m/m$ is justified by the convergent majorants $\sum_{m\ge r} m^{r-1}q^{m-r}$, $r = 1, 2, 3$, and the derivatives of the exponential are bounded by its absolutely convergent series on this ball. These bounds depend only on the chart. At $z = 0$, the function equals X, and its second derivative in X vanishes there. Integrating the mixed derivative $D_z D_X^2$ along the segment sz_e, $0 \le s \le 1$, we therefore find $\|D_X^2 H_e\| \le CR$, while $\|D_X H_e\| \le C$. All segments used here lie in the fixed chart. Since the matrices $\mathrm{Ad}(h_x)$ are orthogonal, these constants do not depend on the matrices h_x or on the number of vertices. By Taylor's formula at x_e, the bound on the mean, and (17.7), we obtain

$$|\mathbb{E}H_e(X_e) - H_e(x_e)| \le C|\mathbb{E}(X_e - x_e)| + CR\,\mathbb{E}|X_e - x_e|^2 \le C_J g_j^2 R.$$

This is the bound on the mean for the reconstruction maps, on the same product of balls. Dividing by the fine mesh, we obtain

$$\|m_j\|_\infty \le C_J \frac{t_j^2}{a_j} b_{j-1} \le C_J g_3^2 b_{j-1}.$$

Together with Step 2, this implies $\sum_{j=l}^{k} \|m_j\|_\infty \le M_l$, after one enlargement of C_J. Both terms of M_l tend to zero as $l \to \infty$, because $a_{\mathrm{cap}} < 1$ and p_l grows linearly in l while $\sqrt{a_{l-1}}$ decays geometrically.

Step 4: the centered part. We define

$$F_j = A_j - \mathbb{E}[A_j \mid \mathcal{F}_{j-1}].$$

Theorem 16.6 applies to F_j conditionally on $\mathcal{F}_{j-1}$. Indeed, the fine mesh is a_j, the side of the coarse lattice of the step is $n_0 B^{j-1} \ge 4$, the depth is d_j^k, the largest coupling is $t_j \le g_*$, the coarse field is in B_r, the horizon is T_0, and the reconstruction maps satisfy the hypotheses of that theorem on the whole product. The same holds for the reconstruction of Theorem 13.2, which we used in Step 3. Let $\beta = \alpha - 1/2 > 0$ and $\ell_j = \log(2 + L/a_j)$. Taking the conditional expectation and then the expectation, we obtain

$$\mathbb{E}\|F_j\|_{-\alpha;T_0} \le C_{J,\alpha} g_3 a_j^\beta \sqrt{\ell_j}.$$

For $h \ge 0$, we have $\ell_{l+h} \le \ell_l + h \log B$ and $a_{l+h} = a_l B^{-h}$. It follows that

$$\sum_{h\ge 0} a_{l+h}^\beta \sqrt{\ell_{l+h}} \le a_l^\beta \Big\{ \frac{\sqrt{\ell_l}}{1 - B^{-\beta}} + \sqrt{\log B} \sum_{h\ge 0} B^{-\beta h} \sqrt{h} \Big\} \le C_{B,\beta} a_l^\beta \sqrt{\ell_l}. \tag{17.8}$$

The last series converges, for instance because $\sqrt{h} \le h + 1$, and $\ell_l \ge \log 2$ absorbs its contribution. Since $A_j - C_j = F_j + m_j$, the bound on the expectation follows from (17.4) applied to m_j and from Step 3.

For the bound in probability, we use the tail bound of Theorem 16.6 at level $j = l + h$ with $u + 2h \log 2$ in place of u. Integrating the conditional probability does not change its upper bound. By a union bound over the finitely many levels, the probability of failure is at most

$$C e^{-u} \sum_{h\ge 0} 4^{-h} \le C' e^{-u}.$$

On the complementary event, we sum the thresholds, using $\sqrt{x+y} \le \sqrt{x} + \sqrt{y}$, (17.8), and the convergent series $\sum_h B^{-\beta h}$ and $\sum_h B^{-\beta h}\sqrt{h}$, and we add the deterministic sum of the means by (17.4). This proves the bound in probability. No independence between levels has been used.

Since all conditional estimates are uniform in the coarse fields that occur and in the stopping field, the same inequalities hold after integration over the law of the stopping field under the conditioned Wilson measure. The argument concerns $A_j - C_j$ throughout, and C_j is never replaced by A_{j-1}. □

17.3 Column cancellation and heat-kernel estimates

The normalization of an input column is essential here. For an operator K from arrays on a lattice of mesh A to componentwise functions on the torus, the volume-normalized absolute column of an input x is $A^{-3}\int |K_x(y)|\,dy$. A zero integral of a column is a separate identity, which no absolute bound implies. On a lattice of mesh δ, the integral is replaced by $\delta^3\sum_y$, still divided by the input volume A^3.

The lemma below concerns the difference D_d between the linearized zero-fluctuation reconstruction and the cell embedding on the coarse lattice. Each column of D_d is concentrated within distance of order A of its input, and it has zero integral. At times $t \gg A^2$, the heat kernel is nearly constant on the scale A, and the zero integral allows us to replace $p_t(z-y)$ by $p_t(z-y)-p_t(z-x)$, which costs the distance from y to x times the gradient of the kernel. This yields the factor $A/\sqrt{t}$.

Lemma 17.2. *Assume the setting of Section 17.1. Let $d \geq 0$, let $A > 0$ be a mesh with $L/A \in \mathbb{N}$ and $L/A \geq 4$, let $a = A/B$, and let $\widehat{\Phi}_d$ be the logarithmic form of the reconstruction map of one renormalization group step at depth d, from the lattice of mesh A to the lattice of mesh a. In units of the coarse lattice, its zero-fluctuation reconstruction has the expansion*

$$\widehat{\Phi}_d(\theta,0) = B^{-1}\overline{A}_d(\theta), \qquad \overline{A}_d(\theta) = \overline{P}_d\theta + \overline{Q}_d(\theta,\theta) + \overline{R}_d(\theta),$$

where $\overline{P}_d = D\overline{A}_d(0)$, $\overline{Q}_d = D^2\overline{A}_d(0)/2$, and $\|\overline{R}_d(\theta)\|_\infty \leq C_{\mathrm{CP}}\|\theta\|_\infty^3$ on a fixed inner ball of coarse fields. The first three derivatives in θ, together with their first spatial differences $\nabla_{1/B}$ in units of the coarse lattice, have weighted row sums and volume-normalized column sums bounded by one constant, uniformly in d, the lattice side, and J, as in Lemma 15.15. Here $\nabla_{1/B} = A\nabla_a$, where ∇_a denotes the first differences at the physical mesh a; thus a physical first difference of $\overline{A}_d$ carries the factor A^{-1}, and a physical first difference of the potential $A^{-1}\overline{A}_d$ carries the factor A^{-2}. The cubic remainder and these finitely many bounds are included in C_{CP} before J is fixed. In physical units the zero-fluctuation reconstruction is $A^{-1}\overline{A}_d(\theta)$.

Let $E_A v$ be the cell embedding on the lattice of mesh A of a coarse lattice potential v, let $P_d v$ be the cell embedding on the lattice of mesh a of the array $A^{-1}\overline{P}_d(Av)$, and let $D_d = P_d - E_A$. For each input link x and input color b, and each output direction and color (i,c), the corresponding column of D_d satisfies

$$\int_{\mathbb{T}_L^3} (D_d)_{(i,c),(x,b)}(y)\,dy = 0, \qquad A^{-3}\int_{\mathbb{T}_L^3} \mathrm{dist}(y,x)\,\big|(D_d)_{(i,c),(x,b)}(y)\big|\,dy \leq C_{\mathrm{CP}}A.$$

Its volume-normalized column sums and its row sums are bounded by C_{CP}, with exponential localization at the scale A. In particular, for $0 < t \leq T_0$,

$$\|P_t D_d v\|_\infty \leq C\min\{1, A/\sqrt{t}\}\,\|v\|_\infty, \qquad \|D_d v\|_{-\alpha;T_0} \leq C_\alpha A^\alpha \|v\|_\infty \quad (0<\alpha<1).$$

Let $m \in \mathbb{N}$ and $\delta = a/m$. Let $P_d^{\mathrm{arr}} v$ be the array on the lattice of mesh a whose cell embedding is $P_d v$, and let

$$D_d^\delta = I_{a\to\delta} P_d^{\mathrm{arr}} - I_{A\to\delta},$$

where the two cardinal interpolations of Lemma 16.3 start from the lattices of meshes a and A, respectively. Then every componentwise column of D_d^δ has zero integral $\delta^3 \sum_y$, its absolute column sums and first moments satisfy the same bounds, and for every integer $q \geq 0$, every product D_δ^q of q physical forward or backward differences, and every $0 \leq t \leq T_0$,

$$\|D_\delta^q P_t^\delta D_d^\delta v\|_\infty \leq C_{J,q}(t + A^2)^{-q/2} \min\{1, A/\sqrt{t + A^2}\} \|v\|_\infty.$$

In the continuum estimates, C depends only on the column and moment bounds, on α where it appears, and on T_0/L^2. In the estimates on the lattice of mesh δ the constant may also depend on J, q, and the function b of the cardinal interpolation. No constant depends on δ/a, the lattice side, the depth, the coupling, or the coarse field. The zero integral is a linear identity for each input column; no zero integral of $\overline{Q}_d$ is asserted.

Proof. The proof has five steps: the expansion, the zero integrals, the localization, the continuum heat estimates, and the estimates on the finer lattice.

Step 1: the expansion and its units. By Lemma 15.15, the reconstruction maps keep the bounds on the first three derivatives of the zero-fluctuation reconstruction in the coarse field and on its first spatial difference in units of the coarse lattice, the volume-normalized columns, and the zero-integral identity of Theorem 15.12. Their common domain contains a fixed inner ball of coarse fields. Taylor's formula on this ball gives

$$\overline{A}_d(\theta) = D\overline{A}_d(0)\theta + \tfrac{1}{2} D^2\overline{A}_d(0)[\theta,\theta] + \overline{R}_d(\theta),$$
$$\overline{R}_d(\theta) = \tfrac{1}{2} \int_0^1 (1-s)^2 D^3\overline{A}_d(s\theta)[\theta,\theta,\theta]\, ds.$$

The value at $\theta = 0$ is zero by global color equivariance. The bound on the third derivative implies $\|\overline{R}_d(\theta)\|_\infty \leq (1/6)\sup\|D^3\overline{A}_d\|\, \|\theta\|_\infty^3$. We enlarge C_{CP} to include this bound, the finitely many derivative bounds, and their first spatial differences in units of the coarse lattice, before J is fixed. This uses the finitely many constants that are uniform in J, not the bounds on all derivatives at fixed J. The conversion to physical units is

$$a^{-1}\widehat{\Phi}_d(\theta, 0) = (A/B)^{-1} B^{-1} \overline{A}_d(\theta) = A^{-1}\overline{A}_d(\theta). \tag{17.9}$$

Step 2: zero integrals. We first restate the zero-integral identity of Theorem 15.12 in these units. The reconstruction satisfies the averaging constraint exactly. Differentiating this identity at $\theta = 0$, we find that the linearized reconstruction preserves the componentwise physical integral of each input column. For each physical input basis vector, at an input link x, with a direction and a color, this gives

$$\int_{\mathbb{T}_L^3} (P_d)_{(i,c),(x,b)}(y)\, dy = \int_{\mathbb{T}_L^3} (E_A)_{(i,c),(x,b)}(y)\, dy.$$

The direction of x is suppressed in the notation, as in the statement. The matching component on the right has integral A^3, and the other components have integral zero. Subtracting, we obtain the zero integral of each column of D_d. This is the exact identity of Theorem 15.12, not a consequence of its absolute bounds. In that identity, the periodic gradient part of the differentiated reconstruction has zero sum, including across the seams of the torus; hence no constant mode has been discarded.

Step 3: localization and the first moment. After a fixed reduction of the exponent of the spatial weight, there exist constants $C, c > 0$, independent of J, such that for every column and every integer $h \geq 0$,

$$A^{-3} \int_{hA \leq \operatorname{dist}(y,x) < (h+1)A} |(D_d)_x(y)|\, dy \leq Ce^{-ch}, \tag{17.10}$$

and the row sums are bounded. These statements follow by subtracting the coarse cell column from the volume-normalized column of P_d, weighted exponentially; moving a point of a cell to the vertex of the cell costs at most $\sqrt{3}A$. The same argument, applied to each weighted row, yields the localization of the rows. Multiplying (17.10) by $(h+1)A$ and summing over h, we obtain

$$A^{-3} \int \operatorname{dist}(y,x) |(D_d)_x(y)|\, dy \leq CA \sum_{h \geq 0} (h+1)e^{-ch} \leq C'A.$$

All sums over directions and colors are finite and included in C.

Step 4: heat-kernel cancellation in the continuum. In this step, all heat estimates use the horizon $T = T_0$ in Lemma 16.1. To pass from the moments of individual columns to a bound on the supremum over outputs, we use the following elementary inequality. For a smooth periodic function f and a cube Q of side A,

$$A^3 \sup_Q |f| \leq C \sum_{S \subset \{1,2,3\}} A^{|S|} \int_Q |\partial_S f(y)|\, dy. \tag{17.11}$$

Indeed, on an interval of length A, we have $|f(x)| \leq A^{-1} \int |f| + \int |f'|$, and applying this successively in the three variables yields (17.11); the endpoints are handled by continuity. If Q is enlarged to the set of points within distance $(h+2)A$, the enlargement is covered by at most $C(h+3)^3$ cubes of side A. Summing the resulting bounds on the supremum over the lattice of inputs costs the same overlap factor $C(h+3)^3$.

Let $A^2 \leq t \leq T_0$ and $f_z(y) = p_t(z-y)$. Since every column has zero integral, we have

$$(P_t D_d v)(z) = \sum_x v_x \int \big[p_t(z-y) - p_t(z-x)\big] (D_d)_x(y)\, dy.$$

On the hth annulus around x, the bracket is at most $(h+1)A$ times the supremum of $|\nabla p_t(z - \cdot)|$ on the enlarged cube around x; a shortest periodic path proves this also

when the annulus crosses a seam. Using (17.10), then (17.11) with the overlap bound, and finally the L^1 bounds on the derivatives of the heat kernel in Lemma 16.1, we obtain

$$\|P_t D_d v\|_\infty \le CA\|v\|_\infty \sum_{h\ge 0} e^{-ch}(h+3)^4 \sum_{r=0}^{3} A^r \|\nabla^{r+1} p_t\|_1 \le C\frac{A}{\sqrt{t}}\|v\|_\infty \qquad (A^2 \le t \le T_0),$$

where in the last inequality we used that each factor $(A/\sqrt{t})^r$ is at most one. For $0 < t \le \min\{A^2, T_0\}$, the contraction of the heat semigroup and the bound on the row sums imply $\|P_t D_d v\|_\infty \le C\|v\|_\infty$. This proves the value estimate, with constants depending only on the column bounds and on T_0/L^2. When $0 < \alpha < 1$, multiplying by $t^{\alpha/2}$ gives at most CA^α in both ranges of time; if $A^2 > T_0$, the bound for small times suffices. This proves the bound on the heat norm.

Step 5: the finer lattice. We now keep the lattices of meshes a and A distinct. Let $m \in \mathbb{N}$ and $\delta = a/m$, so that

$$\frac{a}{\delta} = m \in \mathbb{N}, \qquad \frac{A}{\delta} = Bm \in \mathbb{N}. \tag{17.12}$$

Since $L/A \in \mathbb{N}$ and $L/A \ge 4$, the numbers $L/a = B(L/A)$ and $L/\delta = Bm(L/A)$ are integers at least four. We therefore apply Lemma 16.3 to the pairs of meshes (a,δ) and (A,δ), with integer ratios m and Bm, the same function b, and the horizon $T = T_0$. For a fixed integer $q \ge 0$, D_δ^q denotes any ordered product of q physical forward or backward differences, and the identity if $q = 0$; these are exactly the products allowed in both lemmas of Section 16. Let $p_{z,x}$ be the coefficients of the array P_d^{arr}. By the mass identity of Lemma 16.3, we have, for each componentwise column,

$$\begin{aligned}\delta^3 \sum_y (D_d^\delta)_{y,x} &= \delta^3 \sum_y \sum_{z\in\Lambda_{L/a}} \zeta_3((y-z)/a)\,p_{z,x} - \delta^3 \sum_y \zeta_3((y-x)/A)\,I \\ &= a^3 \sum_z p_{z,x} - A^3 I = 0,\end{aligned} \tag{17.13}$$

where the last equality is the discrete form of the zero integral in Step 2. The identity matrices in this formula involve the matching direction and color only. Since the function b is nonnegative, the mass and moment bounds of the interpolation imply

$$\delta^3 \sum_y \Big|\sum_z \zeta_3((y-z)/a)\,p_{z,x}\Big| \le a^3 \sum_z |p_{z,x}|,$$

$$\delta^3 \sum_y \mathrm{dist}(y,x)\Big|\sum_z \zeta_3((y-z)/a)\,p_{z,x}\Big| \le a^3 \sum_z \big(\mathrm{dist}(z,x) + Ca\big)\,|p_{z,x}|.$$

The interpolated coarse column has mass A^3 and first moment at most CA^4. Both terms of D_d^δ therefore satisfy the bounds of the columns before interpolation, with a fixed enlargement of the constants. Since their supports are displaced by at most $Ca \le CA$,

(17.10) holds with the integral replaced by $\delta^3 \sum_y$. The row sums are bounded as well, by the positive partition of unity of each interpolation.

The argument of Step 4 applies on the lattice of mesh δ, and we only describe its new ingredient. On an interval of $m_A = A/\delta = Bm$ lattice points, averaging the inequality

$$|f(r)| \le |f(s)| + \delta \sum_{u \text{ between } r,s} |D_\delta f(u)|$$

over s yields the one-dimensional analog of (17.11). Taking the product over the coordinates, with an enlargement by one lattice step to include the differences at the boundary, we obtain (17.11) with sums in place of integrals and products of forward differences in place of derivatives. The overlap bound for the enlarged cubes is unchanged. To subtract the kernel, we use (17.13) and a shortest lattice path, whose length is at most a fixed multiple of the torus distance. Then the L^1 bounds on discrete differences of the heat kernel in Lemma 16.1 imply

$$\|P_t^\delta D_d^\delta v\|_\infty \le C \min\{1, A/\sqrt{t}\} \|v\|_\infty \qquad (0 < t \le T_0). \tag{17.14}$$

No constant here depends on a/δ.

For $0 \le t \le \min\{2A^2, T_0\}$, we commute the product of q differences with the heat semigroup and use the derivative bounds of the two interpolations:

$$\|D_\delta^q P_t^\delta D_d^\delta v\|_\infty \le \|D_\delta^q I_{a\to\delta} P_d^{\mathrm{arr}} v\|_\infty + \|D_\delta^q I_{A\to\delta} v\|_\infty \le C_q (a^{-q} + A^{-q}) \|v\|_\infty \le C_{J,q} A^{-q} \|v\|_\infty.$$

For $2A^2 \le t \le T_0$, we split the heat semigroup into two equal halves, use the L^1 bound on the differentiated heat kernel for the first half and (17.14) for the second:

$$\|D_\delta^q P_t^\delta D_d^\delta v\|_\infty \le C_q (t/2 + \delta^2)^{-q/2} \frac{A}{\sqrt{t/2}} \|v\|_\infty \le C_q A t^{-(q+1)/2} \|v\|_\infty.$$

Up to fixed constants, the two ranges of time give the asserted bound with $t + A^2$; they include $t = 0$ and every fixed order of differences. Only the estimate for small times introduces the factor B^q, through $a^{-q} = B^q A^{-q}$, and this factor is allowed in $C_{J,q}$. All the cancellations used in this proof are identities for the columns of linear operators; neither Taylor's formula nor the heat-kernel cancellation yields a zero integral of $\overline{Q}_d$. □

17.4 Conditional quadratic moments

Quadratic maps and their norms. Let Q be a quadratic map from arrays on a lattice of mesh a_{in} to arrays on a lattice of mesh $a_{\mathrm{out}} \le a_{\mathrm{in}}$. We write a scalar output component as

$$Q_y(v, v) = \sum_{x,z} T_{y;x,z} v_x v_z,$$

where the indices include directions and colors. We use the symmetric polarization: replacing $T_{y;x,z}$ by $(T_{y;x,z} + T_{y;z,x})/2$ leaves $Q(v,v)$ unchanged and does not increase any of the coefficient sums below. We write $Q(u,v)$ for the corresponding symmetric bilinear map, and $Q : \mathcal{M}$ for the array with components $\sum_{x,z} T_{y;x,z}\mathcal{M}_{xz}$, for a matrix $\mathcal{M}$ indexed by the inputs. Let $\mathrm{t}(y,x,z)$ be the length of a shortest connected network in $\mathbb{T}_L^3$ containing the locations of y, x, and z, with internal vertices allowed, as in Definition 4.6. We fix a spatial exponent $a'_{\mathrm{sp}} > 0$, smaller than the exponents of the coefficient bounds of Section 15 by a fixed amount, and set

$$\|T\|_{a_{\mathrm{in}},a_{\mathrm{out}}} = \max\Big\{\sup_y \sum_{x,z} e^{a'_{\mathrm{sp}}\mathrm{t}(y,x,z)/a_{\mathrm{in}}}|T_{y;x,z}|,\ \sup_x \frac{a_{\mathrm{out}}^3}{a_{\mathrm{in}}^3}\sum_{y,z} e^{a'_{\mathrm{sp}}\mathrm{t}(y,x,z)/a_{\mathrm{in}}}|T_{y;x,z}|\Big\}. \quad (17.15)$$

By symmetry, the column with the second input fixed has the same bound. In particular, if $a_{\mathrm{in}} = a_i$, $a_{\mathrm{out}} = \delta$, and $\|T\|_{a_i,\delta} \le K_Q$, then

$$\sup_y \sum_{x,z}|T_{y;x,z}| \le K_Q, \qquad \sup_x \frac{\delta^3}{a_i^3}\sum_{y,z}|T_{y;x,z}| \le K_Q. \quad (17.16)$$

The same exponent a'_{sp} is used at every level below; it is not reduced after each composition. At the coarsest level, we set $\overline{b}_0 = r$. For $i \ge 1$, $\overline{b}_i$ always denotes the reconstruction amplitude bound of Lemma 17.1, never a random bound left outside a conditional expectation.

Why a conditional decomposition is needed. For $j \ge 2$, by the reconstruction amplitude bound, the quadratic term $a_{j-1}^{-1}\overline{Q}(\theta_{j-1},\theta_{j-1})$ in (17.1) is at most $Ca_{j-1}^{-1}\overline{b}_{j-1}^2$, which is in general of order $g_3^2 p_{j-1}^2$ and is not summable in j. We therefore regard θ_{j-1} as reconstructed from θ_{j-2}, condition on $\mathcal{F}_{j-2}$, and separate a conditionally centered part, which concentrates, from a conditional expectation error, which is smaller. The conditional expectation is close to the quadratic term evaluated on the linearized reconstruction $L_{j-1}\theta_{j-2}$, and repeating the argument pulls the quadratic coefficient back through the linearized reconstructions. Each pullback contracts the coefficient by the factor a_{cap}^2, one factor for each argument, while dividing by the coarser mesh costs a factor B; the resulting ratio $q_{\mathrm{anc}} = Ba_{\mathrm{cap}}^2 < 1$ makes the final convolution summable. Volume-normalized columns are essential here: with counting column sums, each pullback would lose an additional factor B^3.

Three errors remain in the conditional expectation, and they explain the three terms in the first part of Theorem 17.4 below. Replacing the nonlinear zero-fluctuation reconstruction by its linearization costs $a_{\mathrm{cap}}^2\|\phi\|_\infty^3$. The conditional means of the fluctuation variables and the change of their covariance with the coarse field cost $g_i^2\|\phi\|_\infty$. Here we use that the conditional kernel at the zero coarse field is invariant under constant

color rotations, although it is spatially correlated; an expected adjoint vector built from it therefore vanishes. The terms of higher order in the fluctuations cost $g_i^3 p_i^3$.

The deterministic part of the pullback is the following lemma.

Lemma 17.3. *Let $1 \le i \le j$, let T be the symmetric coefficient array of a quadratic map from arrays on the lattice of mesh a_i to arrays on the lattice of mesh a_j, and let L be the coefficient array of a linear map from arrays on the lattice of mesh $a_{i-1} = Ba_i$ to arrays on the lattice of mesh a_i. Suppose that $\|T\|_{a_i,a_j} \le K$ and that*

$$\sup_x \sum_u e^{a'_{\mathrm{sp}} \operatorname{dist}(x,u)/a_{i-1}} |L_{x,u}| \le a_{\mathrm{cap}}, \qquad \sup_u \frac{a_i^3}{a_{i-1}^3} \sum_x e^{a'_{\mathrm{sp}} \operatorname{dist}(x,u)/a_{i-1}} |L_{x,u}| \le a_{\mathrm{cap}}. \quad (17.17)$$

Then the coefficient array

$$T'_{y;u,v} = \sum_{x,z} T_{y;x,z} L_{x,u} L_{z,v}$$

of the map $v \mapsto Q(Lv, Lv)$ is symmetric and satisfies $\|T'\|_{a_{i-1},a_j} \le K a_{\mathrm{cap}}^2$. If the quadratic map is equivariant under the adjoint action of constant color rotations and L commutes with them, then the map $v \mapsto Q(Lv, Lv)$ is equivariant.

Proof. We first prove the unweighted bounds. The output row of T' is at most Ka_{cap}^2, by the row bounds of T and of L. For the column with the first input u fixed, we use the volume-normalized column of L in the first argument and its row in the second:

$$\frac{a_j^3}{a_{i-1}^3} \sum_{y,v} |T'_{y;u,v}| \le \frac{a_i^3}{a_{i-1}^3} \sum_x |L_{x,u}| \, a_{\mathrm{cap}} \Big(\frac{a_j^3}{a_i^3} \sum_{y,z} |T_{y;x,z}| \Big) \le K a_{\mathrm{cap}}^2.$$

Fixing the second input instead repeats this calculation with x, z and u, v interchanged. The factor $a_i^3 / a_{i-1}^3 = B^{-3}$ cancels the factor B^3 in the counting column sum of L.

The weights cause no additional loss. A shortest network for (y, x, z), joined with shortest paths from x to u and from z to v, is a connected network containing (y, u, v), which implies $\mathtt{t}(y, u, v) \le \mathtt{t}(y, x, z) + \operatorname{dist}(x, u) + \operatorname{dist}(z, v)$; periodic shortest networks satisfy the same inequality. In the units $a_{i-1} > a_i$ of the new input mesh, the weight of the old network is at most its weight in the units a_i, and the weights in (17.17) are already in the units a_{i-1}. The new weight is therefore at most the product of the three old weights, and the preceding calculation applies with these weights inserted and the same exponent. Symmetry of T' follows from that of T. Equivariance is preserved because L commutes with the color rotations. □

Theorem 17.4. *Assume the setting of Section 17.1 and fix $k \ge 1$. Let $\bar{b}_i$, $1 \le i \le k$, be the reconstruction amplitude bounds of Lemma 17.1, and $\bar{b}_0 = r$. Let $a_{\mathrm{cap}} = C_{\mathrm{CP}}/B$ and $q_{\mathrm{anc}} = Ba_{\mathrm{cap}}^2 = C_{\mathrm{CP}}^2/B < 1$, and for $1 \le i \le k$ let $L_i = D_\theta \widehat{\Phi}_{d_i^k, i}(0, 0)$ be the linearized zero-fluctuation reconstruction of the ith step.*

Let $1 \le i \le k$, and let Q be a deterministic quadratic map from arrays on the lattice of mesh a_i to $\mathfrak{su}(2)$-valued arrays on a lattice of mesh $\delta \le a_i$, which is equivariant under the adjoint action of constant color rotations and satisfies $\|T\|_{a_i,\delta} \le K_Q$ for its coefficient array T, with all input and output directions and colors included. Then the following statements hold.

1. *For every coarse field $e^\phi \in B_r$, under the conditional fluctuation kernel of the ith step at the coarse field e^ϕ,*

$$\big\|\mathbb{E}[Q(\theta_i,\theta_i) \mid \theta_{i-1} = \phi] - Q(L_i\phi, L_i\phi)\big\|_\infty \le C_J K_Q \big\{a_{\mathrm{cap}}^2 \|\phi\|_\infty^3 + g_i^2\|\phi\|_\infty + g_i^3 p_i^3\big\}.$$

   Let $\mu_\phi = \mathbb{E}_\phi w$ and $\Sigma_\phi = \mathrm{Cov}_\phi(w,w)$ be the conditional mean and covariance of the fluctuation variables under this kernel (in the notation of Section 26, $\mu_\phi = m_\phi$), and let E_ϕ be the derivative at $w = \mu_\phi$ of the map $w \mapsto g_i^{-1}\widehat{\Phi}_{d_i^k,i}(\phi, (g_{i,s}w_s)_s)$, which includes the ratios $g_{i,s}/g_i$. Then the expectation of $Q(g_iE_\phi(w-\mu_\phi), g_iE_\phi(w-\mu_\phi))$ equals $g_i^2 Q : (E_\phi\Sigma_\phi E_\phi^{\mathsf{T}})$. This contraction vanishes at $\phi = 0$, and

$$\|E_\phi\Sigma_\phi E_\phi^{\mathsf{T}} - E_0\Sigma_0 E_0^{\mathsf{T}}\|_{\mathrm{op}} \le C_J\|\phi\|_\infty.$$

   The first estimate accounts for the value of the reconstruction at μ_ϕ, its displacement from the zero-fluctuation reconstruction, and all remainders of the means and of the covariance; it does not assume that the conditional expectation of a quadratic term vanishes when $\phi \ne 0$.

2. *For every $0 < \alpha < 3/2$, on every sample,*

$$\mathbb{E}\Big[\big\|Q(\theta_i,\theta_i) - \mathbb{E}[Q(\theta_i,\theta_i) \mid \mathcal{F}_{i-1}]\big\|_{-\alpha;T_0} \;\Big|\; \mathcal{F}_{i-1}\Big] \le C_{J,\alpha} K_Q g_i \bar{b}_i a_i^\alpha \sqrt{\log(2 + L/a_i)}.$$

3. *For $2 \le j \le k$ define quadratic maps $Q_{j,i}$ from arrays on the lattice of mesh a_i to arrays on the lattice of mesh a_j, for $0 \le i \le j-1$, by*

$$Q_{j,j-1} = \overline{Q}_{d_j^k,j}, \qquad Q_{j,i-1}(v,v) = Q_{j,i}(L_iv, L_iv) \quad (1 \le i < j),$$

   where $\overline{Q}_{d_j^k,j}$ is the quadratic part of the zero-fluctuation reconstruction of the jth step, as in Lemma 17.2. These maps are equivariant. Let $T_{j,i}$ be the symmetric coefficient array of $Q_{j,i}$, and set $K_{j,i} = \|T_{j,i}\|_{a_i,a_j}$. Then

$$K_{j,i} \le C a_{\mathrm{cap}}^{2(j-1-i)}, \qquad \frac{K_{j,i}}{a_{j-1}} \le C\frac{q_{\mathrm{anc}}^{j-1-i}}{a_i}.$$

4. *For $2 \le j \le k$ and $1 \le i \le j-1$ put*

$$Z_{j,i} = Q_{j,i}(\theta_i,\theta_i) - \mathbb{E}[Q_{j,i}(\theta_i,\theta_i) \mid \mathcal{F}_{i-1}],$$
$$e_{j,i} = \mathbb{E}[Q_{j,i}(\theta_i,\theta_i) \mid \mathcal{F}_{i-1}] - Q_{j,i-1}(\theta_{i-1},\theta_{i-1}).$$

Then, on every sample,

$$\overline{Q}_{d_j^k,j}(\theta_{j-1},\theta_{j-1}) = Q_{j,0}(\theta_0,\theta_0) + \sum_{i=1}^{j-1}(Z_{j,i}+e_{j,i}).$$

Further, with

$$v_i = g_i\overline{b}_i a_i^{\alpha-1}, \qquad u_i = \frac{q_{\mathrm{anc}}\overline{b}_{i-1}^3}{a_{i-1}} + g_3^2\overline{b}_{i-1} + g_3^3\sqrt{a_i}\,p_i^3,$$

we have, for $0<\alpha<3/2$,

$$\mathbb{E}\big\|a_{j-1}^{-1}\overline{Q}_{d_j^k,j}(\theta_{j-1},\theta_{j-1})\big\|_{-\alpha;T_0} \le \frac{Cr^2}{H}q_{\mathrm{anc}}^{j-1} + C\sum_{i=1}^{j-1} q_{\mathrm{anc}}^{j-1-i}\Big\{v_i\sqrt{\log(2+L/a_i)}+u_i\Big\}.$$

5. *For* $1/2<\alpha<3/2$ *and every* $0<\tau<\min\{1/2,-\log q_{\mathrm{anc}}/\log B\}$,

$$\sum_{j=l}^{k}\mathbb{E}\big\|a_{j-1}^{-1}\overline{Q}_{d_j^k,j}(\theta_{j-1},\theta_{j-1})\big\|_{-\alpha;T_0} \le C_\tau a_l^\tau,$$

uniformly in $k\ge l\ge 2$.

The constants depend on the fixed construction parameters and coefficient bounds, on L, H, T_0, α, *and* τ, *and on the fixed coupling* g_3, *but not on* k, *the depth, the ratio* a_i/δ, *or the sample. The identity in the fourth part does not identify compositions of the nonlinear zero-fluctuation reconstructions with products of their linearizations; their difference is contained in* $e_{j,i}$.

Proof. We fix k for the whole proof, so that all coefficients, zero-fluctuation reconstructions, and conditional kernels have the depths $d_i^k = J(k-i)$ of one hierarchy. Intermediate constants in the estimates for a single kernel may depend on J; all estimates are uniform in the depth. The proof has five steps. Steps 1 and 2 prove the first two parts, Step 3 proves the third, Step 4 the fourth, and Step 5 the last.

Step 1: the conditional expectation of a quadratic term. Fix a level i and a coarse field $e^\phi\in B_r$, and write $R=\|\phi\|_\infty$, $g=g_i$, $t=t_i$, and $p=p_i$. In this step, all expectations are under the conditional fluctuation kernel at e^ϕ. Let

$$\mu_\phi = \mathbb{E}_\phi w, \qquad \xi = w-\mu_\phi, \qquad \Sigma_\phi = \mathbb{E}_\phi \xi\xi^{\mathsf{T}}, \qquad \psi_\phi(w) = \widehat{\Phi}_{d_i^k,i}(\phi,(g_{i,s}w_s)_s).$$

The segment of coarse fields $u\phi$, $0\le u\le 1$, stays in B_r. The fluctuation cutoff domain, the free logarithmic coordinates, and the conditional fluctuation potential are those preserved by Theorem 15.13. The domains and bounds on the coupling-scaled fluctuation inputs are those fixed in Section 17.1; hence the whole segment satisfies the domain conditions.

The bounds on means and on the dependence on the coarse field in Theorem 13.10 apply to this kernel, and give

$$\|\mu_\phi\|_\infty \le C_J t R, \qquad \|\Sigma_\phi\|_{\mathrm{op}} \le 2, \qquad \|\Sigma_\phi - \Sigma_0\|_{\mathrm{row+col}} \le C_J t p^3 R, \tag{17.18}$$

where the last norm is the larger of the maximal row and column sums, possibly with a fixed smaller exponential weight; since it is at most their sum, the cited bound holds with either convention. The product of balls does not depend on ϕ. To make precise which normalization enters, let V_ϕ be the conditional fluctuation potential and $S_u = \partial_u V_{u\phi} - \mathbb{E}_{u\phi}\partial_u V_{u\phi}$ its centered potential derivative along the segment. In the notation of Lemma 13.6, $S_u = Q_u$ for this path, and $-S_u$ is the normalized log-density derivative. By differentiation, we have

$$\partial_u \mathbb{E}_{u\phi} F = \mathbb{E}_{u\phi}\partial_u F - \mathbb{E}_{u\phi}(F S_u), \qquad \partial_u \Sigma_{u\phi}(r,s) = -\mathbb{E}_{u\phi}(\xi_r \xi_s S_u). \tag{17.19}$$

Indeed, we differentiate the numerator and the denominator; this is legitimate because the support is compact and fixed and the integrands are smooth. In the second identity, the terms containing the derivative of $\mu_{u\phi}$ multiply $\mathbb{E}\xi = 0$ and cancel. Thus (17.18) refers to the covariance of the interacting truncated kernel and to its centered derivative; there is no boundary term and no reference Gaussian covariance.

By the joint coefficient bounds kept by Lemma 15.15, we may expand the reconstruction map by Taylor's formula at the conditional mean μ_ϕ. We define

$$v_\phi = \psi_\phi(\mu_\phi), \qquad E_\phi = g^{-1} D_w \psi_\phi(\mu_\phi), \qquad B_\phi = (2g^2)^{-1} D_w^2 \psi_\phi(\mu_\phi);$$

the ratios $g_{i,s}/g$ are included in these definitions. The mean lies in the convex product, and so does the segment from it to each w. Since $\|\xi\|_\infty \le 2p$, Taylor's formula with integral remainder and the bound on the third derivative in w imply

$$\theta_i = v_\phi + g E_\phi \xi + g^2 B_\phi(\xi,\xi) + \mathcal{R}_\phi(\xi), \qquad \|\mathcal{R}_\phi(\xi)\|_\infty \le C_J g^3 p^3. \tag{17.20}$$

Each derivative in w contributes its coupling factor, and the joint absolute bound sums the remaining coefficients. These bounds are at fixed J and impose no further condition on J.

By the bounds on the row sums and volume-normalized column sums kept by the reconstruction maps, converted between the finitely many types of fluctuation variables of a step, we have

$$\|E_\phi\|_{\mathrm{op}} + \|B_\phi\|_{\mathrm{abs}} \le C_J,$$

where $\|B_\phi\|_{\mathrm{abs}}$ is the larger of its absolute row and column sums. The joint bounds in the coarse field and the coupling-scaled fluctuation inputs also give

$$\|E_\phi - E_0\|_{\mathrm{op}} + \|B_\phi - B_0\|_{\mathrm{abs}} \le C_J(R + g\|\mu_\phi\|_\infty) \le C_J' R. \tag{17.21}$$

For this bound, we integrate the derivative in the coarse field along $s\phi$ with the coupling-scaled fluctuation inputs equal to zero, and then the derivative in these inputs from zero to $(g_{i,s}\mu_{\phi,s})_s$. Both segments lie in the fixed inner domain, where the normalized coefficients have bounded row and column sums. At the zero coarse field, we have $\mu_0 = 0$ by the global color symmetry, and the endpoint is exactly E_0, B_0. The row and column bounds imply the displayed operator bounds by Schur's test,

$$\sum_x \Big| \sum_y K_{xy} u_y \Big|^2 \le \Big(\sup_x \sum_y |K_{xy}| \Big) \Big(\sup_y \sum_x |K_{xy}| \Big) \sum_y |u_y|^2,$$

and the conversion from volume-normalized to counting column sums costs only a factor depending on J.

Let $\mathcal{Z}_\phi = E_\phi \Sigma_\phi E_\phi^{\mathsf{T}}$. Adding and subtracting $E_0 \Sigma_\phi E_\phi^{\mathsf{T}}$ and $E_0 \Sigma_0 E_\phi^{\mathsf{T}}$, and using (17.18) and (17.21), we obtain

$$\| \mathcal{Z}_\phi - \mathcal{Z}_0 \|_{\mathrm{op}} \le C_J R (1 + t p^3) \le C_J' R. \tag{17.22}$$

This is the covariance comparison of the first part, for the coefficients of the reconstruction maps themselves.

At the zero coarse field, the product of balls and the potential are invariant under every constant adjoint color rotation. This implies $\Sigma_0 = \Sigma_{\mathrm{sp}} \otimes I_3$ for a spatial matrix Σ_{sp}, and the linear coefficient E_0 acts as a scalar on the adjoint color representation. To check this, note that rotations by π about the three coordinate axes force each 3×3 color block commuting with them to be diagonal, and rotations exchanging the axes force its three diagonal entries to agree. The same invariance for the equivariant map Q implies

$$Q : \mathcal{Z}_0 = 0. \tag{17.23}$$

Indeed, each output component of the contraction is an adjoint vector fixed by every rotation, and rotations by π about two different axes force it to vanish. This argument is componentwise in the output and keeps every spatial entry of the covariance; it needs no translation invariance of Q.

The same reasoning shows that $B_0 : \Sigma_0 = 0$. Together with (17.21) and (17.18), this implies

$$\| \mathbb{E}_\phi B_\phi(\xi, \xi) \|_\infty \le C_J R (1 + t p^3) \le C_J' R. \tag{17.24}$$

Here we used that each scalar coefficient matrix of B_ϕ has absolute entry sum at most C_J, and that a contraction against a matrix of operator norm D has absolute value at most $C_J D$, since every entry of that matrix is bounded by D. The same remark justifies contractions against (17.22) without any dependence on the dimension.

The displacement of the reconstruction at the mean satisfies

$$\| v_\phi - \psi_\phi(0) \|_\infty \le C_J g \| \mu_\phi \|_\infty \le C_J g^2 R, \tag{17.25}$$

where we integrated the derivative in w, whose absolute row sums are at most $C_J g$, along the segment from 0 to μ_ϕ, and used that t/g depends only on J. By the bounds on the first three derivatives of the zero-fluctuation reconstruction and the majorant of Lemma 15.15, we have

$$\|\psi_\phi(0) - L_i\phi\|_\infty \le C_J a_{\mathrm{cap}} R^2, \qquad \|L_i\phi\|_\infty \le a_{\mathrm{cap}} R. \tag{17.26}$$

Only the constant in the linear bound, which is uniform in J, enters the choice of a_{cap}; the quadratic bound may have a constant depending on J. By (17.25), (17.26), and $\|Q(u,v)\|_\infty \le K_Q \|u\|_\infty \|v\|_\infty$, we have

$$\|Q(v_\phi, v_\phi) - Q(L_i\phi, L_i\phi)\|_\infty \le C_J K_Q (a_{\mathrm{cap}}^2 R^3 + g^2 R). \tag{17.27}$$

To see every power, let $\epsilon = v_\phi - L_i\phi$; then the left side is at most $2K_Q a_{\mathrm{cap}} R\|\epsilon\|_\infty + K_Q\|\epsilon\|_\infty^2$, with $\|\epsilon\|_\infty \le C_J(a_{\mathrm{cap}}R^2 + g^2 R)$. Since R and g are bounded by fixed constants, the term R^4 is absorbed into R^3 and the remaining terms into $g^2 R$.

We now expand $Q(\theta_i, \theta_i)$ using (17.20). The term linear in $gE_\phi\xi$ has mean zero. The term quadratic in it has mean

$$\mathbb{E}_\phi Q(gE_\phi\xi, gE_\phi\xi) = g^2 Q : \mathcal{Z}_\phi,$$

which is the identity of the first part; by (17.23) and (17.22), it is at most $C_J K_Q g^2 R$. The cross term of v_ϕ with $g^2 B_\phi(\xi,\xi)$ has mean at most $C_J K_Q g^2 R$, by (17.24) and the boundedness of v_ϕ. Every remaining product contains either one linear and one quadratic term in ξ, or a remainder, or two quadratic terms. Their pointwise bounds are $C_J K_Q g^3 p^3$, $C_J K_Q g^3 p^3$, and $C_J K_Q g^4 p^4$, respectively. Products of a remainder with a term of positive degree in ξ satisfy the same bound $C_J K_Q g^3 p^3$, since gp is bounded by a fixed constant, and so does the square of the remainder. In the term $Q(v_\phi, \mathcal{R}_\phi)$, only the boundedness of v_ϕ is needed. Further, $g^4 p^4 \le C_J g^3 p^3$. Combining these bounds with (17.27), we obtain the first estimate.

Step 2: the centered heat norm of a quadratic term. We prove the second part without assuming smoothness of the output. Fix a sample, so that $\phi = \theta_{i-1}$ is fixed and $\|\phi\|_\infty \le \overline{b}_{i-1}$. Let $Y(w) = Q(\theta_i(w), \theta_i(w))$ and $F = Y - \mathbb{E}_\phi Y$. On the whole product of balls, differentiating the polarized map, we find

$$D_w Y = Q(D_w\theta_i, \theta_i) + Q(\theta_i, D_w\theta_i).$$

The absolute row sums of the derivative of θ_i in w are at most $C_J g_i$, and its volume-normalized columns satisfy the same bound. At most a number of fluctuation variables depending only on J is attached to each cell of the lattice of mesh a_i. Further, $\|\theta_i(w)\|_\infty \le \overline{b}_i$ at every point w of the product. Indeed, the recurrence of Step 1 in the proof of

Lemma 17.1 gives $\|\theta_i(w)\|_\infty \le a_{\mathrm{cap}}\bar{b}_{i-1} + C_{\mathrm{rec},J}t_i p_i$, and this is at most $\bar{b}_i$ by (17.5), since $C_J \ge C_{\mathrm{cap},J}$. Let $\mathcal{A} = C_J K_Q g_i \bar{b}_i$. Then the derivative matrix $G = D_w Y$ satisfies

$$\sup_y \sum_r |G_{y,r}| \le \mathcal{A}, \qquad \sup_r \frac{\delta^3}{a_i^3} \sum_y |G_{y,r}| \le \mathcal{A}, \tag{17.28}$$

where r runs over the scalar fluctuation variables. For the column bound, we fix the differentiated fluctuation variable, use the column of Q for its differentiated argument, bound its other argument by $\bar{b}_i$, and then use the volume-normalized column of $D_w\theta_i$; the volume factors multiply to δ^3/a_i^3. Since both differentiated arguments satisfy the same bound, their sum is included in C_J. This holds for all directions and colors.

By Schur's test, the counting ℓ^2 operator norm of G is at most $\mathcal{A}(a_i/\delta)^{3/2}$. For $0 < s \le T_0$, let $\omega_y(s,x) = \int_{Q_y} p_s(x-z)\,dz$ for the output cells Q_y of side δ. For each scalar component of P_sY at a point x, the Lipschitz constant in w is at most

$$C\mathcal{A}\min\{1, a_i^{3/2}s^{-3/4}\}. \tag{17.29}$$

The first bound follows from the absolute row sums and $\sum_y \omega_y = 1$. For the second, we compose the operator bound with $\|\omega(s,x)\|_2 \le C\delta^{3/2}s^{-3/4}$, from Lemma 16.1; the factor $(a_i/\delta)^{3/2}$ cancels the factor $\delta^{3/2}$ of the output cells. By the derivative and time-increment bounds of the same lemma, one spatial derivative of the cell integrals costs $s^{-1/2}$ and one time derivative costs s^{-1} when $a_i^2 \le s \le T_0$, in which case $s \ge \delta^2$. These bounds also hold for differences of two evaluations, by integration along a shortest spatial path or a time segment.

We now take the supremum over times, beginning with times below a_i^2. Let $M_i = \mathbb{E}_\phi\theta_i$. By the amplitude bound, we have $\|M_i\|_\infty \le \bar{b}_i$ as well as $\|\theta_i\|_\infty \le \bar{b}_i$. The output row bound in (17.16) then gives

$$\|Q(\theta_i,\theta_i) - Q(M_i,M_i)\|_\infty \le 2K_Q\bar{b}_i\|\theta_i - M_i\|_\infty,$$

and subtracting the conditional expectation, we obtain

$$\|F\|_\infty \le 2K_Q\bar{b}_i\big(\|\theta_i - M_i\|_\infty + \mathbb{E}_\phi\|\theta_i - M_i\|_\infty\big). \tag{17.30}$$

This uses the output row; a bound on the input columns alone would not imply it. There are $N_i = 9(L/a_i)^3$ scalar coordinates of θ_i on its own lattice. By the bounds on the derivative rows of the reconstruction maps in Lemma 15.15, each of them is a Lipschitz function of w with Euclidean constant at most $C_J g_i$, since the ℓ^2 norm of a row of the derivative is at most its absolute sum. The conditional kernel is the one on a convex product described in Section 17.1 (Lemma 15.10 and Theorem 15.13), with Hessian at least $I/2$. By Theorem 5.4 with $m = 1/2$ and a union bound, we have

$$\mathbb{P}_\phi\{\|\theta_i - M_i\|_\infty > x\} \le \min\{1, 2N_i\exp[-x^2/(C_J g_i^2)]\}. \tag{17.31}$$

To integrate this bound, we take $x_0 = g_i\sqrt{C_J \log(2N_i)}$, and for this integral we let $A^2 = C_J g_i^2$. We use $\int_{x_0}^{\infty} e^{-x^2/A^2}\,dx \le A^2 e^{-x_0^2/A^2}/(2x_0)$, which follows by inserting the factor $x/x_0 \ge 1$ in the integrand. After enlarging the constant, we obtain

$$\mathbb{E}_\phi \|\theta_i - M_i\|_\infty \le C_J g_i \sqrt{\log(2 + L/a_i)}, \qquad \mathbb{E}_\phi \|F\|_\infty \le C_J K_Q g_i \bar{b}_i \sqrt{\log(2 + L/a_i)},$$

where we used $\log(2N_i) \le C \log(2 + L/a_i)$, which holds because $L/a_i \ge 4$. Since the heat semigroup contracts the supremum norm, the expected supremum over $0 < s \le \min\{a_i^2, T_0\}$ of $s^{\alpha/2}\|P_s F\|_\infty$ is at most $C\mathcal{A} a_i^\alpha \sqrt{\log(2 + L/a_i)}$. Only the coordinates on the lattice of mesh a_i have been counted; there is no union bound over the arbitrarily fine output lattice. The mean M_i is the conditional mean of the reconstruction, which need not vanish.

For the remaining times, let $S_h = 2^h a_i^2$, and consider each nonempty interval $[S_h, \min\{2S_h, T_0\}]$, $h \ge 0$. The centered process $s^{\alpha/2}(P_s F)(x)$, with its nine scalar components, has one-point sub-Gaussian parameter at most

$$\sigma_h = C_{J,\alpha} \mathcal{A} a_i^{3/2} S_h^{\alpha/2 - 3/4},$$

by (17.29) and (16.18). Its increments have parameter at most $C\sigma_h$ times

$$\min\{1, \operatorname{dist}(x, x')/\sqrt{S_h}\} + \min\{1, |s - s'|/S_h\};$$

this includes the derivative of $s^{\alpha/2}$, whose relative size on the interval is at most C_α/S_h. Between distinct components, we take the distance to be $C\sigma_h$; adding the Lipschitz constants of the two components justifies this choice. Using spatial nets of spacing $c\eta\sqrt{S_h}$ and temporal nets of spacing $c\eta S_h$, together with the nine components, we obtain covering numbers at most

$$C(1 + L/\sqrt{S_h})^3 \eta^{-4} \qquad (0 < \eta < 1).$$

Since the process is continuous for $s > 0$ and smooth in x on these intervals, a countable dense set of parameters determines its supremum. We apply Lemma 16.4 to the increment function divided by σ_h, with $s = C\sigma_h$, $b = 0$, $D = C$, $A = C(1 + L/\sqrt{S_h})^3$, and $q_{\text{ent}} = 4$; the point z_0 of that lemma has the same one-point bound. At $p = 1$, the lemma bounds the expected supremum over the interval by

$$C\sigma_h \sqrt{\log(2 + L/a_i)},$$

because $\sqrt{S_h} \ge a_i$, so that $A \le C(1 + L/a_i)^3$; no factor depending on the output mesh enters. Since $\sigma_h = C_{J,\alpha} \mathcal{A} a_i^\alpha 2^{-h(3/4 - \alpha/2)}$, the sum over the intervals converges with ratio $2^{\alpha/2 - 3/4} < 1$ when $\alpha < 3/2$. Adding the bound for small times, we obtain

$$\mathbb{E}_\phi \|F\|_{-\alpha; T_0} \le C_{J,\alpha} K_Q g_i \bar{b}_i a_i^\alpha \sqrt{\log(2 + L/a_i)}.$$

Conditionally on $\mathcal{F}_{i-1}$, all constants here are deterministic and uniform over the coarse fields that occur. This is the second part.

Step 3: the pulled-back coefficients. The linearized reconstruction L_i has output mesh a_i and input mesh $a_{i-1} = Ba_i$, and it satisfies (17.17). These are the weighted bounds on the first derivative of the zero-fluctuation reconstruction, with the constant C_{CP}, uniform in J, enlarged as in Section 17.1. By the bounds on the second derivative of the zero-fluctuation reconstruction, the coefficient $Q_{j,j-1} = \overline{Q}_{d_j^k,j}$ has norm at most a fixed constant C. By induction down to the input level i, using Lemma 17.3 at each step, we obtain

$$K_{j,i} \le C a_{\mathrm{cap}}^{2(j-1-i)}.$$

The global color equivariance of the zero-fluctuation reconstruction implies the equivariance of its quadratic part, and each L_i commutes with constant color rotations; hence every $Q_{j,i}$ is equivariant. With $m = j-1-i$, the identity $a_i = B^m a_{j-1}$ gives

$$\frac{K_{j,i}}{a_{j-1}} \le \frac{C B^m a_{\mathrm{cap}}^{2m}}{a_i} = \frac{C q_{\mathrm{anc}}^m}{a_i}. \tag{17.32}$$

Step 4: the telescoping identity and the convolution. Let $Y_i = Q_{j,i}(\theta_i, \theta_i)$ for $0 \le i \le j-1$. By the definitions in the fourth part,

$$Y_i - Y_{i-1} = \big\{ Y_i - \mathbb{E}[Y_i \mid \mathcal{F}_{i-1}] \big\} + \big\{ \mathbb{E}[Y_i \mid \mathcal{F}_{i-1}] - Y_{i-1} \big\} = Z_{j,i} + e_{j,i}.$$

Summing this finite identity over $1 \le i \le j-1$, we obtain the telescoping identity on every sample. Since every conditional expectation is taken under the kernel of the same hierarchy that generated θ_i, Steps 1 and 2 apply with $\phi = \theta_{i-1}$ and the amplitude bound $\overline{b}_{i-1}$ on $\|\theta_{i-1}\|_\infty$.

The term from the coarsest level is bounded deterministically by

$$\Big\| \frac{Q_{j,0}(\theta_0, \theta_0)}{a_{j-1}} \Big\|_{-\alpha;T_0} \le \frac{C r^2}{H} q_{\mathrm{anc}}^{j-1},$$

by (17.4), (17.32) with $i = 0$, $a_0 = H$, and $\|\theta_0\|_\infty \le r$. For the centered terms, the second part and (17.32) give

$$\frac{\mathbb{E}\|Z_{j,i}\|_{-\alpha;T_0}}{a_{j-1}} \le C q_{\mathrm{anc}}^{j-1-i} g_i \overline{b}_i a_i^{\alpha-1} \sqrt{\log(2 + L/a_i)}.$$

For the conditional expectation errors, we use the first part, (17.4), and the three identities

$$\frac{a_{\mathrm{cap}}^2}{a_i} = \frac{q_{\mathrm{anc}}}{a_{i-1}}, \qquad \frac{g_i^2}{a_i} = g_3^2, \qquad \frac{g_i^3}{a_i} = g_3^3 \sqrt{a_i},$$

and obtain

$$\frac{\mathbb{E}\|e_{j,i}\|_{-\alpha;T_0}}{a_{j-1}} \le C q_{\mathrm{anc}}^{j-1-i} u_i.$$

By the triangle inequality, we obtain the convolution estimate of the fourth part, with v_i as defined there. No composition of the nonlinear zero-fluctuation reconstructions has been identified with a product of linearizations; the difference remains in $e_{j,i}$.

Step 5: summation. Let $1/2 < \alpha < 3/2$. By the reconstruction amplitude bound of Lemma 17.1 and (17.6), we have, with constants depending on the fixed H, g_3, and r,

$$\overline{b}_i \le C(1+i)B^{-i/2} \qquad (i \ge 0), \tag{17.33}$$

since $a_{\mathrm{cap}}^i = B^{-\kappa_{\mathrm{term}} i}$ with $\kappa_{\mathrm{term}} > 1/2$; the case $i = 0$ is included by enlarging C. More precisely, inserting the two terms of $\overline{b}_i$, we obtain

$$v_i \le C\big\{B^{-(\kappa_{\mathrm{term}}+\alpha-1/2)i} + (1+i)B^{-\alpha i}\big\},$$

and both exponents exceed $1/2$. In u_i, the part of $\overline{b}_{i-1}^3/a_{i-1}$ coming from the coarsest field decays with the exponent $3\kappa_{\mathrm{term}} - 1 > 1/2$, and the part coming from the fluctuations is at most $C(1+i)^3 B^{-i/2}$; the inequality $(x+y)^3 \le 4(x^3+y^3)$ handles the mixed terms. The other two terms of u_i are at most $C(1+i)^3B^{-i/2}$ directly. It follows that

$$v_i + u_i \le C(1+i)^3 B^{-i/2}. \tag{17.34}$$

For $i < j$, we use the cruder bound $\sqrt{\log(2+L/a_i)} \le \sqrt{\log(2+L/a_j)} \le C\sqrt{1+j}$.

Let $0 < \tau < \min\{1/2, -\log q_{\mathrm{anc}}/\log B\}$, and set $r_1 = q_{\mathrm{anc}} B^\tau < 1$ and $r_2 = B^{\tau-1/2} < 1$. Let $\mathcal{X}_j$ be the deterministic upper bound obtained from the convolution estimate by inserting (17.34) and $\sqrt{\log(2+L/a_i)} \le C\sqrt{1+j}$; it is defined for every $j \ge 2$ and does not depend on k. Writing $j = i + m + 1$, we have

$$\sum_{j\ge 2} B^{\tau j}\mathcal{X}_j \le C\sum_{j\ge 2} B^{\tau j} q_{\mathrm{anc}}^{j-1} + CB^\tau \sum_{i\ge 1}\sum_{m\ge 0} (2+i+m)^{1/2}(1+i)^3 r_1^m r_2^i < \infty.$$

All terms are nonnegative, and $(2+i+m)^{1/2} \le (2+i)(1+m)$ reduces the double series to the product of $\sum_i (2+i)^4 r_2^i$ and $\sum_m (1+m) r_1^m$, which converge by comparison with geometric series. The bound depends only on the fixed data and on the gaps in the strict inequalities for τ. The finite sequence for a given k is bounded by this deterministic majorant; no coefficients from different values of k are identified. We conclude that

$$\sum_{j=l}^{k} \mathbb{E}\big\| a_{j-1}^{-1} \overline{Q}_{d_j^k, j}(\theta_{j-1}, \theta_{j-1})\big\|_{-\alpha; T_0} \le B^{-\tau l} \sum_{j\ge 2} B^{\tau j}\mathcal{X}_j \le C_\tau H^{-\tau} a_l^\tau,$$

and the factor $H^{-\tau}$ is absorbed into C_τ. This is the last part. The proof used only $q_{\mathrm{anc}} < 1$ and the stated choice of τ; no condition of the form $q_{\mathrm{anc}} B^\alpha < 1$ is needed. □

PART VI

Large-field control and the small-field event

SECTION 18

Local coordinates and constrained minimizers on block regions

This section begins the large-field analysis. Its subject is a block region: a union of final blocks of $s \leq J$ consecutive averaging steps, possibly disconnected and with holes, on which the configuration is integrated while the configuration on the fixed complement is held fixed. On a block region, we construct coordinates adapted to the block averaging constraints, compute Haar measure in these coordinates, and construct the constrained minimizers of the effective classical action, with weighted bounds on all their Taylor coefficients. All estimates are uniform in the shape, the topology, and the number of components of the block region.

We need these objects for the following reason. As explained in Section 3.4, the exponential-moment bound for blocked Wilson actions (Theorem 22.1) runs the renormalization group in a localized form. The configurations are partitioned according to the regions where some averaged plaquette has large curvature (Theorem 21.5). Outside these regions, background fields, fluctuation integrals, and effective interactions are constructed on arbitrary unions of blocks, and the link variables in the excluded regions are held fixed as frozen coordinates. This section supplies the finite-dimensional part of that construction. Section 19 compares the constructions on a block region with those on the whole torus, and Section 20 integrates the fluctuations on block regions and tracks the normalization constants. Further, Section 21 uses the change of variables and the coercivity estimate at the first block integration to write exact densities, and Section 23 uses the substitution estimates in its choice of parameters.

Definition 18.1 introduces coefficient norms with exponential weights in the distance to the boundary of the block region, and Lemma 18.3 shows that these norms are stable under contractions, inverses, inverse square roots, and Schur complements. Lemma 18.4 proves that the iterated block averaging map is local for every output side $m \geq 4$. Lemma 18.7 computes the pushforward of Haar measure in the local constraint coordinates of a block region, under the hypothesis that the fiber is covered by the chosen chart. Lemma 18.8 records the derivatives of constrained minimum values, and Lemma 18.9 states how coefficient norms, normalization constants, and determinants change when variables are frozen. The main result is Theorem 18.12: the constrained Hessian of the effective classical action on a block region is bounded below by a constant that does

not depend on the region, and the constrained minimizer is analytic, with weighted coefficient bounds. Its coercivity estimate rests on the patch inequality of Lemma 18.11. Lemma 18.14 identifies the objective of the first block integration with the Wilson action on the block region and gives the exact form and range of its Hessian, as needed in Section 21. Finally, Lemma 18.15 shows that connected expressions containing a perturbation in the fixed complement decay exponentially into the block region, without a factor proportional to the volume of the complement.

The inputs are the coefficient calculus of Lemma 5.3, the local constraint coordinates and Haar disintegration of Lemma 6.3, the nested minimization identity and the weighted coefficient bounds for the effective classical actions in Theorems 10.10 and 10.11, the triangular change of variables of Theorem 12.13, the domains of Definition 14.4, and, from Theorem 14.8, only the inequality $E_{d,\mathrm{sat}} \geq \kappa_* E_0$ for the effective classical action at every depth $d \geq 0$. The geometry of Lemma 7.4 is used only for a comparison.

Two observations organize the argument. The first concerns coercivity. Let u be a linearized variation that satisfies the tree gauge conditions and the linearized block averaging constraints of the block region. If u has zero curl on a single final block, then u is a gradient there, the tree conditions make its potential constant on the block, and hence u vanishes on the block. On two adjacent final blocks, the constraint on the coarse bond between them equates the two constants. Coercivity on these two kinds of patches, a covering with bounded overlap, and an explicit extraction of the free coordinates from u give a lower bound on the constrained Hessian that does not see the topology of the region. The second observation concerns locality. A connected contraction of coefficient tensors that contains a perturbation in the fixed complement must connect each of its external indices in the block region to the complement. Its length therefore bounds the distance of these indices to the boundary, and summing over the positions in the complement with exponential weights gives decay without a volume factor.

The constructions are analytic near the identity. Whether every point of a fiber of the block averaging map lies in the chart is a hypothesis of Lemma 18.7; it is verified in Section 21. Frozen coordinates from earlier block integrations are fixed real parameters: we never differentiate in them or continue them to complex values. Constant terms are tracked separately from the nonconstant Taylor series, and the coefficient norms never bound them.

Charts adapted to the averaging constraints and constrained minimizers of the action (background fields) are central ingredients of Bałaban's renormalization group. Configurations with prescribed averages and the axial gauge conditions on them are introduced in [14, §§A–B]; the minimizers, their analytic dependence on the coarse field, and the decay of their derivatives are constructed in [16, Theorem 1, p. 279, and §G, Proposition 9, p. 309]. We follow that method, but the block regions, the centered averaging map, the constraint coordinates, and the coefficient norms are different, and we prove the estimates

needed here directly. The weighted inverse bounds adapt the exponential conjugation of Combes and Thomas [61]. Gauge fixing along trees by successive Haar translations, the analytic implicit function theorem, the formulas for derivatives of minimum values, Schur complements, the resolvent identity, and the integral formula for inverse square roots are standard.

18.1 Block regions, coordinates, and constants

Fix an odd integer $M = 2R_M + 1 \geq 3$ and an integer $J \geq 1$. Throughout this section $1 \leq s \leq J$ and $m \geq 4$ are integers, and we consider s consecutive averaging steps T_M^s, from the lattice of side $M^s m$ (the input lattice) to the lattice of side m (the output lattice). The lattices of sides $M^{s-i}m$, $0 \leq i \leq s$, are the levels, indexed by i; the integrated intermediate scales have $i < s$. The level $i = 0$ is the input lattice and $i = s$ the output lattice. Distances are measured in units of the output mesh. The final blocks are the centered blocks of M^s input sites per direction at the vertices of the output lattice; they are described precisely in Section 18.3. A block region is a union Ω of final blocks. The fixed complement consists of the input vertices and links not in Ω, and the boundary W of Ω is the set of positions of the input links with one endpoint in Ω and the other in the fixed complement. A block region may be empty, may be disconnected, may have holes, and may contain isolated final blocks.

Labels and positions. A scalar coordinate is one component of the logarithm of a link variable. It is specified by its link, its color, and the level on which the link lives; a frozen coordinate also records the scale at which it was introduced. Coordinates that differ in direction, color, scale, or scale of introduction are different labels, even if their positions coincide. Each label is assigned the position of its link, embedded in output units. Inner products on lists of coordinates are counting inner products. Volume-normalized column sums carry the factors $a_{\mathrm{out}}^3/a_{\mathrm{in}}^3$ of Definition 4.6. Changing the counting unit across at most J scales changes a counting sum by a factor depending only on M and J, and it introduces no volume factor. In analytic formulas we write $E_d(A)$ for $E_d(e^A)$ on the identity chart.

Coordinates. We use the coordinates listed in Table 18.1. The coarse field, the free coordinates, and the tree coordinates are defined precisely in Definition 18.6 and Lemma 18.7, and the normalized fluctuation variables in Lemma 18.9. The logarithms c of the coarse links, the free coordinates z, and the logarithms ξ of the frozen coordinates introduced at the current block integration are analytic variables, and they may be complexified on the construction chart. The frozen coordinates b_{rec} introduced at earlier block integrations are fixed real parameters. Figure 18.1 shows the different kinds of links in a two-dimensional sketch.

Symbol	Meaning	Reference measure	Analytic role
c	logarithms of the coarse links of Ω, that is, of the bonds joining two final blocks of Ω	Haar measure $dH(e^c)$ of the group values	variable; complexified
z_i	free logarithmic coordinates at intermediate scale i, on the free edges $\mathcal{F}_i$	Lebesgue measure, with the density J_i of Lemma 18.7	variable; complexified
w_i	normalized fluctuation variables, $z_i = a_i + g_i K_i^{-1/2} w_i$	Lebesgue measure	variable
$\mathfrak{f}$	tree coordinates (gauge transformations at the nonroot vertices of the trees)	product of Haar probability measures	integrated; never differentiated
ξ	logarithms of the frozen coordinates introduced at the current block integration	Haar measure on the group values	small; complexified
b_{rec}	frozen coordinates introduced at earlier block integrations, at their scales of introduction	product Haar measure	fixed and real; never differentiated

Table 18.1. The coordinates used on a block region.

Uniform constants. In this section a constant is called uniform if it depends only on the following data: M and J; the radius r_E of the identity chart on which the effective classical actions E_d are controlled, the bound C_E on their weighted Taylor coefficients with each index fixed, and their spatial rate $a_E > 0$, all from Theorem 10.11; the constant $\kappa_* > 0$ in the lower bound (18.20) below; the radii of the local constraint coordinates of Lemma 6.3, strictly smaller than their radii of definition, and the coefficient bounds of the finite group products that define them; the label density v_J of (18.1); and fixed ratios of radii and fixed differences of spatial rates, stated where they are used. Uniform constants are independent of L, γ, m, N, K, the depth d_0, the number of preceding block integrations, the number of components and the shape of the block region, the values of the frozen coordinates b_{rec}, and every width chosen later (boundary strips, interior restriction distances, protected neighborhoods, and cells). A bound for a general analytic input may depend in addition on the coefficient bound and the inverse bound assumed for that input. No uniformity as $J \to \infty$ is claimed. This is the dependence described in item (3) of Definition 4.14. Frozen coordinates are fixed before Taylor coefficients are taken or degrees are summed.

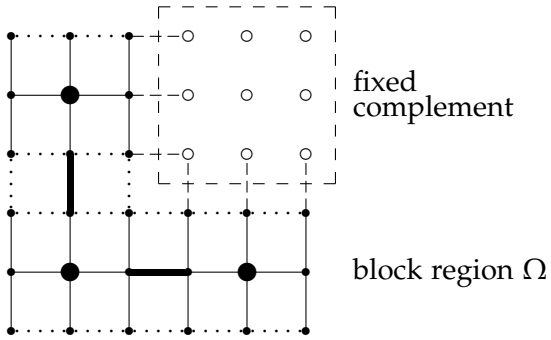

Figure 18.1. A two-dimensional sketch of a block region with $M = 3$ and $s = 1$: three final blocks (filled sites, with enlarged roots) and one final block of the fixed complement (open sites, dashed square). Solid lines are tree edges. The two thick edges are the eliminated edges of the two coarse bonds of Ω. Dotted lines are free edges. Dashed edges are links across the boundary; they are not coordinates of the block region, and they carry frozen coordinates.

18.2 Coefficient norms with boundary decay

In the regional estimates, distances between label positions are periodic shortest-path distances on the common refined position graph: the periodic cubic lattice of mesh $(2M^s)^{-1} \le 1$ in output units, which contains the endpoints and the midpoints of the links of all levels. Its vertices need not carry a coordinate. In this section dist denotes this graph distance, and the boundary distance uses it. The connecting-network length t uses the associated periodic ℓ^1 metric, with internal vertices allowed. If d_2 and t_2 denote the Euclidean distance and network length of Definition 4.6, then $d_2 \le \mathrm{dist} \le \sqrt{3} d_2$ and $\mathsf{t}_2 \le \mathsf{t} \le \sqrt{3}\mathsf{t}_2$. A coefficient bound imported at Euclidean rate b is therefore used at graph rate $b/\sqrt{3}$. The regional norms below are the graph-metric variants of the norms of Definition 4.6 and (4.11), written out for a block region.

Definition 18.1. Fix the data of Section 18.1 and a block region Ω. Assume that the positions of the labels satisfy the density bound

$$\#\{y : R \le \mathrm{dist}(x,y) < R+1\} \le v_J (R+2)^3 \qquad (R \ge 0) \tag{18.1}$$

for every label position x, where the count is over labels y. For a label i, let $d_\Omega(i)$ be the graph distance, on the refined position graph, from its position to the set of positions outside Ω. When a position is removed from a block region, all labels at that position are removed together. A different convention for the positions of link endpoints changes these distances by at most a fixed amount, which is absorbed in the widths below.

Let $\rho > 0$, $a_{\mathrm{sp}} > 0$, and $\alpha_{\mathrm{bd}} > 0$, and let ϕ be a spatially varying analytic radius on Ω, with $0 < \phi(i) \le \rho$. Let $f(v; b_{\mathrm{rec}}) = \sum_\nu f_\nu(b_{\mathrm{rec}}) v^\nu$ be a function of the variables

$v = (v_i)_{i\in\Omega}$ of the block region, given by its Taylor series in v, which depends on the frozen coordinates b_{rec}. Define

$$\mathcal{X}^{\phi}_{\Omega}(f) = \sup_{b_{\mathrm{rec}}} \rho^{-2} \sum_{k\geq 1} \sup_{i\in\Omega} e^{\alpha_{\mathrm{bd}} d_{\Omega}(i)} \sum_{|\nu|=k} \frac{\nu_i}{k} |f_{\nu}(b_{\mathrm{rec}})| e^{a_{\mathrm{sp}}\mathtt{t}(\nu)} \phi^{\nu}.$$

Here $\mathtt{t}(\nu)$ is the length of a shortest connecting network for the positions of the labels in $\operatorname{supp}\nu$, with internal vertices allowed, measured in the periodic ℓ^1 metric of the refined position graph (the graph-metric variant of the length in Definition 4.6), and $\phi^{\nu} = \prod_i \phi(i)^{\nu_i}$. The supremum over i is taken inside the sum over degrees, and the supremum over b_{rec} outside it; b_{rec} ranges over the given compact set of real values of the frozen coordinates, each at the scale at which it was introduced. The norm involves no derivative in b_{rec} and no complex value of b_{rec}. The constant term $f(0; b_{\mathrm{rec}})$ is not part of the norm: it is kept in the effective classical action or in the normalization constant Λ. All nonconstant degrees, including degree one, enter the norm. The norm of a function on the empty block region is zero. If the fixed complement is empty, a boundary perturbation is required to have zero nonconstant part, and its norm is zero. For the effective classical action we use the same definition with its own radius ρ_{cl}, its own radius function, and its own rates.

For $K_* \geq 2$, $w_{\mathrm{bd}} \geq 1$, and $0 < \rho_{\partial} \leq \rho$ we use the radius

$$\phi(i) = \begin{cases} \rho_{\partial}, & d_{\Omega}(i) < w_{\mathrm{bd}}, \\ \rho, & d_{\Omega}(i) \geq w_{\mathrm{bd}}, \end{cases} \qquad \psi_{\mathrm{prof}} = \sqrt{K_*}\,\phi, \qquad \widehat{\phi} = K_*\phi,$$

which is smaller in the boundary strip of width w_{bd}. The enlarged radii ψ_{prof} and $\widehat{\phi}$ are used in Sections 19 and 20, on correspondingly larger analytic domains.

For a coefficient tensor with a set A of external indices and Taylor multi-index ν, put $S = A \cup \operatorname{supp}\nu$ and

$$\mathtt{t}_W(S) = \inf_{w\in W} \mathtt{t}(S \cup \{w\}).$$

The bulk and boundary coefficient norms of such a tensor at rate a are the sums of the absolute values of its coefficients at the given radii, with weights $e^{a\mathtt{t}(S)}$ and $e^{a\mathtt{t}_W(S)}$ respectively, in which one external index is fixed and all other indices are summed; the norm is the maximum over the choice of the fixed index. Differentiated analytic inputs count as external indices. Column sums at input indices are volume-normalized as in Definition 4.6. A tensor has a bulk bound or a boundary bound if the corresponding norm is bounded by a stated constant. The algebraic properties of these norms are collected in Lemma 18.3.

Remark 18.2. The weight $e^{a\mathtt{t}_W(S)}$ of the boundary coefficient norm and the weight $e^{a_{\mathrm{sp}}\mathtt{t}(\nu)+\alpha_{\mathrm{bd}} d_{\Omega}(i)}$ in $\mathcal{X}^{\phi}_{\Omega}$ are different, and a boundary bound at rate a does not by itself

bound $\mathcal{X}_\Omega^\phi$ with $a_{\mathrm{sp}} = \alpha_{\mathrm{bd}} = a$. The two are related by the length inequalities (18.51) and (18.52) in the proof of Lemma 18.15, at the cost of a fixed fraction of the rate.

For example, freezing the variable y at the value c in the function $vy + y^2$ produces the linear term cv and the constant c^2. This is why the norm $\mathcal{X}_\Omega^\phi$ includes degree one, and why constants are tracked separately (see Lemma 18.9).

Lemma 18.3. *Use the norms of Definition 18.1. Fix radii and rates, together with strictly smaller radii and rates; the bounds below hold at the smaller radii and rates, with constants depending only on these choices, on v_J, and on the stated bounds of the factors.*

1. *For a scalar function f, a label i, and $k \geq 1$,*

$$\sum_{|\nu|=k} \frac{\nu_i}{k} |f_\nu| e^{a\mathfrak{t}(\nu)} = \frac{1}{k!} \sum_{i_2,\dots,i_k} |D^k f(0)_{i,i_2,\dots,i_k}| e^{a\mathfrak{t}(i,i_2,\dots,i_k)}. \tag{18.2}$$

   In particular, a bound on the Taylor tensors of f with each index fixed in turn is the same as a bound on the absolute values of its coefficients.

2. *A connected product, contraction, or analytic composition of tensors, in which one factor has a boundary bound and the other factors have bulk bounds, has a boundary bound at every remaining external index. This includes at most J Schur complements of constrained Hessians in the free coordinates.*

3. *For $u > 0$ put $S_J(u) = 8v_J \sum_{r\geq 0} (r+1)^3 e^{-ur}$. For a matrix K on a list of labels let $\|K\|_b$ be the maximum of its absolute row and column sums with weight $e^{b\,\mathrm{dist}(x,y)}$. Let $K_0 = K_0^{\mathsf{T}} \geq \lambda I$ be real with $\|K_0\|_b \leq Q$, and put*

$$\mu = \frac{b\lambda}{8(Q+\lambda)}, \qquad C_R = 2S_J(\mu/2).$$

   Let L be a complex symmetric matrix, analytic in further variables, with bulk coefficient bounds on a larger radius such that $C_R \|L\|_{\mu/2} \leq \lambda/4$, where the norm includes the absolute values of all coefficients at that radius. Then $(K_0 + L)^{-1}$ and the inverse square root $(K_0 + L)^{-1/2}$, obtained by holomorphic continuation from the positive inverse square root of K_0, have bulk coefficient bounds at rate $\mu/2$, depending only on b, λ, Q, v_J, and the ratio of the radii.

4. *For two matrices A and B as in (3) on a common list, a boundary bound on $A - B$ gives boundary bounds on $A^{-1} - B^{-1}$ and $A^{-1/2} - B^{-1/2}$, through the ordered identities*

$$A^{-1} - B^{-1} = -A^{-1}(A - B)B^{-1}$$

   and

$$A^{-1/2} - B^{-1/2} = -\frac{1}{\pi} \int_0^\infty t^{-1/2} (A + t)^{-1} (A - B)(B + t)^{-1}\, dt.$$

The lower bound λ is a hypothesis on the free coordinates only, not on the coarse field. All constants are uniform.

Proof. We begin with the identity (18.2). Fix ν with $|\nu| = k$ and $\nu_i > 0$. An ordered list $(i_2, \dots, i_k)$ whose multiplicities are $\nu - e_i$ occurs $(k-1)!/\prod_j (\nu - e_i)_j!$ times in the sum on the right, and for each such list the derivative is $\nu! f_\nu$. Multiplying these two numbers and dividing by $k!$, we obtain ν_i/k, which proves (18.2). In particular, a bound on Taylor tensors with each index fixed is an absolute coefficient bound, not a bound on a derivative in a single direction.

Next we prove (2). When two factors are contracted at a label, we join their connecting networks at that label. The union spans every remaining external label, and if the first factor carries a boundary bound, it also reaches the point of W of that factor. Hence

$$\mathrm{t}_W(S_{\mathrm{ext}}) \le \mathrm{t}_W(S_1) + \sum_{r \ge 2} \mathrm{t}(S_r), \tag{18.3}$$

where S_{ext} is the set of external labels of the contraction and S_r the label set of the r-th factor. We fix any remaining external index. On the branch leading to that label we use the corresponding input-column bound, and on the other branches we use output-row bounds; these are the contractions of Lemma 5.3, with the same counting measures. A connected matrix cycle with an external insertion can be cut at that insertion, and successive absolute row and column sums give the same bound. (This does not apply to a disconnected scalar trace.) Multiplication of majorant series with nonnegative coefficients sums over the partitions of the Taylor labels, and division by the Taylor factorials turns the multinomial factors into ordinary products of power series. The same reasoning, applied to a composition with its majorant on the given radius, proves (2) for compositions. Fixing a specified analytic input only changes the fixed index. An external index within distance R_0 of W may instead be joined to W at the price of a factor e^{aR_0}. No step involves a sum over the positions of W.

For (3) we first record a density sum. By the density bound (18.1), we have, for every $u > 0$ and every subset of a periodic list of labels,

$$\sup_x \sum_y e^{-u\,\mathrm{dist}(x,y)} \le 8 v_J \sum_{r \ge 0} (r+1)^3 e^{-ur} = S_J(u). \tag{18.4}$$

Here we divided the displacements according to $r \le \mathrm{dist}(x,y) < r+1$ and used $(r+2)^3 \le 8(r+1)^3$. The series is finite, since for large r the ratio of successive summands is at most $e^{-u/2} < 1$.

We now adapt the exponential conjugation of Combes and Thomas [61] to the matrix K_0. Let q be a real function that is one-Lipschitz for the distance on the labels, and

let $D_q = \operatorname{diag}(e^{\mu q(x)})$. The entries of $D_q K_0 D_q^{-1} - K_0$ are $(K_0)_{xy}(e^{\mu(q(x)-q(y))} - 1)$, so the maximum of its unweighted absolute row and column sums is at most

$$Q \sup_{r \geq 0} e^{-br}(e^{\mu r} - 1) \leq \frac{Q\mu}{b - \mu} \leq \frac{\lambda}{8}.$$

For the first inequality we used $e^{\mu r} - 1 \leq \mu r e^{\mu r}$ and $r e^{-(b-\mu)r} \leq (b - \mu)^{-1}$; the second follows from the definition of μ. The Euclidean operator norm is bounded by the row and column sums: by the Cauchy–Schwarz inequality,

$$\|Av\|_2^2 \leq \Big(\sup_x \sum_y |A_{xy}|\Big)\Big(\sup_y \sum_x |A_{xy}|\Big)\|v\|_2^2.$$

For $t \geq 0$ the matrix $(K_0 + t)^{-1}$ has operator norm at most $(\lambda + t)^{-1}$. The Neumann series for the conjugated resolvent therefore converges, and we obtain $\|D_q(K_0 + t)^{-1}D_q^{-1}\|_2 \leq 2/(\lambda + t)$. Taking $q(x) = \operatorname{dist}(x, y)$ for a fixed y and reading off the (x, y) entry, we find

$$|(K_0 + t)^{-1}_{xy}| \leq \frac{2e^{-\mu \operatorname{dist}(x,y)}}{\lambda + t}, \qquad \|(K_0 + t)^{-1}\|_{\mu/2} \leq \frac{C_R}{\lambda + t},$$

where the second bound follows from the first and (18.4).

Next let L be the perturbation in (3). Since $C_R\|L\|_{\mu/2}/\lambda \leq 1/4$, we have

$$(K_0 + L + t)^{-1} = \sum_{n \geq 0} [-(K_0 + t)^{-1}L]^n (K_0 + t)^{-1}, \qquad \|(K_0 + L + t)^{-1}\|_{\mu/2} \leq \frac{4C_R}{3(\lambda + t)}. \tag{18.5}$$

The series converges absolutely in the coefficient norms, uniformly for $t \geq 0$. Bounds with every index fixed, and on the derivatives in the further variables, follow by inserting the differentiated perturbation and its connecting network into this series, or by differentiating its scalar geometric majorant on a strictly smaller radius. Here we use that L has bulk coefficient bounds with every index fixed; a pointwise bound on a matrix-valued function would not suffice.

For the inverse square root we use the scalar identity $\pi^{-1} \int_0^\infty t^{-1/2}(x + t)^{-1}\, dt = x^{-1/2}$ for $x > 0$, which follows from the substitution $t = xu^2$. Diagonalization gives the same formula for a real positive matrix. Expanding the resolvents as in (18.5) proves the formula for the complex perturbations of (3), and shows that it defines the branch obtained by holomorphic continuation from the positive inverse square root. Multiplying out the two resolvents, we have

$$(A + t)^{-1} - (B + t)^{-1} = -(A + t)^{-1}(A - B)(B + t)^{-1}.$$

At $t = 0$ this is the first identity in (4), and integrating it against $\pi^{-1}t^{-1/2}\, dt$ gives the second. The order of the factors matters, since they need not commute. By (2) and

(18.5), the integrand of the second identity has a boundary bound by a constant times $t^{-1/2}(\lambda+t)^{-2}$ times the boundary norm of $A-B$, and $\int_0^\infty t^{-1/2}(\lambda+t)^{-2}\,dt = \pi/(2\lambda^{3/2})$. The integral therefore preserves absolute coefficient bounds and the boundary weight. This proves (3) and (4).

Finally we treat Schur complements, completing the proof of (2). If $K = \left(\begin{smallmatrix} A & B \\ B^{\mathsf{T}} & C \end{smallmatrix}\right) \geq \lambda I$, then $A \geq \lambda I$ and

$$v^{\mathsf{T}}(C - B^{\mathsf{T}}A^{-1}B)v = \min_u (u,v)^{\mathsf{T}}K(u,v) \geq \lambda|v|^2, \tag{18.6}$$

where the equality follows by substituting the minimizer $u = -A^{-1}Bv$. In the coefficient norms the Schur complement is bounded by $\|C\| + \|B^{\mathsf{T}}\|\|A^{-1}\|\|B\|$. To compare two Schur complements, we replace the three factors of the product one at a time; each of the resulting terms contains one difference, possibly the inverse difference of (4), and therefore has a boundary bound by (2). For at most J successive eliminations we obtain a finite recursion: starting from a bound Q_0, the next bound can be taken to be $Q_{k+1} = Q_k + Q_k^2 I_k$, where I_k is the preceding inverse bound from (18.5). We choose the finitely many intermediate rates and radii in advance and take their minimum; there is no loss depending on the Taylor order or on the number of sites. The lower bounds used here are lower bounds for matrices in the free coordinates, and all constants depend only on the quantities listed in the statement. □

18.3 Local coordinates and Haar disintegration on block regions

The coordinates of a block region are obtained by solving, scale by scale, only the block averaging constraints of the coarse bonds that join two blocks of the region, with the local constraint coordinates of Lemma 6.3.

We set $R^{(t)} = (M^t - 1)/2$ for $t \geq 0$, so that $R^{(0)} = 0$ and $R^{(1)} = R_M$. In input lattice units, the final block with anchor v has the vertices $v + [-R^{(s)}, R^{(s)}]^3 \cap \mathbb{Z}^3$. Balanced base-$M$ digits give the disjoint decomposition

$$[-R^{(s)}, R^{(s)}]^3 \cap \mathbb{Z}^3 = \bigsqcup_{x \in [-R^{(s-1)}, R^{(s-1)}]^3 \cap \mathbb{Z}^3} (Mx + [-R_M, R_M]^3 \cap \mathbb{Z}^3). \tag{18.7}$$

To see this in one coordinate, we write an integer uniquely as $Mq + r$ with $-R_M \leq r \leq R_M$; since $MR^{(s-1)} + R_M = R^{(s)}$, the integers in $[-R^{(s)}, R^{(s)}]$ are exactly those with $|q| \leq R^{(s-1)}$. We apply this in each of the three coordinates and iterate. The internal links of a block region have both endpoints in Ω, and the links across the boundary of the block region have exactly one endpoint in Ω. At every intermediate scale we use exactly the blocks of this nested partition that lie in Ω.

Lemma 18.4. *Let $M \geq 3$ be odd, and let $s \geq 1$ and $m \geq 4$ be integers. On the input lattice of side $M^s m$, the value of T_M^s at a final link with endpoints v and $v + M^s e_i$ depends only on the input links with both endpoints in the union of the two centered M^s-blocks at v and $v + M^s e_i$. The tree paths of all intermediate scales inside a final block stay in that block. The same holds for the Borel extension of T_M by the reference-path transport of Definition 4.3. No divisibility of m by four is needed.*

Proof. We begin with one averaging step and write $x = v + \delta$ with $\delta \in [-R_M, R_M]^3 \cap \mathbb{Z}^3$. The coordinate-ordered path $\sigma_{v,x}$ stays in the block at v, since each coordinate of each intermediate vertex lies between its initial and final value. The path $\sigma_{v+Me_i,x+Me_i}$ stays in the translated block for the same reason. Along the straight segment from x to $x + Me_i$, the transverse coordinates stay equal to δ_j, and the longitudinal coordinate lies in $[-R_M, M + R_M]$. Since $M = 2R_M + 1$, we have

$$[-R_M, M + R_M] \cap \mathbb{Z} = ([-R_M, R_M] \cap \mathbb{Z}) \sqcup ([M - R_M, M + R_M] \cap \mathbb{Z}).$$

Every vertex of the segment lies in one of the two endpoint blocks, and its only link between the blocks joins the two adjacent boundary vertices. The reference path from v to $v + Me_i$ satisfies the same containment. Therefore every contour, based loop holonomy, and tree path in the definition (4.3) of the output uses only links with both endpoints in the union of the two blocks. The test whether some based loop holonomy equals $-I$ reads these same holonomies, and the exceptional output is the reference transport, so the Borel extension has no additional dependence.

For the induction, suppose that the assertion holds for r averaging steps. A one-step formula for a link at the next scale reads links whose endpoints lie in its two endpoint M-blocks on the current lattice. Each such link, pulled back through r steps, reads only the two centered M^r-blocks at its endpoints, by the induction hypothesis. By (18.7), these blocks partition the two centered M^{r+1}-blocks at the endpoints. All links that are read, including links between the smaller blocks, therefore have their endpoints in the union of the two large blocks. A tree path inside one block of the current lattice pulls back to tree paths in its smaller blocks and to the links joining these, all inside the same final block. This proves both assertions for $r + 1$ steps, including the exceptional outputs. When $m \geq 4$ the two final blocks lift injectively to a rectangular box in $\mathbb{Z}^3$; alternatively, the same coordinate containment can be read periodically. No step used a tiling, a reflection, or a congruence condition on the side. □

Remark 18.5. When $m \in 4\mathbb{N}$, the dependence in Lemma 18.4 agrees with the geometry of Lemma 7.4, applied with $D = s$ and $n = m$. The reflection and tiling conclusions of that lemma are not needed here. For the other sides $m \geq 4$, and for all shapes of block regions, Lemma 18.4 is the dependence statement used below; it requires no filling across a hole.

When we solve only the block averaging constraints of the internal coarse bonds, their eliminated-edge equations keep their independence and their derivatives after restriction to Ω: by Lemma 18.4, an internal equation reads only links in its two endpoint blocks, and it contains no eliminated edge other than its own. The following definition makes the construction explicit and fixes the linear maps used in the coercivity estimates of Sections 18.6 and 18.7.

Definition 18.6. Fix $1 \le s \le J$ and $m \ge 4$, put $n = M^s m$, and work in input lattice units on $(\mathbb{Z}/n\mathbb{Z})^3$. For an anchor $a \in (M^s\mathbb{Z}/n\mathbb{Z})^3$, let $\mathsf{B}_s(a) = a + \{-R^{(s)}, \dots, R^{(s)}\}^3$ be the final block at a. Let $\mathcal{K}$ be the set of anchors of the final blocks of Ω, let $\Omega_0 = \bigcup_{a\in\mathcal{K}} \mathsf{B}_s(a)$ be the vertex set of Ω, and let $\Omega_i = \Omega_0 \cap (M^i\mathbb{Z}/n\mathbb{Z})^3$ for $0 \le i \le s$, so that $\Omega_s = \mathcal{K}$.

1. *Edges.* For $0 \le i \le s$, let $\mathcal{L}_i$ be the set of positive edges of length M^i with both endpoints in Ω_i. Thus $\mathcal{L}_0 = L_\Omega$ is the set of internal links of Ω, including the links that join two final blocks of Ω, and $\mathcal{L}_s$ is the set of coarse bonds. An input link with exactly one endpoint in Ω_0 is a link across the boundary of the block region; such links are not coordinates of the block region. A reversed edge carries the opposite cochain value and the inverse group value.
2. *Blocks and trees.* For $i < s$ the blocks $\mathsf{B}_i(a) = a + M^i\{-R_M, \dots, R_M\}^3$, $a \in \Omega_{i+1}$, partition Ω_i, by (18.7). Write $\pi_i(x) = a$ for $x \in \mathsf{B}_i(a)$. For $x \in \mathsf{B}_i(a)$, let $\sigma_{a,x}$ be the path from a to x with steps of length M^i that changes the coordinates in the order $1, 2, 3$. In each block these paths form a tree rooted at a, and $\mathcal{T}_i \subset \mathcal{L}_i$ is the union of these trees.
3. *Eliminated and free edges.* For a bond $c' = (a, a + M^{i+1}e_k) \in \mathcal{L}_{i+1}$, its eliminated edge is
$$e_i^*(c') = (a + R_M M^i e_k,\ a + (R_M + 1)M^i e_k) \in \mathcal{L}_i.$$
Let $\mathcal{D}_i = \{e_i^*(c') : c' \in \mathcal{L}_{i+1}\}$, and let $\mathcal{F}_i = \mathcal{L}_i \setminus (\mathcal{T}_i \cup \mathcal{D}_i)$ be the set of free edges at scale i. No constraint and no free coordinate is attached to a link across the boundary.
4. *Linearized maps.* For $c' = (a, a + M^{i+1}e_k) \in \mathcal{L}_{i+1}$ and $x \in \mathsf{B}_i(a)$, let
$$F_{i,c',x} = \sigma_{a,x}[x, x + M^{i+1}e_k]\,\sigma^{-1}_{a+M^{i+1}e_k, x+M^{i+1}e_k},$$
a path with steps of length M^i. With $[\omega : e]$ the signed number of traversals of the edge e by the path ω, define the scalar matrices
$$(Q_i)_{c'e} = M^{-3} \sum_{x\in\mathsf{B}_i(a)} [F_{i,c',x} : e], \qquad \Pi_i^{\mathcal{T}} u = u|_{\mathcal{T}_i},$$
which act on three colors by tensoring with I_3. Put $Q_{[0,0)} = I$ and $Q_{[0,i)} = Q_{i-1}\cdots Q_0$, and define
$$G_\Omega u = \big((\Pi_i^{\mathcal{T}} Q_{[0,i)} u)_{0\le i<s},\ Q_{[0,s)} u\big) \tag{18.8}$$

for edge cochains u on $\mathcal{L}_0$. The last component prescribes zero variation of every coarse bond of Ω; no bond to a final block outside Ω is constrained. The kernel $\ker G_\Omega$ is the space of linearized variations of the block region.

5. *Reconstruction.* For a group field b on $\mathcal{L}_{i+1}$, its coarse-field lift is

$$(\mathcal{H}_i b)_e = \begin{cases} I, & \pi_i(x) = \pi_i(y), \\ b_{(\pi_i(x),\pi_i(y))}, & \pi_i(x) \neq \pi_i(y), \end{cases} \qquad e = (x,y) \in \mathcal{L}_i, \tag{18.9}$$

with the orientation convention in the second line. Start with $U^{(s)} = \exp(c)$ on $\mathcal{L}_s$ and descend by

$$U_e^{(i)} = \exp\big(\Gamma_{U^{(i+1)},e}(z_i)\big)\,(\mathcal{H}_i U^{(i+1)})_e, \qquad e \in \mathcal{L}_i. \tag{18.10}$$

Here Γ_b is the map of local constraint coordinates of Lemma 6.3 at the target $b = U^{(i+1)}$, solving only the constraints indexed by $\mathcal{L}_{i+1}$ for the logarithms on the eliminated edges $\mathcal{D}_i$, with free entries $z_i \in (\mathbb{R}^3)^{\mathcal{F}_i}$ and zero entries on $\mathcal{T}_i$. All products are taken on a common identity chart, smaller than the chart of definition, on which these finitely many inverses exist. Write $\Phi_\Omega(c,z) = U^{(0)}$ for the resulting field on $\mathcal{L}_0$. Thus Φ_Ω receives the logarithm c of the coarse field on $\mathcal{L}_s$, not its group value. The logarithms c of the coarse links, the free coordinates $z = (z_0, \dots, z_{s-1})$, and the logarithms ξ of the current frozen coordinates are independent parameters of this chart. The reference measure of the coarse links is Haar measure of their group values, written $dH(c)$ in Lemma 18.7; in these coordinates it is $dH(e^c) = \prod_e c_{\mathrm{Haar}} j_H(c_e)\, d^3c_e$, with the product over the coarse links, not Lebesgue measure.

6. *Tree-path transports to the basepoints.* For $x \in \Omega_0$ let $x_0 = x$ and $x_{i+1} = \pi_i(x_i)$. For $1 \le k \le s$ and a configuration U on $\mathcal{L}_0$, let

$$\Theta_{x,k}(U) = U^{(k-1)}(\sigma_{x_k,x_{k-1}}) \cdots U^{(0)}(\sigma_{x_1,x_0}), \tag{18.11}$$

where $U^{(i)} = T_M^i U$ on $\mathcal{L}_i$; this is a transport with endpoints x_k and x. A frozen coordinate on a link across the boundary at x that is based at the level-k ancestor x_k is represented by its based transport, obtained by multiplying the link value from the left by $\Theta_{x,k}$; a link across the boundary frozen at the first block integration is based at the root of its final block, $k = s$. We write $\Theta_x = \Theta_{x,s}$.

On the reconstruction we have $T_M^i \Phi_\Omega(c,z) = U^{(i)}$ on $\mathcal{L}_i$, since each Γ solves the constraints of the internal bonds, and these read only internal links by Lemma 18.4. Each factor in (18.11) is a transport along a tree path, and the tree links of (18.10) are equal to I. Hence $\Theta_{x,k}(\Phi_\Omega(c,z)) = I$ identically, also at nonzero (c,z) in the chart. In particular, the based tree gauge transformations fix both endpoints of a frozen coordinate represented by its based transport. The intermediate factors with $k < s$ only describe

the based transport at an earlier scale; they are not additional frozen coordinates. The coarse output on a bond across the boundary of the block region is evaluated from the reconstructed field after this construction; it is not a prescribed target. The frozen coordinates supply the based transports of frozen links across the boundary and the links of the fixed complement, each at the scale at which it was introduced. Arguments of an analytic torus action outside the block region that were outside earlier block regions are set to zero (logarithm zero), as described in Theorem 18.12. Arbitrary data deep in the fixed complement are never arguments of an analytic function.

Lemma 18.7. *Fix $1 \le s \le J$, a block region Ω, and Borel sets $\mathcal{S}_{c,b_{\mathrm{rec}}}$ of free coordinates z in the chart of Definition 18.6, depending measurably on the coarse links c and on the frozen coordinates b_{rec}. For tree coordinates $\mathfrak{f}$, that is, a gauge transformation at the nonroot vertices of the trees of all scales, let $U(c, z, \mathfrak{f}; b_{\mathrm{rec}})$ be the configuration obtained from $\Phi_\Omega(c, z)$ by the based gauge transformation $\mathfrak{f}$ and completed outside Ω by the frozen coordinates. Let the incoming finite positive measure have a Borel density $p(U, b_{\mathrm{rec}})$ with respect to the product of Haar probability measures on the links of Ω and Haar measures on the independently introduced frozen coordinates, each at the scale at which it was introduced; any normalizing constant of the incoming measure is included in p. Let $\chi(U, b_{\mathrm{rec}})$ be the product of all indicators carried by the incoming measure: those of the large-field decomposition, of the coordinate domains, of the small-field conditions of Definition 14.4, and of the fluctuation cutoffs. Assume coverage of the fiber by the chart: every configuration U with $p(U, b_{\mathrm{rec}})\chi(U, b_{\mathrm{rec}}) > 0$ has the form $U(c, z, \mathfrak{f}; b_{\mathrm{rec}})$ with $z \in \mathcal{S}_{c,b_{\mathrm{rec}}}$, after the based tree gauge transformation that fixes its coarse field and the based transports of its frozen coordinates.*

Then the pushforward of the measure with density $p\chi$ to (c, b_{rec}) has the density

$$p^{\mathrm{out}}(c, b_{\mathrm{rec}}) = \int dH(\mathfrak{f}) \int_{\mathcal{S}_{c,b_{\mathrm{rec}}}} \chi(U(c, z, \mathfrak{f}; b_{\mathrm{rec}}), b_{\mathrm{rec}})\, p(U(c, z, \mathfrak{f}; b_{\mathrm{rec}}), b_{\mathrm{rec}}) \prod_{i=0}^{s-1} J_i \prod_{i=0}^{s-1} dz_i$$

with respect to $dH(c) \prod_e dH(b_{\mathrm{rec},e})$, where the product is over the independently introduced frozen coordinates, $dH(\mathfrak{f})$ is the product of Haar probability measures, and we use the letter c both for the coarse links and for their logarithms. If f_i is the number of free group variables at scale i, the Haar disintegration density at scale i is

$$J_i = c_{\mathrm{Haar}}^{f_i} \frac{\prod_{e \in \mathcal{L}_i \setminus \mathcal{T}_i} j_H(\Gamma_{i,e})}{\prod_{c' \in \mathcal{L}_{i+1}} \det D_{X_{e_i^*(c')}} \mathsf{C}_{b,c'}(\Gamma_i)}, \qquad j_H(X) = \operatorname{sinc}^2(|X|/2), \qquad c_{\mathrm{Haar}} = \frac{1}{16\pi^2},$$

where $\Gamma_i = \Gamma_{U^{(i+1)}}(z_i)$ and $\mathsf{C}_{b,c'}$ is the block averaging constraint of c' at the target $b = U^{(i+1)}$. All Haar factors of the eliminated edges appear in the numerator. The determinants are positive on the real chart and continue holomorphically, without zeros, to its complex neighborhood. There is no further Haar density of the coarse field, no Gram determinant, no gauge-orbit volume, and no

Jacobian of a field-dependent choice of gauge. The formula is an identity tested against nonnegative Borel functions, and the displayed integral defines the density at every covered target.

When a frozen coordinate is introduced on a link e across the boundary at a fixed field v of the block region, the change from the link value a_e to the based transport $\widehat{b}_e = U_v(\sigma_e)a_e$, where $U_v(\sigma_e)$ is the tree-path transport of e to its basepoint in the field v, is a Haar translation that is triangular in the coordinates. Frozen coordinates introduced earlier are unchanged, and a blocked image of an earlier frozen coordinate is a function of the existing coordinates, not an additional Haar coordinate. If $p\chi$ is invariant under the based tree gauge transformations that fix the coarse field and the frozen coordinates, the integral over $\mathfrak{f}$ equals one and may be omitted; otherwise it remains in the formula. The identities are finite-dimensional, and the analytic bounds of the chart are uniform. Coverage is a hypothesis of this lemma.

Proof. We first fix one scale and the frozen coordinates. On each block we can remove a leaf of its rooted tree: we replace the variable on that edge by the transport from the root to the leaf, and translate the variables on the other edges at the leaf accordingly. At fixed values of the remaining variables this is a left or right Haar translation. We remove the leaves successively. The inverse map reconstructs each edge variable from the transports to its endpoints and its based value, so this is a bijective triangular change of group coordinates. It gives Haar probability measure in each tree variable at a nonroot vertex and in each based link outside the trees. No division by a stabilizer or by an orbit volume occurs, also for a single isolated block.

For an internal bond its eliminated-edge equation is the equation of Lemma 6.3 on its two endpoint blocks. Its determinant equals $\det(M^{-2}I_3) > 0$ at zero and stays positive on the real chart. We compute the normalization when only internal equations are solved. Let n_i be the number of internal group links outside $\mathcal{T}_i$ and q_i the number of internal constraints, so that $f_i = n_i - q_i$. At a fixed target c_{i+1} we write $U_e = e^{X_e}U_{0,e}(c_{i+1})$, where U_0 is the coarse-field lift. Right translation preserves Haar measure, and these n_i factors have the density $c_{\mathrm{Haar}}^{n_i}\prod_e j_H(X_e)$ with respect to dX, by the coordinate formula for Haar measure in (4.2).

The tested pushforward can be computed by inserting a unit point mass at $T_\Omega U = c_{i+1}$ with respect to Haar measure on the targets, where T_Ω denotes the internal outputs of T_M. More explicitly, if δ_H is the density of the unit point mass at the identity, then

$$\int dH(c_{i+1})\,\delta_H\big((T_\Omega U)c_{i+1}^{-1}\big)\,G(c_{i+1},U) = G(T_\Omega U, U)$$

for nonnegative tests G. This notation only expresses a change of variables. In logarithmic coordinates Y at the identity it reads $\delta_H(e^Y) = c_{\mathrm{Haar}}^{-1}\delta_0(Y)$, since $j_H(0) = 1$. The logarithms of the constraints are $Y_{c'} = \mathsf{C}_{b,c'}(X)$. The local substitution $(X_{e_i^*(c')})_{c'} \mapsto (Y_{c'})_{c'}$, with the free logarithms fixed, has Jacobian equal to the product of the eliminated-edge

determinants, since each equation contains no other eliminated variable. We obtain

$$c_{\mathrm{Haar}}^{n_i-q_i}\frac{\prod_{e\in\mathcal{L}_i\setminus\mathcal{T}_i} j_H(\Gamma_{i,e})}{\prod_{c'}\det D_{X_{e_i^*(c')}}\mathsf{C}_{b,c'}(\Gamma_i)}\,dz_i = J_i\,dz_i,$$

with the Haar density of every solved eliminated edge still in the numerator. The point-mass calculation can equivalently be carried out by first making this invertible local substitution and then integrating the unit mass in Y; no global disintegration theorem is needed. This proves the identity for continuous tests on compact subsets of the chart. Exhaustion of the open chart and monotone approximation extend it to nonnegative Borel tests. The reference measure $dH(c_{i+1})$ is already present in this calculation; expressing it once more in logarithms and keeping its density as another factor would count it twice.

We apply this one-scale identity to a nonnegative Borel test of the coarse links and frozen coordinates, multiplied by the Borel function $p\chi$, keeping the tree variables in the integrand. The internal output Haar variables of scale i are the internal input Haar variables of scale $i+1$. Repeated nonnegative integration therefore gives the product of the J_i, Lebesgue measure in all free logarithms, Haar probability measure in each tree variable of each scale, and Haar measure on the coarse links. This proves the displayed formula against every nonnegative Borel test. Restricting each free integral to $\mathcal{S}_{c,b_{\mathrm{rec}}}$ and keeping χ records the domain of the chart. The coverage hypothesis says that the image of this domain under the based tree gauge transformations contains every point that is pushed forward; without it the argument proves only the identity restricted to the chart.

The local coordinate formulas are Borel, their domains are Borel, and their Jacobians are continuous on the chart. After extension of the integrand by zero outside these domains, the integral is a Borel function of (c, b_{rec}): this holds first for indicators of rectangles, then for nonnegative simple functions, and then by increasing approximation. At an exceptional target its value may be $+\infty$; since the incoming measure is finite, it is finite almost everywhere. No unspecified almost-everywhere density enters the pointwise formula.

When a frozen coordinate is introduced, we hold the field v of the block region fixed. For every nonnegative Borel function G,

$$\int G(v, U_v(\sigma_e)a_e)\,dH(a_e) = \int G(v, \widehat{b}_e)\,dH(\widehat{b}_e),$$

by left invariance of Haar measure. Iterating over the newly frozen links and then integrating over v proves the assertion on Haar translations, although the translations depend on v. If the orientation gives a right translation instead, right invariance gives the same identity. An earlier frozen coordinate is not changed by this operation, and a later blocked value computed from it is a function on the existing coordinate space, not a new independent coordinate. This proves the statement on the reference measure of the frozen coordinates; it makes no claim of probabilistic independence under the density.

If $p\chi$ is invariant under the based gauge transformations in the statement, its value in these coordinates does not depend on $\mathfrak{f}$, since these gauge transformations fix both the target and the endpoints of the based transports of the frozen coordinates. Each Haar probability factor of the tree variables then integrates to one. Finally, the determinants do not vanish on the complex neighborhood of the chart, by the local inverse bounds of Lemma 6.3. Since there are at most J scales, each with bounded stencils and fixed radii, the analytic constants of the chart are uniform. The measure identity itself needs no analyticity of p. □

18.4 Derivatives of constrained minima

The constrained minimizers below are stationary points of an objective in the free coordinates, with the coarse field and the current frozen coordinates as parameters. The identities below hold at complex arguments; positivity of the Hessian, and hence minimization, enters only at real data.

Lemma 18.8. *Let $F(u, y; b_{\mathrm{rec}})$ be holomorphic on a finite-dimensional complex product and real at real arguments, where u denotes free coordinates and y parameters. Let $a(y)$ be a holomorphic branch of solutions of $F_u(a(y), y; b_{\mathrm{rec}}) = 0$ along which $A = F_{uu}$ is invertible. All derivatives below are evaluated at $(a(y), y; b_{\mathrm{rec}})$, with the frozen coordinates b_{rec} fixed. For a direction η of the parameters (the coarse field or the current frozen coordinates), set $V_\eta = (-A^{-1}F_{uy}\eta, \eta)$, and let $F^{\min}(y) = F(a(y), y)$. Then*

$$Da\,\eta = -A^{-1}F_{uy}\eta, \qquad DF^{\min} = F_y, \qquad D^2F^{\min} = F_{yy} - F_{yu}A^{-1}F_{uy},$$

and

$$D^3F^{\min}[\eta_1, \eta_2, \eta_3] = D^3F[V_{\eta_1}, V_{\eta_2}, V_{\eta_3}].$$

At intermediate scale i the effective classical action is $M^iF^{\min}$, and each of its derivatives carries the same factor M^i. Successive and joint constrained minimizers agree wherever all the conditional branches and the joint branch are defined in their stated domains and unique there.

If $F = E \circ \Psi$, then for any directions u, v of the free coordinates or of the parameters,

$$F_{uv} = \Psi_u^{\mathsf{T}} E''(\Psi)\Psi_v + E'(\Psi)\Psi_{uv}.$$

The second term is present also at a constrained minimizer. In particular, differentiation in a current frozen coordinate ξ gives $D_\xi a = -F_{uu}^{-1}F_{u\xi}$, where $F_{u\xi}$ contains both terms. At complex arguments, transposes are bilinear transposes. Higher derivatives of a require only the inverse of F_{uu}. Weighted coefficient bounds on these derivatives hold in the coefficient norms on smaller fixed products, with constants depending on the coefficient bounds of F, on the bound for F_{uu}^{-1}, and on uniform data. No inverse of a Hessian in the coarse field or in the frozen coordinates is used, and no derivative in a frozen coordinate b_{rec} is taken.

Proof. We begin with the existence and uniqueness of the branch near a given point of it. At that point the matrix $A_* = F_{uu}$ is invertible, so the map $u \mapsto u - A_*^{-1} F_u(u, y)$ has derivative zero there. By continuity, there exist a ball of free coordinates on which this derivative has norm at most $1/2$ and a smaller neighborhood of parameters on which the map moves the base point by less than a quarter of the radius of that ball. The iteration is then a contraction of the ball into itself, and the analytic implicit-series statement of Lemma 5.3 gives its holomorphic solution. Local uniqueness identifies this solution with the given branch, and these local constructions agree on their common neighborhoods.

Let $L(y) = (a(y), y)$, with b_{rec} fixed. Differentiating $F_u \circ L = 0$, we obtain

$$A\, Da\, \eta + F_{uy}\eta = 0.$$

This proves the formula for Da and shows that $DL\,\eta = V_\eta$. The first derivative of $F \circ L$ is F_y, since $F_u = 0$. Differentiating this equality once more and inserting the formula for Da, we find the stated Schur complement formula for $D^2F^{\min}$.

For the third derivative it is convenient to keep the tangent vectors. For every vector h of free coordinates and every parameter direction η, we have

$$D^2F[(h,0), V_\eta] = h^{\mathsf{T}}(A\, Da\, \eta + F_{uy}\eta) = 0. \tag{18.12}$$

The second derivative can also be written $D^2(F \circ L)[\eta_1, \eta_2] = D^2F[V_{\eta_1}, V_{\eta_2}]$. Its derivative in the direction η_3 consists of $D^3F[V_{\eta_1}, V_{\eta_2}, V_{\eta_3}]$ and two further terms, in each of which one of the vectors V is differentiated. A differentiated V has the form $(D^2a[\eta_j, \eta_3], 0)$, so both further terms vanish by (18.12). This proves the polarized identity for the third derivative.

By the chain rule, before any stationarity is imposed, we have

$$D_u D_v (E \circ \Psi) = (D_u\Psi)^{\mathsf{T}} E''(\Psi) D_v\Psi + E'(\Psi) D_u D_v \Psi.$$

Stationarity of the constrained objective says only that $E'(\Psi)\Psi_u = 0$ for the free directions u; it does not remove $E'(\Psi)\Psi_{uv}$. Taking v to be the direction of a current frozen coordinate, we obtain the formula for $D_{\check{\zeta}} a$. Since these are polynomial identities between derivatives, their holomorphic versions use the same bilinear transpose, without complex conjugation of the parameters.

We now turn to higher derivatives. Differentiating $F_u \circ L = 0$ in r given directions and using the chain rule indexed by the partitions π of these directions, we obtain

$$0 = \sum_{\pi} D^{|\pi|} F_u(L)\big[D^{|B|} L[\eta_j : j \in B] : B \in \pi\big].$$

For $r \geq 2$ the partition with a single block contributes $A\, D^r a$, since the higher derivatives of the second component of L vanish. Every other partition contains only derivatives

of a of order less than r. The new derivative is therefore obtained by solving one linear equation with the matrix A. For $r = 1$ this is the formula for Da proved above.

A quantitative bound uses given coefficient majorants for F and for the inverse A^{-1}. On a product where these bounds hold, we divide the partition formula by $r!$, use the contraction bounds of Lemma 5.3, and pass to a strictly smaller product of parameters. After the derivative condition for the preconditioned nonlinear map has been imposed, the solution is bounded by the majorant series Y with nonnegative coefficients determined by

$$Y = Ct + \kappa Y + \frac{C(t+Y)^2}{1 - C(t+Y)}, \qquad \kappa < 1.$$

By the implicit-series statement of Lemma 5.3, we obtain the factorial bounds and their versions with a specified input index; the boundary-weighted version is Lemma 18.3(2). The constants depend only on these coefficient bounds, the bound for A^{-1}, and uniform data. The hypotheses of this quantitative application are verified for the objective of a block region in Theorem 18.12.

To compare successive and joint minimizers, we split the free coordinates as (u, v). At a stationary point of the partial minimum value as a function of v, the formula $DF^{\min} = F_y$ implies $F_v = 0$, while the conditional minimizer already satisfies $F_u = 0$. It is therefore the joint stationary point in the given domain. Conversely, the joint stationary point satisfies the conditional stationarity equations, and uniqueness of their branches identifies it with the successive construction. This argument applies only where the conditional minimizers and the joint point lie in their stated domains, and it asserts nothing about other branches. Finally, one application of the nested minimization identity of Theorem 10.10 multiplies the minimum value by M, so after i steps the factor is M^i. Multiplication by a positive constant does not change the minimizer, and every derivative of the value carries the same factor. □

18.5 Freezing variables

When a block region shrinks, the variables at the removed labels are frozen: they are replaced by fixed values, which become frozen coordinates. The next lemma describes how the coefficient norm, a torus interaction, the effective density, and the triangular determinant behave under this substitution.

Lemma 18.9. *Use the norms and the position convention of Definition 18.1. Let D be a set of labels of a block region, with the radius ϕ of Definition 18.1 for D, let $s_{\mathrm{er}} \geq \max\{2, w_{\mathrm{bd}}\}$, let $I \subset \{i \in D : d_D(i) \geq s_{\mathrm{er}}\}$, and let $F = D \setminus I$. The labels in F are frozen. Since $s_{\mathrm{er}} \geq w_{\mathrm{bd}}$, every label of D at which $\phi < \rho$ lies in F; the set I may omit further labels of D, which are additional holes. Let $c = (c_j)_{j \in F}$ satisfy $|c_j| \leq \eta\phi(j)$ with $0 \leq \eta \leq 1/4$. For a function v on I, write*

$v \oplus c$ for the variables on D equal to v on I and to c on F, and for an analytic function f set $T_c f(v) = f(v \oplus c) - f(0 \oplus c)$. The following statements hold.

1. *For $i \in I$ we have $d_D(i) \geq d_I(i) + s_{\mathrm{er}} - 1$, and*

$$\mathcal{X}_I^{\rho}(T_c f) \leq (1-\eta)^{-2} e^{-\alpha_{\mathrm{bd}}(s_{\mathrm{er}}-1)} \mathcal{X}_D^{\phi}(f) \leq 2 e^{-\alpha_{\mathrm{bd}}(s_{\mathrm{er}}-1)} \mathcal{X}_D^{\phi}(f).$$

   The norm on the left includes every remaining nonconstant degree, including degree one. The same statement holds with the separate classical radius and rates.

2. *Let $r_{\mathbb{T}}$ be a function on the torus with no linear term and $\mathcal{B}_{\rho,\bar{a}}(r_{\mathbb{T}}) \leq E$, where $\mathcal{B}_{\rho,\bar{a}}$ is the torus norm of Definition 4.6, with the Euclidean network length, and $\bar{a} \geq \sqrt{3}(a_{\mathrm{sp}} + \alpha_{\mathrm{bd}})$, and assume $|c_j| \leq \beta = \eta\rho$ for $j \in F$. The boundary-completion difference*

$$G_c r_{\mathbb{T}}(v) = r_{\mathbb{T}}(v,c) - r_{\mathbb{T}}(0,c) - r_{\mathbb{T}}(v,0) + r_{\mathbb{T}}(0),$$

   that is, the difference between the substitution of the frozen values c and the substitution of zero, satisfies $\mathcal{X}_I^{\rho}(G_c r_{\mathbb{T}}) \leq 8\eta E$. All torus labels outside D are set to zero in these evaluations. The analogous difference for the effective classical action has its own radius and bound.

3. *Consider a joint density, relative to its given reference measure, of the form*

$$Z^{-1} e^{\Lambda(b_{\mathrm{rec}})}\, W(b_{\mathrm{rec}})\, e^{-E(v,c;b_{\mathrm{rec}})/g^2 - R(v,c;b_{\mathrm{rec}})} \chi(v,c,b_{\mathrm{rec}}),$$

   where $W(b_{\mathrm{rec}}) \geq 0$ is a weight depending only on the frozen coordinates (not to be confused with the boundary W). Freezing c gives the same joint measure, with the same Z, the same indicators, and the same effective classical action E, with the enlarged frozen coordinates (b_{rec}, c), and with

$$R_{\mathrm{new}}(v) = R(v,c) - R(0,c), \qquad \Lambda_{\mathrm{new}} = \Lambda - R(0,c).$$

   If the effective classical action is centered as well, its factor $e^{-E(0,c;b_{\mathrm{rec}})/g^2}$ remains as an external factor. No partition function at fixed frozen coordinates is introduced. At uniform radius, write $R = r_{\mathbb{T}}|_D + f$ with $r_{\mathbb{T}}$ as in (2), and set

$$\epsilon_D(f) = \sum_{k \geq 2} \rho^{k-2} \sup_{i \in D} e^{\alpha_{\mathrm{bd}} d_D(i)} \sum_{|\nu|=k} \frac{\nu_i}{k} |f_\nu| e^{a_{\mathrm{sp}} \mathfrak{t}(\nu)}, \qquad \ell_D(f) = \sup_{i \in D} e^{\alpha_{\mathrm{bd}} d_D(i)} |f_{e_i}|.$$

   If $\|c\|_\infty \leq \beta \leq \rho/4$, then

$$|R(0,c;b_{\mathrm{rec}}) - R(0;b_{\mathrm{rec}})| \leq |F| \big\{ \beta \ell_D(f) + \beta^2 [\epsilon_D(f) + E] \big\}.$$

   This bounds the change of the constant term; it does not bound $R(0;b_{\mathrm{rec}})$ itself.

4. *Consider a sequential normalization by the constrained Hessians,*

$$z_i = a_i(c_{i+1}; b_{\mathrm{rec}}) + g_i K_i(c_{i+1}; b_{\mathrm{rec}})^{-1/2} w_i, \qquad c_{i+1} = c_{i+1}(w_{>i}),$$

where c_{i+1} denotes the coarser fields as functions of the coarser normalized fluctuation variables, and let $d_i = 3f_i$ be the number of scalar free coordinates at scale i. The Jacobian determinant of $w \mapsto z$ is

$$\prod_i g_i^{d_i} \det K_i(c_{i+1}(w_{>i}); b_{\mathrm{rec}})^{-1/2}.$$

Adding and subtracting half of $\log\det K_i(\widehat{c}_{i+1}; b_{\mathrm{rec}})$, where $\widehat{c}_{i+1} = c_{i+1}(0)$, splits this single determinant into its value at zero fluctuation and the logarithmic difference containing all the dependence on the coarser normalized fluctuation variables. Missing Gaussian coordinates and all factors at zero fluctuation remain explicit.

At frozen coordinates represented by their based transports, we have the identity $f(v \oplus c) = T_c f(v) + f(0 \oplus c)$. Every algebraic identity above is finite-dimensional. All bounds are uniform and independent of additional holes, of the number of preceding block integrations, of the widths chosen later, and of the number of frozen labels except through the displayed factor $|F|$.

Proof. We begin with the distance inequality in (1). If I is empty there is no nonconstant coefficient to estimate. If D has no boundary, the boundary perturbation is zero by the convention of Definition 18.1. Otherwise let $i \in I$, and let $h = (2M^s)^{-1} \le 1$ be the mesh of the refined position graph. We choose a shortest path $i = x_0, \dots, x_k$ of vertices of this graph with x_k outside D, so that $kh = d_D(i)$, and we set $s' = \lceil s_{\mathrm{er}}/h \rceil$. Since $kh = d_D(i) \ge s_{\mathrm{er}}$ and k is an integer, we have $k \ge s'$. The vertex $x_{k-s'+1}$ is at distance at most $(s'-1)h < s_{\mathrm{er}}$ from the complement of D, so it is not a position of I. We conclude that

$$d_I(i) \le (k - s' + 1)h \le d_D(i) - s_{\mathrm{er}} + h \le d_D(i) - s_{\mathrm{er}} + 1.$$

Additional holes can only decrease d_I. This proves the distance inequality, with the exact term -1. Removing all labels at a position together is what makes this a statement on the graph of positions. The fixed buffer of Definition 18.1 transfers the same argument to another convention for link endpoints.

Next we prove the coefficient bound in (1). We fix the earlier frozen coordinates and an allowed c, and for each input degree m we set

$$A_m = \rho^{-2} \sup_{i \in D} e^{\alpha_{\mathrm{bd}} d_D(i)} \sum_{|\nu| = m} \frac{\nu_i}{m} |f_\nu| e^{a_{\mathrm{sp}} \mathfrak{t}(\nu)} \phi^\nu.$$

A monomial of degree m splits uniquely as (ν_I, ν_F), of degrees $k \ge 1$ and $j \ge 0$ with $m = k + j$. Every remaining radius is ρ, since all labels with smaller radius are frozen. For a fixed index $i \in I$, the new factor ν_i/k is at most m/k times the old factor ν_i/m, and

$m/k \le 1 + j$. Substituting the frozen values costs at most a factor η^j, and $\mathrm{t}(\nu_I) \le \mathrm{t}(\nu)$. The distance inequality contributes the factor $q = \exp[-\alpha_{\mathrm{bd}}(s_{\mathrm{er}} - 1)]$. Combining these factors, we find that the outgoing summand of degree k is at most $q \sum_{j \ge 0} (1 + j)\eta^j A_{k+j}$; coinciding outgoing monomials are bounded by the triangle inequality. We sum over k after taking the suprema over the fixed index. Since all terms are nonnegative, we obtain

$$\sum_{k \ge 1} q \sum_{j \ge 0} (1 + j)\eta^j A_{k+j} \le q\Big(\sum_{j \ge 0} (1 + j)\eta^j\Big) \sum_{m \ge 1} A_m = q(1 - \eta)^{-2} \sum_{m \ge 1} A_m.$$

This includes $k = 1$, even when the linear term comes from a monomial of high degree. No binomial factor for the choice of frozen factors appears, since the two label sets are fixed. The suprema over the earlier frozen coordinates and over the allowed real values c are taken after this inequality and the degree sums. Since $(1 - \eta)^{-2} \le 16/9 < 2$, this proves the two inequalities in (1). For the classical statement we replace the three parameters by the classical radius and rates in the same calculation; the partition of labels and the ratios of the factors ν_i/k are unchanged.

We now explain why the outgoing norm has uniform radius. We write ϕ_{cl} for the classical radius function. When all labels with smaller radius are frozen, we have

$$\phi|_I \equiv \rho, \qquad \phi_{\mathrm{cl}}|_I \equiv \rho_{\mathrm{cl}}. \tag{18.13}$$

Indeed, $d_D(i) \ge s_{\mathrm{er}} \ge w_{\mathrm{bd}}$ excludes every remaining position from the boundary strip, and additional holes remove labels without changing the radius at the remaining ones. This means that $\mathcal{X}_I^{\rho}(T_c f)$ is the norm with the uniform radius ρ at every remaining variable, and its classical counterpart has uniform radius ρ_{cl}. These are the incoming norms at uniform radius for the next calculation on the same list of labels, with their existing scales of introduction. The new values c are fixed real frozen coordinates, not additional variables with the radius ρ, and no extension beyond an earlier analytic domain is asserted, since each remaining variable already had the radius ρ.

For (2), only monomials that meet both I and F contribute to $G_c r_{\mathbb{T}}$. For any fixed index $i \in I$, the network of such a monomial reaches the complement of I, so its ℓ^1 length is at least $d_I(i)$, as well as at least $\mathrm{t}(\nu_I)$. Since the torus norm uses the Euclidean network length t_2 and $\mathrm{t} \le \sqrt{3}\mathrm{t}_2$, we obtain

$$a_{\mathrm{sp}}\mathrm{t}(\nu_I) + \alpha_{\mathrm{bd}} d_I(i) \le (a_{\mathrm{sp}} + \alpha_{\mathrm{bd}})\mathrm{t}(\nu) \le \sqrt{3}(a_{\mathrm{sp}} + \alpha_{\mathrm{bd}})\mathrm{t}_2(\nu) \le \bar{a}\mathrm{t}_2(\nu).$$

We use (18.2) for the torus norm. The degree calculation above now has $j \ge 1$, and its incoming sum is at most E. We obtain the stronger estimate

$$\mathcal{X}_I^{\rho}(G_c r_{\mathbb{T}}) \le [(1 - \eta)^{-2} - 1]E \le 4\eta E \le 8\eta E.$$

For the middle inequality we wrote the bracket as $\eta(2 - \eta)/(1 - \eta)^2$ and used $\eta \le 1/4$. This calculation counts the linear term produced by the substitution. Setting the other

torus labels to zero only deletes coefficients. For the classical difference we replace the radius, the rates, and the bound by their classical counterparts in the same calculation, with the same factor $\sqrt{3}$ in the rate hypothesis.

For (3), the statement on the measure is an algebraic identity with the given reference measure. Indeed,

$$e^{\Lambda - R(0,c)} e^{-[R(v,c)-R(0,c)]} = e^{\Lambda - R(v,c)}.$$

The weight $W(b_{\mathrm{rec}})$, every indicator, and the term $E(v,c;b_{\mathrm{rec}})/g^2$ are unchanged. Splitting E into $E(v,c) - E(0,c)$ and $E(0,c)$ gives the external classical factor in the statement. Fubini's theorem with the given reference measure proves the identity of joint measures, with the same Z; no normalization at fixed frozen coordinates has taken place. If the frozen variables are based transports, the identity is evaluated at those same values; it is a substitution in existing variables.

Only monomials supported in F contribute to $R(0,c;b_{\mathrm{rec}}) - R(0;b_{\mathrm{rec}})$. At each degree m, we assign such a monomial to its labels with weights ν_i/m, whose sum is one, and drop the network and distance weights, which are at least one. In degree one the sum is at most $|F|\beta\ell_D(f)$. For $m \geq 2$ we use $\beta^m \leq \beta^2\rho^{m-2}$. Summing over $i \in F$ and then over m bounds the contribution of f by $|F|\beta^2\epsilon_D(f)$ and that of the torus part by $|F|\beta^2 E$. The constant terms cancel in this difference, which is why the bound says nothing about an arbitrary incoming $R(0;b_{\mathrm{rec}})$. This proves the bound on the change of the constant term.

Finally we prove (4). We order the blocks of free coordinates from the coarser scales to the finer ones. The sequential map has the blocks

$$z_i = a_i(c_{i+1};b_{\mathrm{rec}}) + g_i K_i(c_{i+1};b_{\mathrm{rec}})^{-1/2} w_i, \qquad c_{i+1} = c_{i+1}(w_{>i}).$$

Its derivative is block triangular, with diagonal blocks $g_i K_i(c_{i+1}(w_{>i});b_{\mathrm{rec}})^{-1/2}$, so the determinant is the product in the statement. This is the triangular argument of Theorem 12.13, applied to the list of free coordinates of the block region; the dimensions $d_i = 3f_i$ are those of this list, not of the torus. With $L_i(w) = \log\det K_i(c_{i+1}(w_{>i});b_{\mathrm{rec}})$ and $\widehat{L}_i = \log\det K_i(\widehat{c}_{i+1};b_{\mathrm{rec}})$, the splitting reads

$$\det D_w z = \Big(\prod_i g_i^{d_i}\Big) e^{-\frac{1}{2}\sum_i \widehat{L}_i} e^{-\frac{1}{2}\sum_i [L_i(w)-\widehat{L}_i]}.$$

The second exponential contains all the dependence on the coarser normalized fluctuation variables. This is one determinant, with its real positive branch and its analytic continuation. If some free labels are absent, their Gaussian coordinates are absent from this product and remain explicit in any comparison, and the factors at zero fluctuation remain constant factors. The only estimates were sums of coefficients with a fixed index and graph distances, and neither introduces a dependence on the number of preceding block integrations, the number of holes, or the later widths, beyond the displayed factor $|F|$. □

18.6 Coercivity and analytic constrained minimizers

We first prove the patch inequality, which bounds a linearized variation of a block region by its curl on single final blocks and on pairs of adjacent final blocks. The patches and the restriction maps are defined explicitly, so that the inequality applies both to the effective classical action (Theorem 18.12) and to the Wilson action at the first block integration (Lemma 18.14).

Definition 18.10. Use the notation of Definition 18.6. The set $\mathfrak{P}_\Omega$ of patches of Ω consists of every final block $\mathsf{B}_s(a)$ with $a \in \mathcal{K}$ and of every union $\mathsf{B}_s(a) \cup \mathsf{B}_s(a + M^s e_k)$ of two adjacent final blocks with both anchors in $\mathcal{K}$. For $P \in \mathfrak{P}_\Omega$, let $\mathcal{E}(P)$ be the set of positive input edges with both endpoints in P, and $\mathcal{P}(P)$ the set of elementary positive plaquettes with all four vertices in P; thus P is a complete cuboid, with its boundary edges and faces. Construct $\mathcal{L}_i(P)$, Q_i^P, and $\Pi_i^{\mathcal{T},P}$ by the rules of Definition 18.6, using only the final block or blocks of P, and let

$$G_P h = \big((\Pi_i^{\mathcal{T},P} Q^P_{[0,i)} h)_{0 \le i < s},\ Q^P_{[0,s)} h \big), \qquad \mathcal{V}_P = \ker G_P. \tag{18.14}$$

For a single block $\mathcal{L}_s(P)$ is empty, and for a pair it consists of its one coarse bond. The tree conditions are imposed at every scale, not only at the finest one. Let d_P be the signed plaquette incidence matrix (the curl) of the cuboid P. For an edge cochain u on $\mathcal{L}_0$, the restriction to the patch is $(R_P u)_e = u_e$ for $e \in \mathcal{E}(P)$. For a patch that crosses a periodic seam we use the orientations induced by its rectangular lift.

Lemma 18.11. *Use Definitions 18.6 and 18.10. Let $\dot{\mathcal{H}}_i$ be the derivative of the coarse-field lift $\mathcal{H}_i$ at the identity, let $I_{\mathcal{F}_i}$ and $I_{\mathcal{D}_i}$ be the inclusions of coordinates on $\mathcal{F}_i$ and $\mathcal{D}_i$ into cochains on $\mathcal{L}_i$, and let $\Pi_{\mathcal{F}_i}$ be the restriction to $\mathcal{F}_i$. Define*

$$\Gamma'_i = I_{\mathcal{F}_i} - M^2 I_{\mathcal{D}_i} Q_i I_{\mathcal{F}_i}, \qquad A_\Omega z = \sum_{i=0}^{s-1} \dot{\mathcal{H}}_0 \cdots \dot{\mathcal{H}}_{i-1} \Gamma'_i z_i, \tag{18.15}$$

where the product preceding Γ'_0 is the identity, and

$$(B_{\mathrm{ext}} v)_i = \Pi_{\mathcal{F}_i} (I - \dot{\mathcal{H}}_i Q_i) Q_{[0,i)} v. \tag{18.16}$$

For a matrix B write $\|B\|_\infty = \sup_x \sum_y |B_{xy}|$ and $\|B\|_1 = \sup_y \sum_x |B_{xy}|$. The following statements hold.

1. *The map A_Ω is the derivative of $\operatorname{Log} \Phi_\Omega(0, \cdot)$ at $z = 0$. It maps the free coordinates bijectively onto $\ker G_\Omega$, and B_{ext} is its inverse on $\ker G_\Omega$.*
2. *We have*
$$\|A_\Omega\|_\infty \le J(1 + 4M^3), \qquad \|A_\Omega\|_1 \le M^{2(J-1)}(1 + 24M^3),$$

$$\|B_{\mathrm{ext}}\|_\infty \le b_\infty = (1+4M)(4M)^{J-1}, \qquad \|B_{\mathrm{ext}}\|_1 \le b_1 = (1+24M^3)\sum_{i=0}^{J-1}(24M)^i.$$

Consequently $\|z\|_2 \le C_{\mathrm{ext},J}\|A_\Omega z\|_{\mathcal{L}_0}$ *with* $C_{\mathrm{ext},J} = \max(1, \sqrt{b_\infty b_1})$. *Every nonzero entry of* A_Ω *or* B_{ext} *joins two positions at periodic maximum distance at most* $R_{M,J} = 2\sum_{i=0}^{J-1} M^{i+1}$ *in input units, hence also in output units.*

3. *Let* $u \in \ker G_\Omega$, *and let* du *be the curl of any edge cochain on all input edges that agrees with* u *on* $\mathcal{L}_0$. *For every patch* P, *we have* $R_P u \in \mathcal{V}_P$ *and* $(d_P R_P u)_p = (du)_p$ *for* $p \in \mathcal{P}(P)$.
4. *There is* $\sigma_J > 0$, *depending only on* M *and* J, *such that* $\|h\|^2 \le \sigma_J^{-1}\|d_P h\|^2$ *for every patch* P *and every* $h \in \mathcal{V}_P$. *For every* $u \in \ker G_\Omega$,

$$\|u\|^2_{\mathcal{L}_0} \le \sum_{P\in\mathfrak{P}_\Omega} \|R_P u\|^2 \le \sigma_J^{-1} \sum_{P\in\mathfrak{P}_\Omega} \|d_P R_P u\|^2 \le \frac{7}{\sigma_J} \sum_{p\in\mathcal{P}_\Omega} |(du)_p|^2, \tag{18.17}$$

where $\mathcal{P}_\Omega = \bigcup_{P\in\mathfrak{P}_\Omega} \mathcal{P}(P)$.

All constants are independent of m, *of the block region, of its number of components and holes, and of its topology. For an empty list of free coordinates all statements hold with the conventions for zero-dimensional spaces.*

Proof. We begin with the derivatives of the block averaging map at the identity. Differentiating the averaging formula (4.3) at the identity gives Q_i: the derivative of the reference transport in the averaged logarithm cancels the derivative of the final reference factor. The exceptional rule plays no role, since all based loop holonomies are close to I in a neighborhood of the identity. For a scalar vertex function φ and a bond $c' = (a, a + M^{i+1}e_k)$, each contour $F_{i,c',x}$ telescopes, and hence

$$(Q_i \nabla \varphi)_{c'} = \varphi(a + M^{i+1}e_k) - \varphi(a). \tag{18.18}$$

This holds at every scale, and it uses only the contours of internal bonds; no gradient is extended across a hole.

The derivative $\dot{\mathcal{H}}_i$ copies a coarse value to each edge of the interface of its bond and vanishes on the interiors of the blocks. We have

$$Q_i \dot{\mathcal{H}}_i = I, \qquad \Pi_i^{\mathcal{T}} \dot{\mathcal{H}}_i = 0, \qquad Q_i I_{\mathcal{D}_i} = M^{-2} I. \tag{18.19}$$

For the first identity, each contour of c' crosses the interface of c' exactly once, with positive orientation, and its tree parts lie in block interiors. The second holds since tree edges lie in block interiors. For the third, a contour of a different bond never uses the eliminated edge of c', and among the M^3 contours of c' exactly M use $e_i^*(c')$, each once with positive orientation. Since tree paths stay in their blocks, these identities hold also for an internal bond next to a final block outside Ω.

The linearized constraint at the identity is $Q_i X = 0$ for a cochain X on $\mathcal{L}_i$ with zero tree entries, and (18.19) gives its unique solution with free entries z_i:

$$\Gamma_i' z_i = I_{\mathcal{F}_i} z_i - M^2 I_{\mathcal{D}_i} Q_i I_{\mathcal{F}_i} z_i, \qquad \Pi_i^{\mathcal{T}} \Gamma_i' = 0, \quad Q_i \Gamma_i' = 0, \quad \Pi_{\mathcal{F}_i} \Gamma_i' z_i = z_i.$$

No inversion of a matrix of unbounded range occurs, since the coefficient matrix of the eliminated edges is $M^{-2} I$. Thus Γ_i' is the derivative at zero of the local constraint coordinates at the identity target. Since $\Gamma_b(0) = 0$ for every target b, differentiating (18.10) at $(c, z) = (0, 0)$, we obtain

$$u_s = 0, \qquad u_i = \dot{\mathcal{H}}_i u_{i+1} + \Gamma_i' z_i, \qquad u_0 = A_\Omega z,$$

where u_i is the derivative of $\operatorname{Log} U^{(i)}$ in the direction z. By (18.19), we have $u_i = Q_{[0,i)} u_0$, $\Pi_i^{\mathcal{T}} u_i = 0$, and $u_s = 0$, so $u_0 \in \ker G_\Omega$. Conversely, let $v \in \ker G_\Omega$ and set

$$v_i = Q_{[0,i)} v, \qquad z_i = \Pi_{\mathcal{F}_i} (v_i - \dot{\mathcal{H}}_i v_{i+1}).$$

The cochain $v_i - \dot{\mathcal{H}}_i v_{i+1}$ has zero tree entries and satisfies $Q_i (v_i - \dot{\mathcal{H}}_i v_{i+1}) = v_{i+1} - v_{i+1} = 0$. By (18.19) its eliminated entries are determined by its free entries, so it equals $\Gamma_i' z_i$. Since $v_s = 0$, descending induction shows that $v = A_\Omega z$. We conclude that A_Ω maps the free coordinates bijectively onto $\ker G_\Omega$, with inverse (18.16). This is the successive extraction of the averaged fields and of their free coordinates, written as a matrix, and it proves (1).

Next we prove (2). A contour has at most $4M - 3$ steps, so

$$\|Q_i\|_\infty \le 4M, \qquad \|Q_i\|_1 \le 24M, \qquad \|\dot{\mathcal{H}}_i\|_\infty \le 1, \qquad \|\dot{\mathcal{H}}_i\|_1 \le M^2.$$

For the column bound for Q_i, an interior edge of a block occurs in the contours of at most the six bonds incident to its block, and an interface edge only in the contours of its own bond; each such row has absolute sum at most $4M$. A bond has M^2 interface edges, which gives the column bound for $\dot{\mathcal{H}}_i$. We obtain $\|\Gamma_i'\|_\infty \le 1 + 4M^3$ and $\|\Gamma_i'\|_1 \le 1 + 24M^3$, and the bounds for A_Ω follow from (18.15), since a column of A_Ω belongs to a single scale $i \le J - 1$. For B_{ext} we multiply the row and column bounds of the factors in (18.16); stacking over i takes the maximum of the row bounds and the sum of the column bounds. By the Cauchy–Schwarz inequality, we have $\|Bv\|_2^2 \le \|B\|_\infty \|B\|_1 \|v\|_2^2$, and therefore $\|z\|_2 = \|B_{\mathrm{ext}} A_\Omega z\|_2 \le C_{\mathrm{ext},J} \|A_\Omega z\|_{\mathcal{L}_0}$. These estimates apply to each color and to the Euclidean norms over the colors.

We now prove the range bound. We assign to each edge its midpoint. Each nonzero entry of Q_i, $\dot{\mathcal{H}}_i$, or Γ_i' joins positions at periodic maximum distance at most $2M^{i+1}$, so every product in (18.15) or (18.16) has range at most $R_{M,J}$. Dividing coordinates by $M^s \ge 1$ only decreases this range. All these estimates hold after restriction to a block region: only equations of internal bonds were used, and deleting other equations does not increase a row sum, a column sum, or a range.

We now prove (3). For a patch P and each i, let r_i^P select the edges of $\mathcal{L}_i(P)$ among those of $\mathcal{L}_i$. Since all contours of a bond stay in its two complete endpoint blocks (Lemma 18.4), we have the matrix identity

$$Q_i^P r_i^P = r_{i+1}^P Q_i,$$

where the right side has zero coefficients on the input edges outside P; these zeros come from the supports of the contours, not from an extension of u by zero. The same identity holds for the rows of the trees. Iterating it and using $G_\Omega u = 0$, we obtain $G_P R_P u = 0$, that is, $R_P u \in \mathcal{V}_P$. This holds for every patch, including the patches next to the boundary of Ω. Every plaquette in $\mathcal{P}(P)$ has its four edges in $\mathcal{E}(P) \subset \mathcal{L}_0$, so $(d_P R_P u)_p = (du)_p$ for $p \in \mathcal{P}(P)$.

Next we show that the curl is injective on each space $\mathcal{V}_P$. A single block or an adjacent pair lifts injectively to a rectangular cuboid in $\mathbb{Z}^3$: its longest side has at most $2M^s - 1$ links, which is less than $n/2$ since $m \geq 4$. Let $h \in \mathcal{V}_P$ with $d_P h = 0$. A closed cochain on a rectangular cuboid is a gradient, as we now recall. Fix a corner o, and for a vertex x let τ_x be the coordinate-ordered path from o to x. For an edge (x, y), the closed chain $\tau_x + (x, y) - \tau_y$ is an integer combination of elementary squares in the cuboid: we move the last coordinate step through the portions of τ_x in later coordinates, and all squares used lie between the relevant coordinate values, hence in the cuboid. Pairing with h shows that $\varphi(x) = h(\tau_x)$ satisfies $h_{xy} = \varphi(y) - \varphi(x)$. By (18.18), $Q^P_{[0,i)} h$ is the gradient of the values of φ at the anchors of scale i. The tree equations at the finest scale make φ constant on each block of the first scale. If φ is constant on the blocks of scale i, the tree equations at scale i equate these constants along a connected tree in each block of scale $i + 1$. After s steps φ is constant on each final block. On a single block this implies $h = 0$. On a pair, the remaining equation of G_P for its coarse bond says, by (18.18), that the two final constants agree, so $h = 0$ on the pair as well. No equation with an endpoint in a final block outside Ω was used.

For $1 \leq s \leq J$ there are finitely many cuboids of these types, including the directions of the pairs. For each one with $\mathcal{V}_P \neq \{0\}$, we take an orthonormal basis matrix B_P of $\mathcal{V}_P$ and let σ_P be the least eigenvalue of $B_P^\mathsf{T} d_P^\mathsf{T} d_P B_P$, which is positive by the injectivity just proved; if $\mathcal{V}_P = \{0\}$ we set $\sigma_P = 1$. Let σ_J be the minimum of these finitely many numbers. It depends only on M and J, and we have $\|h\|^2 \leq \sigma_J^{-1} \|d_P h\|^2$ for $h \in \mathcal{V}_P$.

It remains to prove the covering and overlap bounds in (18.17). Every edge of $\mathcal{L}_0$ has its endpoints either in one final block or in two adjacent final blocks of Ω; the first kind is covered by the single block and the second by the pair. This gives the first inequality, including for isolated blocks. The second inequality follows from (3) and the bound on each $\mathcal{V}_P$. For the third, fix a plaquette p and one of its vertices x. Every patch containing p contains x, hence the final block of x. There are at most seven such patches: that block and the pairs formed with its six possible neighbors. So each plaquette occurs in at most

seven of the sets $\mathcal{P}(P)$; a plaquette that meets three or four final blocks may occur in none. Using (3), we obtain (18.17). □

We now state the main result. Its objective is the effective classical action at depth d_0, evaluated on the reconstruction of a block region and completed outside Ω as described in the statement.

Theorem 18.12. *Fix M and J, and let $\kappa_* > 0$ be the constant of Theorem 14.8. Then*

$$E''_{d_0}(0) \geq \kappa_* \operatorname{curl}^{\mathsf{T}} \operatorname{curl} \qquad \text{for every depth } d_0 \geq 0, \tag{18.20}$$

as quadratic forms on real link variations. Let $1 \leq s \leq J$, $m \geq 4$, let Ω be a block region and $d_0 \geq 0$ a depth, and set

$$F_R(c, z; \xi) = E_{d_0}(\Psi_R(c, z; \xi)).$$

Here $\Psi_R(c, z; \xi)$ is the logarithm, on all links of the torus, of the reconstruction $\Phi_\Omega(c, z)$ of Definition 18.6, completed outside Ω by the small values with logarithms ξ prescribed by the current frozen coordinates (at the first block integration, by the completion of Definition 18.13), and with logarithm zero at the torus labels that lay outside earlier block regions. The parameters ξ may be complexified on the construction chart. Frozen coordinates from earlier block integrations and arbitrary data in the fixed complement are not arguments of this analytic action. The following statements hold with uniform constants and radii; in particular they are independent of the widths chosen later, of the shape of Ω (which may contain isolated final blocks), of d_0, and of the values of the frozen coordinates.

1. *On a common list of coordinates, the linearizations at zero E_1 and E_0 of the reconstruction on Ω and of the reconstruction on the whole torus with the complementary coordinates set to zero, defined in* (18.22)*, satisfy $E_1 = E_0 + D_W$; here E_0 and E_1 denote linear embeddings, not effective classical actions. Both indices of every nonzero entry of D_W lie in a band of fixed width L_J around the boundary W, the weighted rows and columns of D_W are at most C_J, and its rank is at most $C_J|W|$. On matched coordinates in the common chart, the nonlinear formulas for the outputs in Ω of the two reconstructions agree away from this band. Prescribed values in the fixed complement may differ; their effect is estimated as a bounded source in Lemma 18.15. Coarse outputs on bonds across the boundary of the block region that are not prescribed are holomorphic functions of $(c, z; \xi)$, with all their derivatives. This compares two embeddings; it does not identify their fibers.*
2. *There are $\nu_J, C_{\mathrm{ext},J}, \lambda_J, Q_J > 0$ with the following properties. Let $u = D_z\Psi_R(0)z$; its restriction to $L_\Omega = \mathcal{L}_0$ lies in* $\ker G_\Omega$*. Then*

$$\|\operatorname{curl} u\|_2^2 \geq \nu_J \|u\|_{L_\Omega}^2, \qquad \|z\|_2 \leq C_{\mathrm{ext},J} \|u\|_{L_\Omega},$$

$$K_R^0 = F_{R,zz}(0) \geq \lambda_J I, \qquad \lambda_J = \kappa_* \nu_J / C_{\mathrm{ext},J}^2, \qquad \|K_R^0\|_{a_J} \leq Q_J.$$

One may take $\nu_J = \sigma_J/7$ and $C_{\mathrm{ext},J}$ as in Lemma 18.11. Every principal block of K_R^0 and every real Schur complement of K_R^0 is bounded below by $\lambda_J I$. Let z_H be the free coordinates of the torus outside Ω. On the common list (z_L, z_H), the Hessian at $(c, z, \xi) = 0$ of the interpolation between the joint objective on the torus and $F_R + \|z_H\|_2^2/2$ is bounded below by $\lambda_{U,J} I$, where $\lambda_{U,J} = \min(\lambda_J, \lambda_{T,J}, 1) > 0$ and $\lambda_{T,J}$ is the corresponding flat bound on the torus.

3. *There are radii $r_{a,J}, r_{z,J}, \rho_J, \beta_{\mathrm{rec},J} > 0$, a rate $a_J > 0$, and an inverse bound I_J such that, on an open product containing*

$$\|c\|_\infty \le 2\rho_J, \qquad \|z\|_\infty \le r_{z,J}, \qquad \|\xi\|_\infty \le 2\beta_{\mathrm{rec},J},$$

the reconstruction lies in $B_{r_{a,J}}$, inside the identity chart on which E_{d_0} is controlled, and

$$\|F_{R,zz} - K_R^0\|_{a_J} \le Q_J(\|c\|_\infty + \|z\|_\infty + \|\xi\|_\infty) \le \lambda_J/8.$$

Mixed derivative matrices, and tensors of order $l \ge 2$ with each index fixed in turn, are bounded by $l! C_J^{l+1}$. The inverse of the complex free Hessian has weighted row-column norm at most I_J at a fixed smaller rate.

4. *Choose the parameter radii below the solution radius so that*

$$I_J Q_J(2\rho_J + 2\beta_{\mathrm{rec},J}) < r_{z,J}/16, \qquad 8G_J(2\rho_J + r_{z,J} + 2\beta_{\mathrm{rec},J}) < \min(r_{\Gamma,J}, r_E),$$

where G_J and $r_{\Gamma,J}$ are the coefficient bound and the radius of the reconstruction in (18.21)*. Then there exists a unique holomorphic stationary point $z_R = z_R(c;\xi)$ in the free box,*

$$F_{R,z}(c, z_R; \xi) = 0, \qquad \|z_R\|_\infty \le C_J(\|c\|_\infty + \|\xi\|_\infty) < r_{z,J}/8.$$

It has factorial coefficient bounds on output rows and on volume-normalized input columns on a smaller fixed product. For real data it is the unique minimizer of $F_R(c, \cdot\,; \xi)$ in the convex free box.

5. *Conditional minimizers over initial segments of the scales exist on smaller products of the coarser free coordinates around this joint minimizer, chosen so that the bounds* (18.31) *on the Hessian and on the inverse times the gradient hold. No claim is made on other slices of the joint box.*

Proof of Theorem 18.12. The proof has six steps. In the first, we construct the reconstruction with coefficient bounds that do not depend on the size of the lattice, and compare the embeddings on Ω and on the torus. In the second, the patch inequality gives the coercivity of the curl. In the third, we derive (18.20) from Theorem 14.8 and obtain the lower bound on K_R^0. In the fourth, we bound the Hessian on a complex product and choose the radii. In the fifth, we construct the minimizer by a contraction argument, and in the sixth, the conditional minimizers. All constants are constructed on larger products before any of the later widths is chosen. If the list of free coordinates is empty, the minimizer is empty and the matrices are zero-dimensional, so we assume that it is nonempty.

Step 1: local charts and comparison of embeddings. For one averaging step the reconstruction is the eliminated-edge solution of Lemma 6.3, restricted to internal bonds as in Definition 18.6. Let L_M bound its stencil radius in output units of one step. Its local scalar majorants can be chosen of the form $G_M t/(1 - G_M t)$ on a fixed radius. This absolute coefficient bound does not depend on the size of the lattice, for the following reason. Each defining group product reads a bounded number n_M of variables. Matrix exponentials are bounded coefficientwise by e^t, and on $\|V - I\| < 1$ the logarithm has the convergent series $\sum_{k\geq 1}(-1)^{k+1}(V-I)^k/k$. The inverse of the linear coefficient of an eliminated edge is $M^2 I_3$, and the nonlinear equation for that edge has zero constant term and a quadratic remainder after its linear part is removed. On a sufficiently small fixed radius, the implicit-series statement of Lemma 5.3 gives G_M and factorial coefficients for the local inverse. Since only n_M variables occur in each local equation, summing over its finite stencil, also with any input fixed, we obtain absolute row and column bounds.

By composing at most J such maps, with the embeddings of positions, we obtain numbers $G_J, L_J, r_{\Gamma,J} > 0$ such that the logarithm Ψ_R of the reconstruction is holomorphic, vanishes at zero, and has a majorant series with nonnegative coefficients on that radius, with the bounds

$$\|\Psi_R\|_{\text{coeff}} \leq \frac{G_J T}{1 - G_J T}, \qquad \|D^l \Psi_R\|_{\text{all indices}} \leq l! G_J^{l+1} \quad (l \geq 1) \tag{18.21}$$

on a fixed smaller product. Here $T = r_c + r_z + r_\xi$, where r_c, r_z, and r_ξ are the maximal radii of the coarse logarithms c, of the free coordinates z, and of the current frozen coordinates ξ, respectively; the second bound absorbs the fixed ratios of radii. The first norm is a row majorant for the image; the derivative bounds include every input column. One may take $L_J \geq \sum_{i=0}^{J-1} M^i L_M$, and enlarge G_J for the finitely many compositions. There are at most a fixed multiple of JM^{3J} labels per unit cube of the output lattice, and v_J includes this multiplicity. Volume-normalized input columns acquire their mesh-volume ratios under composition, by Lemma 5.3, and these factors are bounded by fixed powers of M^J.

We now compare the embeddings, before any minimization. Let $\Psi_T(c_T, z_T)$ be the logarithm of the reconstruction on the whole torus, and let P_L insert the free coordinates of Ω into the list of free coordinates of the torus, with zero in every other slot. At matched data we use $c_T = c \oplus 0$ and $z_T = P_L z$. The two linearized embeddings on this common list are

$$E_1 z = D_z \Psi_R(0, 0; 0) z, \qquad E_0 z = \frac{d}{dt} \Psi_T(0, t P_L z)\Big|_{t=0}. \tag{18.22}$$

The symbols E_0 and E_1 in this formula and in (18.23) denote linear embeddings, not effective classical actions. All current frozen coordinates and logarithms of the coarse links vanish in these derivatives, and both reconstructions vanish there. At one scale, the equations on Ω and on the torus for an internal bond have the same two endpoint blocks,

the same internal target, and the same free values, so their eliminated-edge solutions agree by local uniqueness. The additional equations of the torus concern bonds meeting the complement. Descending through the scales, a change in such an equation can propagate only through the accumulated stencil of width L_J of Lemma 18.4. Therefore, with matching free values in Ω and zero complementary torus values, the nonlinear formulas for the outputs in Ω agree outside a band of fixed width around W. Prescribed values in the fixed complement are separate formulas and may differ there. An input in Ω farther than one further stencil from the band cannot affect a changed formula, and we enlarge L_J once to include that stencil. Differentiating with the conventions of (18.22), we obtain

$$E_1 = E_0 + D_W, \qquad (D_W)_{ex} = 0 \text{ unless } e, x \text{ lie in the } L_J\text{-band around } W. \tag{18.23}$$

Here the L_J-band is the set of positions within distance L_J of W. The weighted row and column bounds follow from the finite range, (18.21), and the density bound. We cover the band by balls of radius $L_J + 1$ around the positions of W. Each ball contains at most $Cv_J(L_J + 2)^3$ labels, so the number of nonzero output rows of D_W, and hence its rank, is at most $C_J|W|$.

Every coarse output on a bond across the boundary of the block region that is not prescribed is obtained by applying the finite group products of T^s_M to the reconstructed field. In the chart it is a holomorphic function of (c, z, ξ), with all its derivatives given by these products and (18.21). No equation sets it to a prescribed value, so (18.23) compares two embeddings of a common list and asserts no equality of their fibers.

Step 2: coercivity of the curl. Let $u = D_z\Psi_R(0)z$. On $\mathcal{L}_0$ it equals $A_\Omega z$, by Lemma 18.11(1), so its restriction lies in $\ker G_\Omega$. Then (18.17) implies

$$\|u\|^2_{\mathcal{L}_0} \le \frac{7}{\sigma_J} \sum_{p \in \mathcal{P}_\Omega} |(du)_p|^2 \le \frac{7}{\sigma_J} \|\operatorname{curl} u\|_2^2,$$

where $\operatorname{curl} u$ is the curl of the completed variation on all plaquettes of the torus. In the last inequality we used that restricting a sum of squares to the plaquettes of the patches can only decrease it; since these plaquettes have all their edges in $\mathcal{L}_0$, variations of the completed boundary values induced by the tree-path transports to the basepoints do not enter. This proves the first inequality of (2) with $\nu_J = \sigma_J/7$. The second inequality is Lemma 18.11(2); it shows in particular that a nonzero vector of free coordinates is visible on the internal links, also for an isolated final block.

Step 3: the lower bound on the Hessian at the identity. The quadratic form $E''_{d_0}(0)$ is the Hessian at the identity, that is, the effective Maxwell quadratic form of Theorem 8.3 (see Theorem 10.10). We derive (18.20) from Theorem 14.8, which gives $E_{d,\mathrm{sat}} \ge \kappa_* E_0$ for every integer $d \ge 0$ on the domain of the gauge-invariant extension $E_{d,\mathrm{sat}}$ of E_d, whether or

not an effective interaction is attached to that depth. We choose a ball of link logarithms at the identity that is contained both in the construction chart of that extension and in the domain used here; on it, $E_{d,\mathrm{sat}}$ equals the analytic function E_d. For a fixed real variation u, we choose $|t|$ so small that tu lies in this ball. Then for every $d_0 \geq 0$ we have $E_{d_0}(tu) \geq \kappa_* E_0(tu)$, with the same κ_*. Both functions vanish at zero and are stationary there: for E_{d_0} this follows from Theorems 10.10 and 10.11 by induction from the Wilson action. Further, $E_0(tu) = t^2 \| \operatorname{curl} u\|_2^2/2 + O(t^3)$, by expanding the plaquette product and using $4q(e^X) = |X|^2/2 + O(|X|^4)$. Dividing the inequality by $t^2/2$ and letting $t \to 0$ proves (18.20) for every integer depth. Only this inequality from Theorem 14.8 has been used, and this step gives no positivity at a nonflat coarse field.

By Lemma 18.8, the Hessian of $E_{d_0} \circ \Psi_R$ at zero has no term involving the gradient of the action, since $DE_{d_0}(0) = 0$. Using (18.20) and Step 2, we obtain

$$z^{\mathsf{T}} K_R^0 z \geq \kappa_* \| \operatorname{curl} D_z \Psi_R(0) z\|_2^2 \geq \frac{\kappa_* \nu_J}{C_{\mathrm{ext},J}^2} \|z\|_2^2, \tag{18.24}$$

which is the claimed value of λ_J. The same patch construction with every final block of the torus gives a lower bound $\lambda_{T,J} > 0$ for the joint free Hessian on the torus. Every principal block of either joint matrix has the same lower bound, and (18.6) implies the same lower bound for its real Schur complements. On the common list (z_L, z_H), where z_L are the free coordinates of Ω, the interpolating Hessian at the identity is

$$H_t^0 = (1-t) H_T^0 + t(K_R^0 \oplus I_H), \qquad 0 \leq t \leq 1,$$

where H_T^0 is the joint Hessian at the identity on the torus and I_H the identity on the z_H coordinates. It is bounded below by $\lambda_{U,J} = \min(\lambda_J, \lambda_{T,J}, 1) > 0$. This is a convex combination of two objectives on a common list of coordinates, not an identification of fibers. All the flat and nonflat estimates below can be chosen uniformly in t, using this common lower bound and the maximum of the two coefficient bounds.

Step 4: analytic products and the inverse of the free Hessian. Let $b_J > 0$ be smaller than the rate a_E of the torus tensors after the transfer of positions to output units and the conversion to the graph metric; this conversion divides a Euclidean rate by $\sqrt{3}$. We include the finite-stencil weights of (18.21). We compose the torus tensors of Theorem 10.11 with the majorant series of Ψ_R, using Lemma 5.3. The scalar composition converges on a fixed product, and after enlarging C_J and Q_J we have

$$\|D^l F_R\|_{b_J,\text{all indices}} \leq l! C_J^{l+1} \quad (l \geq 2), \qquad \|K_R^0\|_{b_J} \leq Q_J. \tag{18.25}$$

The mixed matrices in z, c, and ξ satisfy the same bound after enlargement. The labels of ξ have their positions on the input lattice and their own density, not the density of the output lattice. The volume-normalized column bounds follow from the contraction rule, with the volume factors kept in each factor.

At a general point of the product, the Hessian is

$$F_{R,zz} = \Psi_{R,z}^{\mathsf{T}} E''_{d_0}(\Psi_R)\Psi_{R,z} + E'_{d_0}(\Psi_R)\Psi_{R,zz}, \tag{18.26}$$

and the last term, which contains the gradient of the action, is kept. The gradient bound $\|E'_{d_0}(A)\|_\infty \le C_E\|A\|_\infty$ is part of Theorem 10.11. We integrate the third-derivative bound of the composed objective along the segment from zero to (c, z, ξ), which lies in its product domain. In the weighted row-column norm, we obtain

$$\|F_{R,zz}(c, z; \xi) - K_R^0\|_{b_J} \le Q_J(\|c\|_\infty + \|z\|_\infty + \|\xi\|_\infty), \tag{18.27}$$

$$\|F_{R,z}(c, 0; \xi)\|_\infty \le Q_J(\|c\|_\infty + \|\xi\|_\infty). \tag{18.28}$$

These estimates also follow by expanding all the terms of (18.26); integrating the complete third derivative ensures that none of the terms involving the gradient of the action or the second derivative of the coordinates is omitted.

We apply Lemma 18.3(3) with the lower bound $\lambda_{U,J}$, the bound Q_J, and the rate b_J to every flat principal block of free coordinates and to every interpolating Hessian. We obtain a common smaller rate $a_J > 0$ and a flat inverse bound; we take I_J so large that it bounds these inverses and their perturbations. For example, the constants μ and C_R of that lemma give the flat bound $C_R/\lambda_{U,J}$ and the perturbed bound $4C_R/(3\lambda_{U,J})$ on a sufficiently small coefficient product. We enlarge I_J and Q_J if necessary; these enlargements precede every choice of radius. Bounds at the rate b_J imply the same bounds at the rate a_J.

We now choose the radii, on a product larger than the one in the statement. Let $r_0 = \min(r_{\Gamma,J}, r_E)$, where r_E is replaced by a strictly smaller radius of the torus chart if necessary. We first choose $r_{z,J} > 0$, and then $\rho_J, \beta_{\mathrm{rec},J} > 0$, so that, with $T_+ = 2r_{z,J} + 4\rho_J + 4\beta_{\mathrm{rec},J}$,

$$\begin{gathered} Q_J T_+ < \min\{\lambda_{U,J}/8, (8I_J)^{-1}\}, \qquad 8G_J T_+ < r_0, \\ I_J Q_J(4\rho_J + 4\beta_{\mathrm{rec},J}) < r_{z,J}/16. \end{gathered} \tag{18.29}$$

We also require that the nonconstant part of the Hessian on this product satisfies the condition of Lemma 18.3(3) with the factor $1/4$ in (18.5). By (18.25) this perturbation tends to zero with T_+, so this is one more upper bound on the radii. All these inequalities can be satisfied: we first choose $r_{z,J}$ to satisfy the two inequalities that involve it alone, with strict inequality, and then make the two parameter radii sufficiently small. We choose $r_{a,J} < r_E$ larger than the bound on the image in (18.21) at T_+, which is possible by the inequality $8G_J T_+ < r_0$.

These choices hold on the open product defined by $\|z\|_\infty < 2r_{z,J}$, $\|c\|_\infty < 4\rho_J$, and $\|\xi\|_\infty < 4\beta_{\mathrm{rec},J}$, which contains the closed product of the statement. In particular the right side of (18.27) is at most $\lambda_{U,J}/8 \le \lambda_J/8$ there, the image lies in $B_{r_{a,J}}$, and (18.29) implies both inequalities on the parameter radii in (4). The inverse of the complex free Hessian is bounded by I_J at its smaller rate by the resolvent series (18.5), not by a positivity argument at complex data. This proves (3).

Step 5: the constrained minimizer and its coefficients. On the free box we use the map

$$\mathcal{T}_{c,\xi}(z) = z - (K_R^0)^{-1} F_{R,z}(c, z; \xi).$$

By (18.27) and (18.29), its derivative has maximal row norm at most $1/8$. By (18.28), its value at zero is at most $I_J Q_J(\|c\|_\infty + \|\xi\|_\infty) < r_{z,J}/16$ on the larger parameter product. Thus it maps the closed box of radius $r_{z,J}$ into itself, strictly. Starting at zero, its iterates satisfy $\|z^{(n+1)} - z^{(n)}\|_\infty \le 8^{-n} r_{z,J}/16$. Their geometric sum converges to a fixed point in the box, and it is unique, since the distance between two fixed points would be at most one eighth of itself. Since $\|z_R\|_\infty \le \|\mathcal{T}_{c,\xi}(0)\|_\infty + \|z_R\|_\infty/8$, we have

$$\|z_R\|_\infty \le \frac{8}{7} I_J Q_J(\|c\|_\infty + \|\xi\|_\infty) < r_{z,J}/8,$$

which gives the stated C_J. The iterates are holomorphic, and their convergence is geometric and uniform on compact subsets of the product. By the Cauchy integral formula in each coordinate, the limit is holomorphic: the integral of the uniform tail tends to zero, also on each smaller contour used for derivatives.

For the absolute coefficient bounds with each index fixed, we use the majorant version of this iteration. We subtract the flat linear part. By (18.25), the nonlinear remainder is quadratic and has the majorant $C_J(t + Y)^2/[1 - C_J(t + Y)]$. The coefficients of the solution, and their versions with a specified input index, are therefore bounded by the majorant series Y with nonnegative coefficients determined by

$$Y = C_J t + \tfrac{1}{2} Y + \frac{C_J(t + Y)^2}{1 - C_J(t + Y)}. \tag{18.30}$$

All hypotheses of the implicit-series statement of Lemma 5.3 have now been checked: zero constant term, a bounded inverse of the linear part, tensor bounds with each index fixed, the bound $1/8$ on the derivative, and a strictly larger product. The lemma therefore gives factorial coefficient bounds on a smaller fixed product. Fixing a chosen current input index in the same majorant series, we obtain the bound on volume-normalized columns. One spatial rate is used throughout, with at most the single initial reduction for external trees described in Lemma 5.3.

At real data the objective and the chart are real. Complex conjugation maps a stationary point in the box to a stationary point in the same box, and uniqueness shows that z_R is real. Throughout the box the real Hessian is at least $7\lambda_{U,J} I/8$, by (18.27) and (18.29). For a real z in the convex box, by Taylor's formula at z_R with $h = z - z_R$, we have

$$F_R(c, z; \xi) - F_R(c, z_R; \xi) = \int_0^1 (1 - t) h^{\mathsf{T}} F_{R,zz}(c, z_R + th; \xi) h \, dt \ge \frac{7\lambda_{U,J}}{16} \|h\|_2^2.$$

We conclude that z_R is the unique minimizer in the box. This proves (4).

Step 6: domains for the conditional minimizers. It remains to specify the domains of the conditional minimizers. Let I be an initial segment of the scales, write $z = (u, y)$ with $u = z_I$ and $y = z_{I^c}$, and let $z^0 = z_R(c;\xi)$. We use the parameters $v = y - z^0_{I^c}$ and solve for $h = u - z^0_I$. The matrix $A_I = F_{R,uu}(c, z^0; \xi)$ has a common inverse bound I'_J, by the estimates for principal blocks proved above. We choose a solution radius $r_I > 0$ inside the larger domain, and then a smaller radius $\eta_I > 0$ for the coarser parameters v, such that throughout the corresponding product

$$\begin{aligned} \|A_I^{-1}(F_{R,uu} - A_I)\|_{\mathrm{coeff}} &\le 1/4, \\ \|A_I^{-1} F_{R,u}(c, z^0_I, z^0_{I^c} + v; \xi)\|_{\mathrm{coeff}} &\le r_I/8. \end{aligned} \tag{18.31}$$

The first condition holds after shrinking the product, by the convergent majorant of the third derivative. In the second, the gradient vanishes at $v = 0$, and its change is

$$\int_0^1 F_{R,uy}(c, z^0_I, z^0_{I^c} + tv; \xi) v \, dt.$$

Its coefficient norm is at most $Q'_J \|v\|$, by the bounds on mixed derivatives, so $I'_J Q'_J \eta_I \le r_I/8$ suffices. The solution radius is chosen first and the parameter radius second; they are not equal.

The map $h \mapsto h - A_I^{-1} F_{R,u}$ now has derivative at most $1/4$ and value at most $r_I/8$ at $h = 0$. It maps the box of radius $r_I/2$ into itself, and the convergence and majorant arguments of Step 5 apply. The conditional minimizer a_I is holomorphic, real at real data, and satisfies

$$a_I(c, z^0_{I^c}; \xi) = z^0_I, \qquad D_y a_I = -F_{R,uu}^{-1} F_{R,uy}.$$

Since there are at most J initial segments, their solution radii and parameter radii have a common positive minimum. For a sequential application we also choose a smaller radius for the fluctuation inputs. The finite composition of these conditional minimizers and of their inverse square roots equals the joint minimizer when all the inputs $g_i w_i$ vanish, and its deviation has a majorant $C_{\mathrm{seq},J} t / (1 - C_{\mathrm{seq},J} t)$. We choose $r_q > 0$ so that this expression is less than a quarter of the least of the preceding solution and parameter radii. All sequential images then lie in the domains of the conditional minimizers. This is a choice for finitely many scales, independent of the number of sites. Lemma 18.8 identifies successive and joint minimizers there and gives the factors M^i. The real lower bounds for principal blocks and Schur complements persist there by (18.6), and their complex coefficient bounds follow from the Schur calculus of Lemma 18.3.

The conditions (18.31) are part of the smaller products just constructed. Every constant used to obtain them comes from the finite local formulas, the tensor bounds on the torus, the constants of the patch inequality, and the density bound. Taking maxima and minima over $s \le J$ and over initial segments therefore gives uniform constants, independent in particular of isolated final blocks, of the later widths, and of the values of the frozen coordinates. This completes the proof. □

18.7 The first block integration

At depth zero, we identify the completed objective with the part of the Wilson action that depends on (c, z), and we give the exact form and range of its Hessian, uniformly in the arbitrary frozen group values deep in the fixed complement, as used in Section 21. The restriction and extraction maps are those of Lemma 18.11.

Definition 18.13. Use Definition 18.6 at the first block integration, and let $\mathcal{E}(\Lambda)$ be the set of all positive input links.

1. *Dependencies.* Collect in a finite list all contours $F_{i,c',x}$ with $c' \in \mathcal{L}_{i+1}$, their reference paths and tree paths, and the tree-path transports (18.11) to the basepoints of frozen coordinates on links across the boundary, with the edges of the coarser scales expanded recursively through the definition of T_M. The formulas of the local constraint coordinates and of the Haar disintegration densities are included in this list. Let $\mathcal{E}_\Omega^{\mathrm{dep}}$ be the union of the input links on which these formulas depend. If a further formula at the boundary is to be used analytically, its input links are added to this list before the near links are fixed.
2. *Near and deep links.* Let $\mathcal{P}_{\mathrm{inc}}$ be the set of plaquettes p with at least one edge in $\mathcal{L}_0$, and set
$$\mathcal{E}_\Omega^{\mathrm{near}} = \Big(\mathcal{E}_\Omega^{\mathrm{dep}} \cup \bigcup_{p \in \mathcal{P}_{\mathrm{inc}}} \partial p\Big) \setminus \mathcal{L}_0, \qquad \mathcal{E}_\Omega^{\mathrm{deep}} = \mathcal{E}(\Lambda) \setminus (\mathcal{L}_0 \cup \mathcal{E}_\Omega^{\mathrm{near}}). \tag{18.32}$$
Further links may be added to $\mathcal{E}_\Omega^{\mathrm{near}}$; none is needed below.
3. *Near values.* Assume that every near link carries a value in the identity chart. The near values b^{near} are independent small group values on $\mathcal{E}_\Omega^{\mathrm{near}}$: on a link with both endpoints outside Ω_0 the value itself, and on a link across the boundary its based transport. If a link (x, y) across the boundary is first given by its value a_{xy}, we set $b_e = \Theta_x(U) a_{xy}$ at fixed field of the block region; this is the Haar translation of Lemma 18.7, and all indicators are kept under this substitution. The logarithms of the near values are denoted ξ.
4. *Completion.* For a link $e = (x, y)$ across the boundary, with $x \in \Omega_0$, $y \notin \Omega_0$, and based transport b_e, set
$$U_{xy}^{\mathrm{act}} = \Theta_x(\Phi_\Omega)^{-1} b_e; \tag{18.33}$$
for a positive link whose endpoint in Ω_0 is its terminal endpoint, we apply this rule to the reversed link and invert. On the remaining links we set
$$U_e^{\mathrm{act}}(c, z; \xi, \eta) = \begin{cases} \Phi_{\Omega,e}(c, z), & e \in \mathcal{L}_0, \\ b_e, & e \in \mathcal{E}_\Omega^{\mathrm{near}} \text{ with both endpoints outside } \Omega_0, \\ \eta_e, & e \in \mathcal{E}_\Omega^{\mathrm{deep}}, \end{cases} \tag{18.34}$$

where $\eta \in \mathrm{SU}(2)^{\mathcal{E}_\Omega^{\mathrm{deep}}}$ are the frozen group variables in the fixed complement on the deep links (the deep frozen group variables); they are arbitrary real group values, not small analytic logarithms. The analytic completion $U^{\mathrm{an}}(c, z; \xi)$ is defined by the same rules with $\eta_e = I$ on the deep links, and we write $\Psi_R = \operatorname{Log} U^{\mathrm{an}}$, componentwise on the chart.

5. *Varying plaquettes.* Let $f_p(c, z; \xi) = 4q(U_p^{\mathrm{an}}(c, z; \xi))$, and

$$\mathcal{P}_{\min} = \{p \in \mathcal{P}_{\mathrm{inc}} : f_p(\cdot, \cdot\,; \xi) \text{ is nonconstant in } (c, z) \text{ for some small real } \xi\}. \quad (18.35)$$

Fix a list $\mathcal{P}_{\mathrm{var}}$ with $\mathcal{P}_{\min} \subseteq \mathcal{P}_{\mathrm{var}} \subseteq \mathcal{P}_{\mathrm{inc}}$, and define the objective of the first block integration

$$F_{\mathrm{bare}}(c, z; \xi) = \sum_{p \in \mathcal{P}_{\mathrm{var}}} f_p(c, z; \xi). \quad (18.36)$$

Every link across the boundary is a near link: if $x \in \Omega_0$ is the endpoint of such a link in direction k, a step from x in a transverse direction toward the interior of the final block of x gives a plaquette that contains the link and an edge of $\mathcal{L}_0$, since a final block has at least three vertices per side. This holds also at corners and at periodic seams. The requirement that the near values lie in the identity chart is the condition imposed on the protected neighborhoods in Section 21; the conversion between the value a_{xy} and the based transport b_e is a finite group product, whose smallness is also controlled there. Since $\Theta_x(\Phi_\Omega(c, z)) = I$, the value (18.33) of such a link equals b_e on the reconstruction. Hence, at fixed frozen coordinates, the derivatives in (c, z) of all links outside Ω vanish. Completion by zero means logarithm zero, that is, the group value I; it does not mean solving the block averaging constraints of the torus with the missing targets set to zero. Coarse outputs on bonds across the boundary of the block region are evaluated by T_M on the completion, and they are not imposed as additional equations. Exceptional values of the Borel extension of T_M at the deep frozen group variables are kept in the measure, and no logarithm of such a value enters U^{an}.

The list $\mathcal{P}_{\min}$ is fixed on the chart, not chosen anew at each value of the frozen coordinates. A plaquette function outside $\mathcal{P}_{\min}$ is also independent of the complex variables: its derivatives in (c, z) vanish on the real product, hence, by the identity theorem applied successively in each scalar coordinate, on the complex product. If the split is made before some internal constraint coordinates are eliminated, the list of varying plaquettes may be larger than $\mathcal{P}_{\min}$. All conclusions below hold for every fixed list between $\mathcal{P}_{\min}$ and $\mathcal{P}_{\mathrm{inc}}$.

For the statement of the next lemma, let $d_{\mathrm{var}} u = ((du)_p)_{p \in \mathcal{P}_{\mathrm{var}}}$, let ι_Ω be the extension by zero from edge cochains on $\mathcal{L}_0$ to all input links, and let $\widehat{A}_\Omega = \iota_\Omega A_\Omega$, with A_Ω as in (18.15). For a patch P define a linear map from cochains on the varying plaquettes to

cochains on the plaquettes of P by

$$(R_P^{(2)} v)_p = \begin{cases} v_p, & p \in \mathcal{P}(P) \cap \mathcal{P}_{\mathrm{var}}, \\ 0, & p \in \mathcal{P}(P) \setminus \mathcal{P}_{\mathrm{var}}. \end{cases} \tag{18.37}$$

Lemma 18.14. *Use Definition 18.13. The following statements hold.*

1. *For $p \in \mathcal{P}_{\mathrm{inc}}$, the plaquette variables of U^{act} and U^{an} agree for every η. The sum of the Wilson terms of the plaquettes not in $\mathcal{P}_{\mathrm{var}}$, evaluated at U^{act}, is independent of (c, z); denote it by $E_{\mathrm{hole}}(\xi, \eta)$. Then*

$$S_W(U^{\mathrm{act}}) = F_{\mathrm{bare}}(c, z; \xi) + E_{\mathrm{hole}}(\xi, \eta) \tag{18.38}$$

and

$$E_0(\Psi_R(c, z; \xi)) = F_{\mathrm{bare}}(c, z; \xi) + C_\Omega(\xi), \qquad C_\Omega(\xi) = \sum_{p \notin \mathcal{P}_{\mathrm{var}}} f_p(0, 0; \xi), \tag{18.39}$$

where $E_0 = S_W$ is the Wilson action. The function C_Ω is not the energy of the deep frozen group variables. Every derivative that involves (c, z) is the same on the two sides of (18.39).

2. *Let $u = D_z \operatorname{Log} U^{\mathrm{an}}(0, 0; 0) z$ and $K_\Omega = \partial_z^2 F_{\mathrm{bare}}(0, 0; 0)$. Only the variables of the block region and the near values vanish here; the deep frozen group variables η are arbitrary, and the same u on the varying plaquettes and the same K_Ω are obtained from U^{act}, independently of η. Then $u = \widehat{A}_\Omega z$, and for every patch P,*

$$R_P u \in \mathcal{V}_P, \qquad d_P R_P u = R_P^{(2)} d_{\mathrm{var}} u. \tag{18.40}$$

Further,

$$\|u\|_{\mathcal{L}_0}^2 \le \sum_{P \in \mathfrak{P}_\Omega} \|R_P u\|^2, \qquad \sum_{P \in \mathfrak{P}_\Omega} \|R_P^{(2)} d_{\mathrm{var}} u\|^2 \le 7 \|d_{\mathrm{var}} u\|^2, \tag{18.41}$$

$$\|d_{\mathrm{var}} u\|^2 \ge \frac{\sigma_J}{7} \|u\|_{\mathcal{L}_0}^2, \qquad z = B_{\mathrm{ext}} u|_{\mathcal{L}_0}, \qquad \|z\|_2 \le C_{\mathrm{ext},J} \|u\|_{\mathcal{L}_0}, \tag{18.42}$$

with σ_J, B_{ext}, and $C_{\mathrm{ext},J}$ as in Lemma 18.11.

3. *We have*

$$K_\Omega = \widehat{A}_\Omega^{\mathsf{T}} d_{\mathrm{var}}^{\mathsf{T}} d_{\mathrm{var}} \widehat{A}_\Omega, \qquad \lambda_{M,J} I \le K_\Omega \le Q_{M,J} I, \qquad \lambda_{M,J} = \frac{\sigma_J}{7 C_{\mathrm{ext},J}^2}, \tag{18.43}$$

where $Q_{M,J} = 16 a_1 a_\infty$ with $a_\infty = J(1 + 4M^3)$ and $a_1 = M^{2(J-1)}(1 + 24M^3)$. In positions measured in output units,

$$(K_\Omega)_{ab} = 0 \qquad \text{if } \operatorname{dist}_\infty(a, b) > D_{M,J} = 2R_{M,J} + 2. \tag{18.44}$$

Principal submatrices of K_Ω satisfy the same lower bound, the same upper bound, and the same range condition. Real Schur complements of K_Ω are bounded below by $\lambda_{M,J}$ and have uniform exponentially weighted row and column bounds; no finite range is asserted for them.

4. *There are a chart radius $\epsilon_{M,J} > 0$ and a constant C_{lip}, depending in addition only on a fixed choice of the local analytic chart, such that for real (c, z, ξ) with $\max(\|c\|_\infty, \|z\|_\infty, \|\xi\|_\infty) \le \epsilon_{M,J}$,*

$$\partial_z^2 F_{\mathrm{bare}}(c, z; \xi) \ge \tfrac{1}{2}\lambda_{M,J} I. \tag{18.45}$$

All constants depend only on M, J, and the coordinate conventions, and are independent of m, of the block region, of its number of components and holes, of its topology, of the widths of the protected neighborhoods, and of the deep frozen group variables. No uniformity as $J \to \infty$ is claimed. For an empty list of free coordinates the statements on matrices and on the extraction hold with the conventions for zero-dimensional spaces. By (18.39)*, K_Ω is the matrix K_R^0 of Theorem 18.12 at depth zero, where* (18.20) *holds with $\kappa_* = 1$, and* (18.43) *is the corresponding case of that theorem, with $\nu_J = \sigma_J/7$.*

Proof. We begin with (1). Let $p \in \mathcal{P}_{\mathrm{inc}}$. By (18.32), each edge of p lies in $\mathcal{L}_0$ or in $\mathcal{E}_\Omega^{\mathrm{near}}$, so the deep values do not enter U_p^{act}, and $U_p^{\mathrm{act}} = U_p^{\mathrm{an}}$ for every η. A plaquette outside $\mathcal{P}_{\mathrm{inc}}$ has no edge in $\mathcal{L}_0$. On the reconstruction its edges are constant in (c, z): links across the boundary are equal to b_e, other near links to b_e, and deep links to η_e. Its Wilson term is therefore independent of (c, z). A plaquette in $\mathcal{P}_{\mathrm{inc}} \setminus \mathcal{P}_{\mathrm{var}}$ is not in $\mathcal{P}_{\mathrm{min}}$, so its term is independent of (c, z) as well. This proves that E_{hole} is independent of (c, z), and (18.38) follows by splitting the sum over all plaquettes. The same argument for U^{an} shows that $E_0(\Psi_R) = F_{\mathrm{bare}} + \sum_{p \notin \mathcal{P}_{\mathrm{var}}} f_p(c, z; \xi)$ with each summand independent of (c, z) and hence equal to $f_p(0, 0; \xi)$. This proves (18.39). If the list $\mathcal{P}_{\mathrm{var}}$ contains additional plaquettes whose terms are constant in (c, z), only the complementary constants change.

Next we prove (2). On $\mathcal{L}_0$ the derivative u equals $A_\Omega z$, by Lemma 18.11(1). The links outside Ω are constant in z at zero near-link logarithms and fixed deep frozen group variables, as noted after Definition 18.13, so $u = \widehat{A}_\Omega z$. The first assertion of (18.40) is Lemma 18.11(3). Let $p \in \mathcal{P}(P)$. All four edges of p belong to $\mathcal{L}_0$, so $p \in \mathcal{P}_{\mathrm{inc}}$, and the link variables of U^{act} and U^{an} on p are equal, independently of the deep frozen group variables. At $(c, z, \xi) = 0$ all these links are equal to I. The Wilson expansion of a single term is

$$f_p(0, tz; 0) = \tfrac{1}{2} t^2 |(du)_p|^2 + O(t^3). \tag{18.46}$$

Indeed, the first derivative of the plaquette product is the signed sum of the derivatives of its four edge logarithms, and $4q(e^X) = |X|^2/2 + O(|X|^4)$. If $p \notin \mathcal{P}_{\mathrm{var}}$, then $f_p(0, tz; 0)$ is constant, equal to its value zero at $t = 0$, and (18.46) implies $(du)_p = 0$. This holds for every $u \in \ker G_\Omega$, since A_Ω maps onto $\ker G_\Omega$ by Lemma 18.11(1); it does not assert that every plaquette of a patch is a varying plaquette. On a varying plaquette of P the entries of $d_P R_P u$ are those of du, and on the other plaquettes of P both sides vanish. This proves the second assertion of (18.40).

The first inequality of (18.41) is the first inequality of (18.17). The second follows since every plaquette lies in at most seven of the sets $\mathcal{P}(P)$, as shown in the proof of Lemma 18.11. Using the bound $\|h\|^2 \le \sigma_J^{-1}\|d_P h\|^2$ on $\mathcal{V}_P$ and (18.40), we obtain

$$\|u\|_{\mathcal{L}_0}^2 \le \sum_P \|R_P u\|^2 \le \sigma_J^{-1} \sum_P \|R_P^{(2)} d_{\mathrm{var}} u\|^2 \le \frac{7}{\sigma_J}\|d_{\mathrm{var}} u\|^2.$$

Together with Lemma 18.11(1) and (2), this proves (18.42).

For (3), all varying plaquettes have only internal or near links, by (18.32). At their common zero they are identity plaquettes, even when the deep links are arbitrary. Summing (18.46) over the varying plaquettes proves the formula for K_Ω in (18.43). In particular, the term in the Hessian of a composition that involves the gradient of the action vanishes here, since each plaquette term has zero first derivative at the identity; it is not being dropped at a nonflat field. The lower bound follows from (18.42): we have $z^{\mathsf{T}} K_\Omega z = \|d_{\mathrm{var}} u\|^2 \ge (\sigma_J/7)\|u\|_{\mathcal{L}_0}^2 \ge \lambda_{M,J}\|z\|_2^2$.

For the upper bound and the range, note that each row of the curl matrix has four entries, and each positive edge lies in four plaquettes, so its row and column norms are at most 4. Using Lemma 18.11(2) for A_Ω, we find that $16 a_1 a_\infty$ bounds both the operator norm and the unweighted absolute row and column norms of K_Ω. If $(K_\Omega)_{ab} \ne 0$, then two edges in the supports of the columns a and b of A_Ω belong to a common plaquette, so their midpoints are within maximum distance 2 in input units. Since each column of A_Ω is supported within maximum distance $R_{M,J}$ of its label, this proves (18.44). This is a finite range after the elimination of the trees and of the eliminated edges, before any minimization over a whole scale; no orthonormal basis of $\ker G_\Omega$ was used as coordinates.

We record the cases at the boundary. If a final block of Ω is next to the fixed complement, all trees of that block and all equations used for its restriction still lie in the complete block, and a pair is used only when both of its blocks lie in Ω. No missing target of a link across the boundary is set to zero: such a link is fixed through (18.33), and its tree-path transport to the basepoint is identically I on the reconstruction. Plaquettes that contain an internal link and a near link belong to $\mathcal{P}_{\mathrm{inc}}$, have only small links, and contribute nonnegative squares of curls at zero; the estimate above is already obtained from the plaquettes of the patches. If a plaquette of a patch has become constant in (c, z) after the elimination of the constraints, (18.46) shows that its curl vanishes, so no missing energy term is needed, and no boundary condition is imposed on a face of a hole.

At the boundary between near and deep links, a plaquette containing a deep link cannot contain a link of $\mathcal{L}_0$, by (18.32). All its links are constant on the reconstruction, and it belongs to E_{hole} even when some of its other links are near links. Likewise, a deep link occurs in none of the formulas for the coordinates and the Haar disintegration densities. Changing η therefore changes neither A_Ω, B_{ext}, F_{bare}, nor any of their derivatives in (c, z). There is no smallness or branch condition on η, and no derivative in η is taken.

In particular, an exceptional value of the Borel averaging map at the deep frozen group variables cannot affect an internal formula or the matrices above.

Next we treat principal submatrices and Schur complements. Principal submatrices keep the lower bound, the upper bound, and the range. For a decomposition $K = \left(\begin{smallmatrix} K_{II} & K_{IR} \\ K_{RI} & K_{RR} \end{smallmatrix}\right)$ of a matrix with $\lambda I \le K \le Q I$, the real Schur complement satisfies

$$\lambda \|y\|^2 \le y^{\mathsf{T}} (K_{RR} - K_{RI} K_{II}^{-1} K_{IR}) y = \min_{x} (x,y)^{\mathsf{T}} K (x,y) \le Q \|y\|^2. \tag{18.47}$$

The lower inequality uses $\lambda(\|x\|^2 + \|y\|^2) \ge \lambda \|y\|^2$, and the upper one the choice $x = 0$. This proves the lower bound for the Schur complement of every initial segment of the scales. The factors M^i of the effective classical actions multiply whole quadratic forms and lie between 1 and M^J.

We now prove locality without asserting a finite range for Schur complements. In output units, the number of scalar labels in a ball of radius r is at most $v_{M,J}(r+2)^3$ for a fixed $v_{M,J}$. Indeed, there are at most J scales and at most $9M^{3J}$ scalar edge labels per scale and per unit cube of the output lattice, with a fixed enlargement for the boundaries of the cubes. For a principal matrix K of K_Ω let $a = 2Q_{M,J}$ and $T = I - K/a$. Its operator norm is at most $q = 1 - \lambda_{M,J}/a < 1$. The matrix T^k has range $k D_{M,J}$ in the maximum distance, hence range at most $3kD_{M,J}$ in the graph distance dist, its entries are bounded by q^k in absolute value, and its rows and columns are supported on at most $C_{M,J}(k+1)^3$ labels. For $b > 0$ so small that $q e^{3bD_{M,J}} < 1$, the series

$$K^{-1} = a^{-1} \sum_{k \ge 0} T^k, \qquad K^{-1/2} = a^{-1/2} \sum_{k \ge 0} \binom{2k}{k} 4^{-k} T^k \tag{18.48}$$

converge in the norm $\|\cdot\|_b$ of Lemma 18.3(3), uniformly, since their scalar majorants are constant multiples of $\sum_{k \ge 0} (k+1)^3 (q e^{3bD_{M,J}})^k$; the second series is the binomial series of $(1-x)^{-1/2}$, whose coefficients are at most one. The norm $\|\cdot\|_b$ is submultiplicative by the triangle inequality for the distance, so a Schur complement S satisfies

$$\|S\|_b \le \|K\|_b + \|K\|_b^2 \|K_{II}^{-1}\|_b, \qquad S \ge \lambda_{M,J} I,$$

and these bounds can be repeated through the at most J eliminations of initial segments.

Finally we bound the inverse and the inverse square root of such an exponentially localized matrix directly. Suppose $S \ge \lambda I$ and $\|S\|_b \le H$. For a one-Lipschitz real function f and $W_f = \operatorname{diag}(e^{\mu f})$ with $0 < \mu < b$, we have

$$\|W_f S W_f^{-1} - S\|_2 \le \frac{H\mu}{b - \mu},$$

by $|e^t - 1| \le |t| e^{|t|}$, the inequality $r e^{-(b-\mu)r} \le 1/(b-\mu)$, the row and column bounds, and the Cauchy–Schwarz inequality. We choose μ so that the right side is at most $\lambda/2$.

The Neumann series about $S + tI$ then bounds the conjugated resolvent by $2/(\lambda + t)$ for every $t \geq 0$. Taking $f = \operatorname{dist}(\cdot, y)$, we obtain

$$|(S + tI)^{-1}_{xy}| \leq \frac{2e^{-\mu \operatorname{dist}(x,y)}}{\lambda + t}.$$

The density of labels sums this bound in the weighted norm at rate $\mu/2$. At $t = 0$ it bounds S^{-1}, and the formula

$$S^{-1/2} = \frac{1}{\pi} \int_0^\infty t^{-1/2} (S + tI)^{-1} \, dt$$

bounds $S^{-1/2}$, since $\int_0^\infty t^{-1/2}(\lambda + t)^{-1} \, dt = \pi/\sqrt{\lambda}$. The integral formula follows by orthogonal diagonalization of the positive matrix and the substitution $t = \lambda x^2$ in the scalar integral. This proves the assertions on Schur complements in (3), without a finite range for them.

It remains to prove (4). We fix local constraint coordinates of Lemma 6.3 on strictly smaller charts. Their finite-dimensional analytic bounds and (18.10) give a common complex product $\max(\|c\|_\infty, \|z\|_\infty, \|\xi\|_\infty) < 2\delta$, for some $\delta > 0$ depending only on M, J, and the radii of these charts. To check that δ does not depend on the region, we start at scale s, reduce its target and free radii so that its image lies strictly inside the target chart of the next scale, and repeat at most J times. Since the inverse at one scale depends on at most $6M^3$ links, this finite sequence of choices does not depend on the number of blocks. The completion outside Ω is by constants on the reconstruction.

On this product each f_p depends on at most N_* scalar labels, and each label occurs in the dependency lists of at most N_{inc} plaquettes; both numbers depend only on the finite stencils and on M and J. There are finitely many patterns of final blocks of Ω in one stencil. Let C_3 be the maximum, over these patterns and all scalar indices, of the absolute values of the third derivatives of a single f_p on the closed product of radius δ. It is finite, since each local function is holomorphic on the larger product and the list of functions and of their arguments is finite; this also describes exactly how C_3 depends on the chart. Integrating the third derivative from zero to $x = (c, z, \xi)$ and summing over the second free index, we obtain

$$\|\partial_z^2 F_{\mathrm{bare}}(x) - K_\Omega\|_\infty \leq C_{\mathrm{lip}} \|x\|_\infty, \qquad C_{\mathrm{lip}} = N_{\mathrm{inc}} N_*^2 C_3.$$

The column bound is the same by symmetry, so this is also a bound on the operator norm. The calculation differentiates the whole composition, including the term with the gradient of the action at nonzero x. We take $\epsilon_{M,J} \leq \min(\delta, \lambda_{M,J}/(2\max(1, C_{\mathrm{lip}})))$. For real data the Hessian is real symmetric, and (18.45) follows. All plaquette functions in F_{bare} are independent of η before differentiation, so the uniformity in the deep frozen group variables persists. □

18.8 Decay of connected boundary perturbations

We finally consider expressions, built from the objects of Theorem 18.12, that contain one perturbation located in the fixed complement or near the boundary: for example the difference between the reconstructions on Ω and on the torus, or a bounded source in the fixed complement. A contraction network is a finite contraction, or a convergent sum of contractions, of the following tensors: the tensors of the chart and of the effective classical action, with coefficient bounds with each index fixed; inverses of constrained Hessians; at most J Schur complements; and the convergent Neumann and implicit-function series of these operations. Its coefficients are summed with the convergent coefficients of these operations, so a network may contain arbitrarily many inverse or implicit vertices. One constant cannot, however, bound expressions of unbounded algebraic complexity; multiplying an allowed expression by a large scalar already destroys any common bound. We therefore consider families of networks with one common scalar majorant. A perturbation factor has a stated bound on its amplitude. If it depends analytically on current variables, these variables occur among its external indices and satisfy the coefficient bounds of the family; a fixed real source needs only its amplitude bound. The perturbation factor must lie in the same connected component of the network as the external index in the block region.

Lemma 18.15. *Use the products of Theorem 18.12. Let H be the fixed complement, let H_{L_J} be its enlargement by the fixed width L_J, and for $b > 0$ put*

$$S_J(b) = Cv_J \sum_{r \geq 0} (r+1)^3 e^{-br} < \infty.$$

1. *On every periodic subset of labels we have $\sup_x \sum_y e^{-b\,\mathrm{dist}(x,y)} \leq S_J(b)$. For $0 < a < b$ and every position u in Ω,*

$$e^{a\,\mathrm{dist}(u,W)} \sum_{h \in H_{L_J}} e^{-b\,\mathrm{dist}(u,h)} \leq e^{aC_J} S_J(b-a).$$

2. *Let $\mathfrak{N}$ be a family of connected contraction networks, each with at least one external index in Ω and with a perturbation factor at a position of H_{L_J} in the same connected component. The perturbation may be a bounded source s_h at any position h of H_{L_J}, with $|s_h| \leq s_*$. Assume that the diagram sums of all members of $\mathfrak{N}$ are bounded, on one common coefficient product and including all mesh-volume factors, by one common scalar majorant $\mathcal{P}$ with nonnegative coefficients. Then there are $c_J, C_J > 0$, depending only on uniform data, on $\mathcal{P}$, and on s_*, such that every tensor T_l of order $l \geq 1$ in $\mathfrak{N}$ with a specified external index i_1 in Ω satisfies*

$$\sup_{i_1 \in \Omega} e^{c_J\,\mathrm{dist}(i_1,W)} \sum_{i_2,\dots,i_l} e^{c_J \mathfrak{t}(i_1,\dots,i_l)} |T_l(i_1,\dots,i_l)| \leq l! C_J^{l+1}.$$

A single fixed reduction of the spatial rate suffices, independently of the Taylor order and of the number of contractions.

3. *For a member of $\mathfrak{N}$ with output index e and Taylor series $T_e(v) = \sum_\nu f_{e;\nu} v^\nu$, and an input index x, let*

$$\mathcal{C}_{ex} = \sum_{\nu : \nu_x > 0} \nu_x |f_{e;\nu}| \, r^{\nu - e_x}$$

be the entrywise absolute coefficient envelope of $\partial_x T_e$ at the radii r of a strictly smaller coefficient product. Let v_e and v_x be the mesh volumes of the lattices on which e and x live. Then

$$\sup_{x \in \Omega} \sum_{e \in \Omega} \frac{v_e}{v_x} \, e^{c_J[\operatorname{dist}(e,W) + \operatorname{dist}(e,x)]} \, r_x \, \mathcal{C}_{ex} \le C_J. \tag{18.49}$$

In particular, if x and e lie in Ω, then $\mathcal{C}_{ex} \le C_J e^{-c_J[\operatorname{dist}(e,W) + \operatorname{dist}(e,x)]}$, where the fixed conversions of radii and mesh volumes are absorbed in C_J. For two Hessian indices e and f in Ω,

$$|T_{ef}| \le C_J e^{-c_J[\operatorname{dist}(e,f) + \operatorname{dist}(e,W) + \operatorname{dist}(f,W)]},$$

with factorial joint versions that include every differentiated background and free index in the external network. These statements also apply to derivatives in the current frozen coordinates on their construction chart, at the density of their labels.

Traces confined to H, which have no external index in Ω, remain sums over H; no bound on them independent of the size of H is asserted. Differences of coordinates deep in H need only be bounded on their construction domain; they need not be exponentially small. The constants do not depend on the volume of H, on the area of W, on the shape or number of components of Ω, on the number of preceding block integrations, or on the widths chosen later.

Proof. We begin with (1). The first bound is (18.4), with $C = 8$, possibly enlarged to account for a fixed change between positions of links and of their endpoints. It holds on every periodic subset, since restriction deletes terms from a sum of nonnegative terms. A shortest path from a position u in Ω to a position in H crosses W. If $h \in H_{L_J}$ lies in Ω, we add a path of length at most L_J to H and then its crossing of W. In both cases

$$\operatorname{dist}(u, W) \le \operatorname{dist}(u, h) + C_{\mathrm{band},J}, \tag{18.50}$$

where the fixed buffer for link endpoints is included in $C_{\mathrm{band},J}$. Multiplying termwise by $e^{a \operatorname{dist}(u,W)}$ and using (18.4), we obtain

$$e^{a \operatorname{dist}(u,W)} \sum_{h \in H_{L_J}} e^{-b \operatorname{dist}(u,h)} \le e^{aC_{\mathrm{band},J}} \sum_h e^{-(b-a) \operatorname{dist}(u,h)} \le e^{aC_{\mathrm{band},J}} S_J(b-a).$$

This proves (1), after enlarging C_J. The bound sums over all of H, with no separate constant for each face of the boundary.

Next we record how a network acquires its distance to the boundary. For the coefficient of each factor we choose a connected network spanning its external indices and Taylor labels, with length as close as desired to its shortest connecting length, and for each

matrix propagator a shortest path between its endpoints. Joining these networks at the contracted labels gives a connected network $\mathcal{N}$ of total length ℓ. If S is the set of its external positions, then

$$\mathrm{t}(S) \le \ell, \qquad \operatorname{dist}(i, W) \le \ell + C_{\mathrm{band},J} \quad (i \in S \cap \Omega). \tag{18.51}$$

For the second inequality, we follow a route in $\mathcal{N}$ from i to its perturbation vertex $h \in H_{L_J}$ and use (18.50). The same route reaches a point of W, after a segment of length at most $C_{\mathrm{band},J}$ if necessary, so also $\mathrm{t}_W(S) \le \ell + C_{\mathrm{band},J}$. Adding these inequalities, we obtain for all rates $a, \alpha \ge 0$ and every external index i in Ω

$$e^{a\mathrm{t}(S)+\alpha \operatorname{dist}(i,W)} \le e^{\alpha C_{\mathrm{band},J}} e^{(a+\alpha)\ell}, \qquad e^{a\mathrm{t}_W(S)} \le e^{aC_{\mathrm{band},J}} e^{a\ell}. \tag{18.52}$$

This is how the two weights of Remark 18.2 are related: both are bounded by the weight of the total length of the joined network, at a fixed rate. For two external indices e and f in Ω we have the three inequalities

$$\operatorname{dist}(e, f) \le \ell, \qquad \operatorname{dist}(e, W) \le \ell + C_{\mathrm{band},J}, \qquad \operatorname{dist}(f, W) \le \ell + C_{\mathrm{band},J} \tag{18.53}$$

simultaneously; they do not require a separate perturbation for each index. Summing them, we find, for every $c \ge 0$,

$$e^{c[\operatorname{dist}(e,f)+\operatorname{dist}(e,W)+\operatorname{dist}(f,W)]} \le e^{2cC_{\mathrm{band},J}} e^{3c\ell}. \tag{18.54}$$

We now divide the spatial rate. Let $b_0 > 0$ be a common rate for the coefficients of the factors, including the smaller rate of the inverse of the free Hessian. We take all contraction and implicit-series estimates first at the rate $b_0/2$, and we choose $0 < c_J \le b_0/32$. A factor $e^{b_0\ell}$ is available in the absolute product bounds at the rate b_0. We use at most $e^{b_0\ell/4}$ of it for the desired external network and the distances in (18.51) and (18.53). For example, the network length plus one distance to the boundary is at most $2\ell + C_{\mathrm{band},J}$, and the network length plus the three distances in (18.53) is at most $4\ell + 2C_{\mathrm{band},J}$. The choice of c_J covers either sum and leaves a positive fixed fraction of $b_0\ell$ for the internal summations. The fixed added lengths contribute at most the factor $e^{2c_J C_{\mathrm{band},J}}$.

Next we give the summation. We orient a finite tree of contractions toward the specified external index and sum the labels on the outermost branches first, using the corresponding row bounds. On the unique branch containing a specified input index we use the input-column bound instead. The network weights multiply by (18.3), and Lemma 5.3 gives the product of the bounds for the factors, with the normalization of the columns unchanged. A redundant edge or a matrix cycle with a fixed external index is bounded by a further absolute row sum after cutting it at an attached vertex; alternatively, its propagators can be expanded into their convergent chains. All internal sums then use

the same row and column bounds. In particular, a final sum over a bounded source s_h, $h \in H_{L_J}$, uses

$$\sum_{h \in H_{L_J}} |s_h| e^{-u \operatorname{dist}(i,h)} \leq \|s\|_\infty S_J(u),$$

or the weighted version proved in (1), rather than the bound $|H|\|s\|_\infty$. Only one source insertion is needed; further perturbation vertices already present in a coefficient do not require independent sums of this kind.

A fixed product or composition has a finite scalar majorant, obtained by multiplying or composing the majorants of the factors. Each inverse or resolvent series is an infinite sum of chains with geometric ratio at most $1/4$ on the larger product, as in (18.5). The perturbation in an inverse difference stays in its single difference factor. A difference of Schur complements is the finite telescoping sum of Lemma 18.3, and at most J such operations have a fixed complexity. The common majorant $\mathcal{P}$ bounds the number of summed chains and contractions. The division of the spatial rate is applied once to each complete joined network, not anew at each vertex of an infinite expansion.

For an implicit series we make this precise. Let $Y(t)$ be the solution with nonnegative coefficients of (18.30). A derivative in a parameter that inserts the perturbation once gives an equation whose majorant satisfies

$$Z \preceq H(t, Y(t)) + A(t) Z, \qquad A(t) = \tfrac{1}{2} + \partial_Y \frac{C_J(t+Y)^2}{1 - C_J(t+Y)}\Big|_{Y=Y(t)}. \tag{18.55}$$

Here $\preceq$ denotes domination of coefficients, and $H(t, Y)$ is the series with the source inserted (not to be confused with the fixed complement H); its constant and higher coefficients have the bounds with a fixed index just proved. The implicit series is obtained by repeated substitution, so all its coefficients are bounded by those of

$$\sum_{n \geq 0} A(t)^n H(t, Y(t)) = \frac{H(t, Y(t))}{1 - A(t)}.$$

We choose a radius $t_0 > 0$ strictly inside the radius of the solution such that $A(t_0) \leq 3/4$; this is possible since $Y(0) = 0$ and $A(0) = 1/2$. The series converges absolutely at t_0, and its value is at most $4H(t_0, Y(t_0))$. This is a bound on the value of a series with nonnegative coefficients; it is not the false coefficientwise inequality $Z_l \leq 4H_l$. A derivative in another analytic input differentiates this convergent series on a strictly smaller radius, where the additional geometric denominators are bounded; this gives the estimate with a specified input index. All indices are allowed, since all factor tensors and all inserted inverses were controlled with every index fixed.

For example, consider the interpolation from Step 3 of the proof of Theorem 18.12, and let $d_a = \Psi_R - \Psi_T$ on the common list of link variables. Its changed formulas in Ω are

confined to the band of width L_J, and its values in the fixed complement are bounded on the construction domain. The difference of the two objectives is

$$\Delta F = \int_0^1 DE_{d_0}(\Psi_T + t d_a)[d_a]\, dt + \tfrac{1}{2}\|z_H\|_2^2. \tag{18.56}$$

The segment of integration lies in the torus chart, by the choice of radii in that proof. If a derivative in a current or free variable acts on d_a, the changed formula keeps its perturbation. If it acts on the action or on another argument of the chart, the tensor of the action connects that derivative to the remaining position of d_a. The auxiliary quadratic form has only indices in the complement, and it reaches an index in Ω only through a connected contraction. A derivative at a remote background position therefore cannot disconnect the perturbation. Differentiating the stationarity equation in the interpolation parameter, we obtain $\dot z = -F_{zz}^{-1}(\Delta F)_z$, which is an instance of (18.55). This verifies that the implicit networks used here have a perturbation connected to every external index, rather than an unrelated scalar factor.

To pass from convergence to the factorial bounds in (2), we fix a common radius t_1 with $0 < t_1 < t_0$ and let D_J bound the preceding majorants with a fixed index there, after the division of the spatial rate. If a_l denotes their Taylor coefficients of order l, normalized as in (18.2), nonnegativity implies $a_l t_1^l \le D_J$. Hence the derivative tensors of order l are bounded by $l! D_J t_1^{-l}$. Taking $C_J \ge \max(D_J, t_1^{-1}, 1)$ proves the bound in (2). Every degree sum and every supremum over the fixed index in this argument has been taken at fixed frozen coordinates, and the uniform bound permits the final supremum over their real values.

For (3), we keep both the input index x and the output index e in the complete network before summing the other leaves. The length then covers $\operatorname{dist}(e, W)$ and $\operatorname{dist}(e, x)$ at the rate c_J. For each differentiated occurrence we have $\operatorname{dist}(e, W) + \operatorname{dist}(e, x) \le 2\ell + \mathrm{C}_{\mathrm{band},J}$, by (18.51). Summing the differentiated majorant series on a smaller product over e, with the input column of x and its volume normalization, we obtain (18.49). Each entry is then at most $(v_x / v_e) r_x^{-1} C_J e^{-c_J[\operatorname{dist}(e,W)+\operatorname{dist}(e,x)]}$; since at most J scales are involved and r_x is a fixed radius of the smaller product, this gives the entrywise bound after enlarging C_J. This bound includes the multiplicity of the input in the differentiated series; it is not only a bound on a first derivative at zero. For two Hessian indices we use (18.53). A background or free coefficient of order k is bounded by

$$\frac{(k+2)!}{k!} C_J^{k+3} R^k = C_J^3 (k+1)(k+2)(C_J R)^k,$$

whose sum over k is $2C_J^3/(1 - C_J R)^3$ for $C_J R < 1$. The external network at this order includes both Hessian indices and all k further leaves. Reducing R by a fixed factor gives the bound on T_{ef} and its joint factorial versions. Derivatives in the current frozen

coordinates use the same tensors and the same counting, at the density of the labels on the input lattice.

No step of the proof estimates a trace confined to the complement by fixing an index in Ω, and no step requires decay of a coordinate difference at a position deep in the complement. For example, a prescribed small link $\exp(\varepsilon\tau_a)$ in the complement can differ from the corresponding link I of the torus completion by the logarithm $\varepsilon\tau_a$, whatever its distance from W; its effect at an index in Ω is bounded instead by (18.50) and the convergent sum over sources. All choices used only fixed coefficient bounds, the density of labels, and fixed rates, so no volume, area, number of components, number of preceding block integrations, or later width enters c_J and C_J. The empty block region and the convention for a block region without boundary give the remaining degenerate cases. □

SECTION 19

Comparison of reconstructions on block regions

This section compares one renormalization group step on a block region with the same step on the whole torus. Fix a composition T_M^s of $s \leq J$ averaging steps and a union Ω of blocks of its output lattice. In Section 18 we reconstructed the fine configuration on Ω from the coarse field on Ω and free logarithmic coordinates, with the coordinates outside Ω held fixed. We also constructed the stationary point of the effective classical action in these coordinates and proved a gap for its free Hessian. Here we prove that the regional construction differs from the torus construction with the coarse field extended by zero outside Ω only by terms which decay exponentially with the distance to the boundary of Ω. We also prove that the regional construction is stable under small analytic perturbations of the incoming action. All estimates are bounds on absolute Taylor coefficients. Their constants do not depend on the shape of Ω, the number of its components, the depth, the number of preceding renormalization group steps, or the values of previously frozen coordinates.

We use these estimates in the localized renormalization group analysis behind the exponential-moment bound for blocked actions (Step 1 in Section 3.4). There the configurations are decomposed according to the regions where some averaged plaquette has large curvature, and the renormalization group is run outside these regions with the link variables inside them held fixed. Section 20 integrates the fluctuations on block regions using the reconstructions and perturbation estimates proved here. Section 21 uses the gauge transformation of Lemma 19.5 and the perturbation theorem Theorem 19.9 to construct large-field decompositions, and Section 23 uses the domain conditions of Lemmas 19.3 and 19.7 and Theorem 19.9 to choose the parameters.

The results, in order, are as follows: Lemma 19.3 treats successive minimization; Theorem 19.4 compares the regional and torus stationary points, together with the minimized actions, the Hessians, and the Haar disintegration densities; Lemma 19.5 constructs a gauge transformation which is the identity at prescribed vertices; Theorem 19.6 compares the gauge-transformed reconstructions and bounds their input columns; Lemma 19.7 collects the conditions on the radii; and Theorem 19.9 proves stability under perturbations of the incoming action.

The inputs are Theorem 18.12 (regional coordinates, the gap of the free Hessian, and the regional stationary point), Lemma 18.15 (coefficient bounds for connected networks which reach the fixed complement), Lemma 18.8 (derivatives of constrained stationary

values), Lemma 18.9 (freezing of coordinates), the coefficient algebra of Definition 18.1, the target-dependent gauge transformation of Theorem 13.2, the classical coefficient bounds of Theorem 10.11, and the equality of effective classical actions on compact gauge overlaps, Theorem 11.6.

We compare constrained minimizers through the implicit equation for their response, and we control the response by an exponentially decaying inverse of the constrained Hessian. This approach follows Bałaban's analysis of the variational problem for background fields [16, (182)–(190), pp. 307–308, and Proposition 9, p. 309], although our constraints, coordinate domains, and coefficient norms differ from his. The comparison between the regional and the torus problems and the gauge transformation fixing the prescribed endpoints are constructed here. The exponentially weighted resolvent bound, proved in Lemma 18.3, is the finite-dimensional version of the exponential-conjugation method of Combes and Thomas [61].

The mechanism. The regional problem and the torus problem with coarse field extended by zero have the same constraints away from a fixed neighborhood of the boundary of Ω. If we restrict the torus stationary point to the regional coordinates, the gradient of the regional objective at this point is therefore concentrated near the boundary, up to exponentially decaying tails. This residual gradient has two sources, which are the two terms of the formula for r_R in Theorem 19.4. First, the reconstructed fine field changes. Second, the tangent map of the constraints changes, since the regional problem omits the coarse constraints on links leaving Ω. Writing p for the restricted torus stationary point and z_R for the regional stationary point, we have $z_R - p = -\mathcal{A}_R^{-1} r_R$, where r_R is the residual gradient and $\mathcal{A}_R$, the regional Hessian averaged along the segment from p to z_R, has a positive gap. Since this inverse decays exponentially in the distance, the two stationary points differ by an amount which decays exponentially away from the boundary. The remaining work is to make this mechanism stable under differentiation, composition, and successive minimization. This requires bounds on all Taylor coefficients, with any one external index fixed. A bound on the values of a holomorphic map does not give the spatial weights and the fixed-index sums which are needed when these functions are composed later.

Figure 19.1 shows the sets which appear below. Two of them play different roles: the prescribed vertices, where the gauge transformation must be the identity, and the complement of the incoming list, which controls the spatial decay of the perturbation in Theorem 19.9.

19.1 Setting and conventions

Geometry. Throughout this section $M \geq 3$ is odd, $J \geq 1$ is fixed, $1 \leq s \leq J$, and $B_s = M^s$. The composition T_M^s of s averaging steps maps configurations of side $M^s m$ to

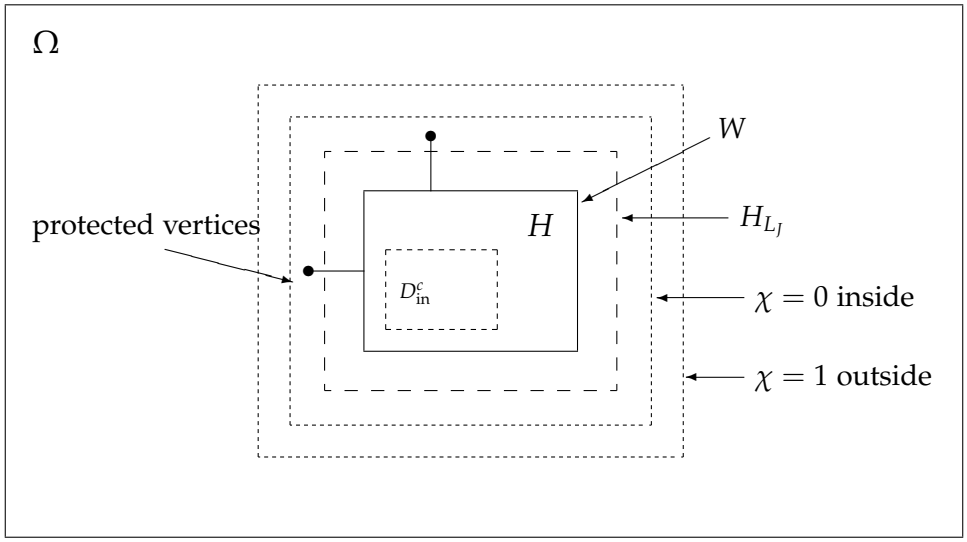

Figure 19.1. The geometry in the output lattice (schematic). The solid inner rectangle is the fixed complement $H = \Omega^c$, and its boundary is the interface W. The dashed rectangle bounds the enlargement H_{L_J} of H by the reconstruction stencil. The cutoff χ of Lemma 19.5 vanishes inside the inner dotted rectangle and equals one outside the outer dotted rectangle. The black dots are protected vertices, here the endpoints of the paths of two based transports of frozen coordinates. The small dotted rectangle inside H is the complement of the incoming list D_{in} of Theorem 19.9, which lies within a fixed distance of H.

configurations of side $m \geq 4$, and the prior depth $d_0 \geq 0$ is an arbitrary integer. When $s = J$ the composition is one renormalization group step, with blocking factor $B = M^J$. Positions are measured in units of the output lattice, of side m. Let Ω be a union of blocks of the output lattice, let $H = \Omega^c$ be its fixed complement, let W be the interface between Ω and H, and let H_{L_J} be the enlargement of H by the fixed reconstruction stencil L_J of Theorem 18.12. A coordinate is a label carrying a position, a direction, a color, and a scale index; its position is taken at the lattice where the coordinate was introduced and embedded in output units. In particular the newly frozen coordinates are counted with the density of the lattice on which they were introduced, not as coordinates of the output lattice. The density constant v_J of Definition 18.1 includes the colors, the directions, and the at most J scale indices. For a label i in Ω we write $\delta(i) = \operatorname{dist}(i, W)$. Here dist and t are the graph distance and the ℓ^1 network length of the refined position graph fixed before Definition 18.1; coefficient bounds imported at a Euclidean rate b are used at rate $b/\sqrt{3}$. If Ω is empty, every statement below with a fixed index in Ω is void. If H is empty, every boundary difference considered below is zero; we never use an expression of the form $0 \cdot e^{\infty}$.

Coordinates. We use the following coordinates.

- The coarse field c is the logarithm of the output links internal to Ω, and $c \oplus 0$ is its extension by zero to all output links of the torus.
- The free logarithmic coordinates $z = (z_i)_{0 \le i < s}$ of Theorem 18.12 parametrize the solutions of the block averaging constraints in Ω, with one block z_i for each intermediate scale i; here $i = 0$ is the finest scale. On the torus we write $z = (z_L, z_H)$, where z_L are the coordinates of the regional list and z_H are the remaining torus coordinates.
- $\Psi_R(c, z; \xi)$ is the logarithm of the regional reconstruction of the fine field before gauge transformation, including its prescribed small values outside Ω, and $\Psi_T(c_T, z_T)$ is the logarithm of the torus reconstruction before gauge transformation. We call the links of the input lattice of T_M^s fine links.
- In the successive reconstruction the free coordinates of scale i are $a_i + K_i^{-1/2} q_i$, where a_i is the conditional stationary point and K_i the constrained Hessian of that scale, and q_i is the fluctuation increment. The increments q_i replace $g_i w_i$, where w_i are the normalized fluctuation variables; no coupling is absorbed into K_i.
- In Section 19.7 we also use the jointly normalized coordinates u, defined by $z = z_0 + K_0^{-1/2} u$, where z_0 is the joint stationary point and K_0 the Hessian there.
- The newly frozen coordinates ξ are the small logarithmic coordinates frozen at the present step; they enter Ψ_R through its prescribed values outside Ω. The previously frozen coordinates b_{rec} are fixed real parameters, kept at the lattices on which they were introduced.

The points $z = 0$, $q = 0$, and $u = 0$ are different. Both $q = 0$ and $u = 0$ correspond to the joint stationary point $z = z_0$ (for q this is part of Lemma 19.3). The point $z = 0$ is the origin of the constraint coordinates.

Frozen coordinates and stationary points. No derivative in the previously frozen coordinates b_{rec} is taken or asserted in this section. In Theorems 19.4 and 19.6 the newly frozen coordinates ξ are analytic variables, which may be complexified and differentiated. In Theorem 19.9 the perturbed objects are differentiated only in the coarse field, the free coordinates, and the interpolation parameter, at fixed real (ξ, b_{rec}). All stationary points below are the holomorphic stationary branches in the coordinate domains of Theorem 18.12. At real data the positive free Hessian makes them local minima, and the conditional stationary points are the conditional constrained minimizers of the successive minimization.

Dependence of constants. All constants and radii in this section have the dependence described in item (3) of Definition 4.14. They may depend on M and J, on the larger classical and reconstruction domains and the ratios of their radii, on the coefficient bounds on these domains, on the gaps of the free Hessians and the bounds on their weighted inverses, on the fixed spatial decay exponents, on v_J, and on any fixed bound

on the size of the perturbation. In Lemma 19.7 and Theorem 19.9 they may also depend on the fixed analytic radii, on K_*, and on the ratios of these radii. They do not depend on L, γ, the lattice side, the depth d_0, the shape or topology of Ω, the number of components of Ω or H, the values of the previously frozen coordinates, or the number of preceding renormalization group steps. They are evaluated before the later choices of the boundary-layer width w_{bd}, the erosion width, the widths of the protected neighborhoods, the bound β_{rec} on newly frozen coordinates, and the enclosing product domains of Section 20. Each constant includes a finite maximum over $1 \le s \le J$ and over the finitely many initial segments. We do not assert uniformity as $J \to \infty$. Theorem 18.12 provides the gap of the free Hessian at every integer depth d_0, and when only this classical estimate is used, no condition on an effective interaction is imposed.

The torus construction domain. Every use of Theorem 13.2 below takes place on its construction product. For a composition of s averaging steps, we denote the radius and coefficient constant of that theorem by r_s and $C_s^{\mathbb{T}}$. Before the later profiles and widths are chosen, we fix positive U_T, Q_T in the common larger product of coarse fields and free coordinates such that

$$U_T + Q_T < \frac{1}{2} \min_{1 \le s \le J} r_s, \qquad C_T(U_T + Q_T) < \frac{1}{2}, \qquad C_T = \max_{1 \le s \le J} C_s^{\mathbb{T}}. \tag{19.1}$$

Decreasing U_T, Q_T if necessary, we may assume that the intermediate classical, inverse, and Haar-density margins of Theorem 13.2 hold. Later radii for coarse fields and free coordinates are chosen below U_T and Q_T, so each use of Theorem 13.2 has $u + v < r_s$, a positive denominator, and its intermediate margins. The rational row bound of that theorem alone does not show that a larger product is allowed.

Coefficient bounds. We use the coefficient algebra of Definition 18.1, Theorem 18.12, , and Lemma 18.15 and its coefficient bounds with each external index fixed in turn. A rooted coefficient sum of a tensor fixes one external index, its root, which is either an output or an input, and sums the absolute values of the Taylor coefficients over the remaining indices, with the weight $e^{a\mathsf{t}}$, where t is the ℓ^1 length of a shortest connected network spanning the positions involved. For a fixed input index the sum is the volume-normalized column sum of Definition 4.6, with the mesh of that input. A coefficient bound is a bound on all these sums, with any external index fixed. Taylor tensors at complex arguments use bilinear transposes. A majorant series is the series of absolute coefficients after the prescribed rooted sums and weights; the original coefficients need not be positive. In a scalar majorant the variable t is a radius after these rooted sums, never a sum of radii over all lattice sites. We say that a tensor, or a convergent series of tensors, has boundary-localized coefficient bounds if it satisfies the bounds of Lemma 18.15: with any index i in Ω fixed, its rooted coefficient sums carry the additional weight $e^{c\delta(i)}$ for a fixed $c > 0$.

A product or contraction joins the connecting networks of its factors at the contracted indices. We root the joined network at any external index and sum over the internal indices, using the corresponding rooted bounds of the factors. The boundary-localized estimate applies if one factor is boundary-localized, or if the joined network visits H_{L_J}. An index deep in H is bounded there, and the decay comes from its connection to the fixed index in Ω. In particular, for decay exponents $b > a > 0$, the sum over such indices is bounded by

$$e^{a\delta(e)} \sum_{h \in H_{L_J}} e^{-b\,\mathrm{dist}(e,h)} \le e^{aL'_J} S_J(b-a), \qquad S_J(u) = C v_J \sum_{r \ge 0} (r+1)^3 e^{-ur}, \tag{19.2}$$

where L'_J also includes the fixed convention for link endpoints. This is the case of a fixed index in Ω in Lemma 18.15; there is no factor of the volume of H.

Implicit series. The implicit equations below are solved in the absolute coefficient algebra. After the construction constant C_J is increased, the scalar majorant of the solution without boundary weight can be taken to satisfy

$$Y = C_J t + \frac{1}{2} Y + \frac{C_J (t+Y)^2}{1 - C_J (t+Y)}. \tag{19.3}$$

Fix $t_0 > 0$ such that, on $0 \le t \le t_0$ and $0 \le Y \le 4C_J t_0$, the rational term has Y-derivative at most $1/4$ and denominator at least $1/2$, and its value at $(t, 4C_J t)$ is at most $C_J t$. Such a t_0 exists and depends only on C_J, since these are finitely many strict inequalities which hold at $t = 0$. Iteration from zero produces series with nonnegative coefficients which stay below $4C_J t$. The iteration converges uniformly on every smaller disc, since the derivative in Y of the right side of (19.3) is at most $3/4$ on its majorant disc. The degree-l coefficients of the solution are bounded by $4C_J t_0^{1-l}$, and dividing Taylor tensors by $l!$ before this comparison gives factorial tensor bounds. The argument works in the absolute multivariate coefficient algebra because each product satisfies the rooted contraction bound just described. Uniform convergence of the power series implies holomorphy.

A derivative which inserts one difference factor, localized near H, has the majorant

$$Z \preceq H(t, Y(t)) + A(t) Z, \qquad A(t) = \frac{1}{2} + \partial_Y \frac{C_J (t+Y)^2}{1 - C_J (t+Y)}\bigg|_{Y = Y(t)}, \tag{19.4}$$

where $\preceq$ denotes coefficientwise domination and $H(t, Y)$ is the series with the difference factor inserted. On a smaller fixed radius $A(t) \le 3/4$, and the solution is majorized coefficientwise by $H(t, Y(t))/(1 - A(t))$; this is a convergent majorant series with one inserted difference factor (compare (18.55)). Fixing an analytic input differentiates this same series and keeps the index of that input. By Lemma 18.15, the connecting network and the route to the boundary are bounded once for the whole network, and their exponent is not divided by the Taylor order.

Matrix functions. We use matrix functions only on free coordinate spaces where a gap has been proved. The next lemma collects the facts we need.

Lemma 19.1. *Let $A^b \geq \lambda I$ be a real symmetric free matrix whose two-sided weighted Schur norm at exponent b is at most Q, and set*

$$\mu = \frac{b\lambda}{8(Q+\lambda)}, \qquad C_R = 2S_J(\mu/2).$$

1. *For every $t \geq 0$, the entries of $(A^b + t)^{-1}$ are bounded by $2e^{-\mu \operatorname{dist}(x,y)}/(\lambda + t)$, and its weighted Schur norm at exponent $\mu/2$ is at most $C_R/(\lambda + t)$; the constant C_R is the same for every subset of the label list.*
2. *If L is a complex coefficient perturbation with $C_R\|L\|_{\mu/2}/\lambda \leq 1/4$, then the series*

$$(A^b + L + t)^{-1} = \sum_{k\geq 0} [-(A^b + t)^{-1}L]^k (A^b + t)^{-1} \tag{19.5}$$

   converges normally, and its coefficient Schur norm is at most $4C_R/[3(\lambda + t)]$.
3. *For positive definite real matrices A, B,*

$$A^{-1/2} = \frac{1}{\pi}\int_0^\infty t^{-1/2}(A + t)^{-1}\,dt, \tag{19.6}$$

$$A^{-1/2} - B^{-1/2} = -\frac{1}{\pi}\int_0^\infty t^{-1/2}(A + t)^{-1}(A - B)(B + t)^{-1}\,dt, \tag{19.7}$$

$$\log A - \log B = \int_0^\infty (A + t)^{-1}(A - B)(B + t)^{-1}\,dt, \tag{19.8}$$

   and these identities extend holomorphically to the complex perturbations in (2).
4. *If $T = \begin{pmatrix} A & B \\ C & D_0 \end{pmatrix}$ is invertible with invertible blocks A and $D_0 - CA^{-1}B$, then*

$$(T^{-1})_{LL} - A^{-1} = A^{-1}B(D_0 - CA^{-1}B)^{-1}CA^{-1}. \tag{19.9}$$

Proof. Parts (1) and (2) are the Combes–Thomas bounds proved in Lemma 18.3(3); see (18.5). We recall the choice of constants. For a real one-Lipschitz function f on the label metric, conjugation by $\operatorname{diag}(e^{\mu f})$ changes A^b by a matrix of Schur norm at most $Q\mu/(b - \mu) \leq \lambda/8$; here we used $e^{\mu r} - 1 \leq \mu r e^{\mu r}$ and $\sup_{r\geq 0} r e^{-(b-\mu)r} \leq (b - \mu)^{-1}$. By the geometric resolvent series, the conjugated resolvent has operator norm at most $2/(\lambda + t)$ for $t \geq 0$. Taking $f(x) = \operatorname{dist}(x, y)$, we obtain the entry bound, and summing at exponent $\mu/2$ gives $C_R/(\lambda + t)$, uniformly over every subset of the label list. Under the condition in (2) each term of (19.5) after the first is smaller than the preceding one by the factor $1/4$, which gives the bound $4C_R/[3(\lambda + t)]$.

For (3), we diagonalize the positive matrices and substitute $t = \lambda u^2$ in each eigenvalue integral, which gives (19.6). The resolvent identity $(A + t)^{-1} - (B + t)^{-1} =$

$-(A+t)^{-1}(A-B)(B+t)^{-1}$ fixes the order of the three factors and gives (19.7) after integration against $\pi^{-1}t^{-1/2}\,dt$. For (19.8), we integrate $(1+t)^{-1}I-(A+t)^{-1}$ to obtain $\log A$ and subtract the corresponding formula for B. The series (19.5) extends these identities holomorphically to the complex perturbations in (2). Their majorants are integrable: they are bounded by $C_J t^{-1/2}(\lambda+t)^{-2}$ and $C_J(\lambda+t)^{-2}$ for the two differences, whose integrals are $\pi/(2\lambda^{3/2})$ and $1/\lambda$. Thus a boundary-localized middle factor $A-B$ gives boundary-localized differences of these functions, rooted at every index, and differentiation under the integral is justified by the same normally convergent majorants. Restricted diagonal sums are taken after this calculation; only a complete scalar trace permits a cyclic permutation of the factors. Part (4) follows by block multiplication. □

Additive constants. The coefficient seminorm with boundary decay $\mathcal{X}$ of Definition 18.1 vanishes on constants, so it never estimates additive constants. The constant term of a difference of minimized actions remains in the full action. Scalar determinants, Haar disintegration densities, and traces over H, which have no index in Ω, are kept as their exact finite values. The difference between two exterior extensions of the classical action is kept with all its constants (Theorem 19.9). After freezing at c, replacing an effective interaction $R(v,c)$ by $R(v,c)-R(0,c)$ changes the normalization constant from Λ to $\Lambda-R(0,c)$ and preserves the density, as in Lemma 18.9.

19.2 Conditional minimization and successive substitution

The reconstruction of the fine field proceeds from the coarsest intermediate scale to the finest. At scale i the free coordinates are $a_i(c,z_{>i})+K_i^{-1/2}q_i$, where a_i is a conditional stationary point which depends on the coarser coordinates $z_{>i}$ already reconstructed. We must check two things. First, for every fixed value of the coarser coordinates in some domain, the conditional stationary point exists. Second, the coarser coordinates produced by the earlier substitutions lie in that domain. The first does not imply the second, as the following example shows.

Example 19.2. Let $F_0(x,y)=(x^2+y^2)/2$ and $F_1(x,y)=F_0(x,y)-\delta y$ with $\delta>0$, and eliminate x first, so that y is the coarser coordinate. For every fixed y the conditional stationary point of F_1 in x is $x=0$, and the joint Hessian is the identity. The joint stationary point of F_1 is $(0,\delta)$. If the conditional stationary points are constructed only for $|y|<\eta$ with $\eta<\delta$, the successive substitution never reaches the joint stationary point, however small the fluctuation radius in x is chosen. The quantity δ_V of Lemma 19.3 detects this: for the initial segment consisting of both coordinates it equals δ, so the condition in part (3) of the lemma fails.

In the next lemma, I is an initial segment of the finer scale coordinates eliminated in the successive minimization, and $y = z_{I^c}$ denotes the coarser coordinates held as parameters. The segment containing all free coordinates is included.

Lemma 19.3. *Fix the larger construction domains of Theorem 18.12, within* (19.1)*, and the margins of their coefficient, inverse, and image bounds and of the lower bound for the real constrained Hessian. Let $F_0(c, z; \xi)$ be the unperturbed regional objective and $z^0(c; \xi)$ its joint stationary point. For each initial segment I write $y = z_{I^c}$, and let $a_I(c, y; \xi)$ be the conditional stationary point of F_0 in the variables z_I.*

1. *One can first choose a solution radius $r_I > 0$, and then a strictly smaller radius η_I for the deviation $y - z^0_{I^c}(c; \xi)$, uniformly over the coarse fields in the domain, such that*

$$a_I(c, z^0_{I^c}; \xi) = z^0_I, \qquad D_y a_I = -F^{-1}_{0,II} F_{0,II^c}, \qquad \|a_I - z^0_I\|_{\mathrm{coeff}} \le C_J \|y - z^0_{I^c}\|_{\mathrm{coeff}}.$$

   The derivative identity is evaluated at the conditional stationary point. We write $\mathcal{T}_I$ for the resulting domain of y.

2. *Let $F_\lambda = F_0 + \lambda V$, $0 \le \lambda \le 1$, be holomorphic and real at real arguments, with the same coefficient bounds on the larger domains. Set $A_I = F_{0,II}(c, a_I, y; \xi)$ and assume that, throughout the domains of part (1), in the operator norm of the coefficientwise majorant,*

$$\|A_I^{-1} F_{\lambda,I}(c, a_I, y)\| \le r_I/4, \qquad \|A_I^{-1}(F_{\lambda,II} - A_I)\| \le 1/2.$$

   Assume also that the real Hessian is perturbed by less than half of the lower bound for the constrained Hessian, and that the complex resolvent condition of Lemma 19.1(2) holds. Then for each I and each $y \in \mathcal{T}_I$ there is a unique holomorphic stationary point $a_{\lambda,I}(c, y; \xi)$ of F_λ in z_I within distance $r_I/2$ of a_I. It is real at real data and a local real minimum there, and it is unique in the convex domain on which the second inequality holds.

3. *Put $V = \partial_\lambda F_\lambda$ and*

$$\delta_V = \max_I \sup_{y \in \mathcal{T}_I} \|A_I^{-1} V_I(c, a_I(c, y; \xi), y)\|_{\mathrm{coeff}},$$

   where the coefficient norm includes the common product of coarse fields, uniformly at fixed real frozen coordinates, and let $\varepsilon_{\mathrm{tube}}$ be the minimum over I of the solution and parameter margins at I. Then, for every I and every $y \in \mathcal{T}_I$,

$$\|a_{\lambda,I}(c, y; \xi) - a_I(c, y; \xi)\|_{\mathrm{coeff}} \le 2\lambda \delta_V.$$

   Assume further that $\delta_V < \infty$, that the mixed coefficient bounds hold uniformly on the larger domains, and that $r_q > 0$ satisfies

$$C_{\mathrm{seq},J}(2\delta_V + r_q) < \frac{1}{2}\varepsilon_{\mathrm{tube}},$$

where $C_{\mathrm{seq},J}$ is the constant given in the proof. Let $a_{\lambda,i}$ be the conditional stationary point of F_λ at scale i, and let $K_{\lambda,i}$ be M^i times the Schur block of F_λ at scale i in input units. Then, whenever $\max_i \|q_i\|_\infty \le r_q$, the successive substitutions in the original free coordinates

$$z_i = a_{\lambda,i}(c, z_{>i}; \xi) + K_{\lambda,i}^{-1/2}(c, z_{>i}; \xi) q_i$$

stay in every parameter domain and every solution domain, with half of each margin unused. At $q = 0$ they give the joint stationary point.

The radii are chosen in the following order: first the unperturbed product, for which $\delta_V = 0$; then a bound on the size of the perturbation on the fixed larger unperturbed products, and a smaller perturbed product; only afterwards the smaller enclosing and fluctuation radii. Reducing r_q does not reduce the radius of the coarse field, since the chain at $q = 0$ is the joint stationary point. All radii and constants have the dependence of Section 19.1, independently of the later widths, the depth, and the geometry of Ω.

Proof. Part (1) is a quantitative implicit function argument about the joint stationary point, and part (2) is the same argument about a_I. The new point is part (3), which first bounds the displacement of the conditional stationary points at every fixed y and then propagates these bounds through the successive substitution by a finite recurrence.

Step 1: the unperturbed conditional stationary points. Fix I and write $y = z^0_{I^c}(c; \xi) + v$. This shift is an analytic change of coordinates with the coefficient bounds of Theorem 18.12. In these coordinates we set $u = z_I - z^0_I(c; \xi)$ and

$$B_I(c; \xi) = F_{0,II}(c, z^0(c; \xi); \xi).$$

By the bounds on the inverse and on the joint third derivative, there exist constants I_0, C_0 on the fixed larger products such that

$$\|B_I^{-1} F_{0,I}(c, z^0_I, z^0_{I^c} + v; \xi)\|_{\mathrm{coeff}} \le I_0 C_0 \|v\|_{\mathrm{coeff}}, \tag{19.10}$$

$$\|B_I^{-1}(F_{0,II}(c, z^0_I + u, z^0_{I^c} + v; \xi) - B_I)\|_{\mathrm{coeff}} \le I_0 C_0 (\|u\|_{\mathrm{coeff}} + \|v\|_{\mathrm{coeff}}). \tag{19.11}$$

For the first inequality we integrate F_{0,II^c} in v, starting from the joint stationarity $F_{0,I}(c, z^0; \xi) = 0$; for the second we integrate the third derivative tensor in (u, v). These are coefficient inequalities, since integration along a segment from the origin multiplies each term of positive degree by a number at most one, and the rooted bounds on the larger domains control the products.

Fix $r_I > 0$ within a fixed fraction of the solution margin of the chart, with $I_0 C_0 r_I < 1/8$. Then fix $0 < \eta_I < r_I$ within the parameter margin, with $I_0 C_0 \eta_I < r_I/8$ and $I_0 C_0 (r_I + \eta_I) < 1/4$. For $\|v\| \le \eta_I$, the map

$$u \longmapsto u - B_I^{-1} F_{0,I}(c, z^0_I + u, z^0_{I^c} + v; \xi)$$

has derivative $-B_I^{-1}(F_{0,II} - B_I)$, whose norm is less than $1/4$ on $\|u\| \le r_I/2$ by (19.11), and its value at $u = 0$ has norm less than $r_I/8$ by (19.10). It is therefore a coefficient contraction of the ball $\|u\| \le r_I/2$ into itself. Its Picard iterates converge in the coefficient norm, and their power series converge locally uniformly on the parameter product, which implies that the limit $a_I - z_I^0$ is holomorphic. At $v = 0$ the stationary point is the joint one, which proves the first identity of part (1). Differentiating the gradient equation at the conditional stationary point and using Lemma 18.8, we obtain

$$D_y a_I = -F_{0,II}^{-1} F_{0,II^c}.$$

The inverse and the mixed matrices have convergent coefficient bounds on a product larger than the chosen one. Integrating this identity from $y = z_{I^c}^0$ to y, we obtain the Lipschitz bound of part (1), with C_J a common bound for the product of these matrices. The choices are uniform in the coarse field, because the estimates were made on its fixed larger domain before v was introduced.

Step 2: the perturbed conditional stationary points. We write $z_I = a_I + Y$ and consider on the solution domain the map

$$\mathcal{T}_\lambda(Y) = Y - A_I^{-1} F_{\lambda,I}(c, a_I + Y, y). \tag{19.12}$$

Since $D_Y \mathcal{T}_\lambda = -A_I^{-1}(F_{\lambda,II} - A_I)$, the two inequalities of part (2) imply

$$\|\mathcal{T}_\lambda(0)\| \le r_I/4, \qquad \|D_Y \mathcal{T}_\lambda\| \le 1/2.$$

Then $\mathcal{T}_\lambda$ maps the coefficient ball of radius $r_I/2$ into itself and contracts differences by the factor $1/2$. Iterating from zero proves existence and convergence. The sum of the successive differences is a geometric series in the coefficient norm, so the limit is holomorphic. The differentiated series converge on a fixed smaller domain: they satisfy an equation $Z = H + TZ$ in which the majorant of T is at most $1/2$, and the solution is $\sum_{j \ge 0} T^j H$. This gives the coefficient bounds with any parameter index fixed.

If two stationary points lie in the convex domain on which the derivative bound holds, their difference is unchanged by (19.12) and has norm at most half of itself, so the two points coincide. Since F_λ is real at real arguments, every Picard iterate is real at real data, and so is the limit. The margin on the real Hessian keeps at least half of the lower bound for the constrained Hessian on a neighborhood of the stationary point. Integrating the real Hessian along segments shows a positive quadratic increase away from it, so it is a local real minimum. The complex resolvent condition is a hypothesis, which provides the inverse square roots used below.

Step 3: the displacement at fixed coarser coordinates. For part (3), note that $F_{0,I}(c, a_I, y) = 0$, so the map (19.12) satisfies $\mathcal{T}_\lambda(0) = -\lambda A_I^{-1} V_I(c, a_I, y)$. Writing $Y_{\lambda,I} = a_{\lambda,I} - a_I$ in the fixed point equation, we obtain for every $y \in \mathcal{T}_I$

$$\|Y_{\lambda,I}\|_{\text{coeff}} \le \lambda \delta_V + \frac{1}{2} \|Y_{\lambda,I}\|_{\text{coeff}}, \qquad \text{hence} \qquad \|Y_{\lambda,I}\|_{\text{coeff}} \le 2\lambda \delta_V. \tag{19.13}$$

This estimate is uniform on the whole domain $\mathcal{T}_I$, with the common product of coarse fields. In particular it can be used after moving coarser coordinates have been substituted; only their range enters, not a derivative in the frozen coordinates.

Step 4: the Lipschitz bound in the coarser coordinates. By the coefficient bounds on the larger domains, the mixed matrices F_{λ,II^c} are bounded by a common constant Q_{mix} and the reference inverse by I_0. The second inequality of part (2) and the Neumann series imply that $\|F_{\lambda,II}^{-1}\| \le 2I_0$. Implicit differentiation at the perturbed conditional stationary point yields

$$D_y a_{\lambda,I} = -F_{\lambda,II}^{-1} F_{\lambda,II^c}, \qquad \|D_y a_{\lambda,I}\|_{\mathrm{coeff}} \le 2I_0 Q_{\mathrm{mix}}. \tag{19.14}$$

The rooted versions follow from the same ordered products on a fixed smaller domain. From now on let C_0 denote a bound for these maps and their unperturbed versions, and let C_S bound the rows of the inverse square roots. These constants depend on the common bound for the mixed tensors, not on δ_V or on the later free radius.

Step 5: successive substitution. Let $\varepsilon_{\mathrm{tube}}$ be as in part (3). We use the successive maps in the original free coordinates, with $K_{\lambda,i}$ equal to M^i times the Schur blocks in input units. Let A_i bound all deviations of the coarser coordinates and all displacements of intermediate solutions at scale i, relative to the unperturbed joint stationary point. For the initial segment of all free coordinates, (19.13) bounds the perturbed joint displacement by $2\delta_V$. At each finer scale we first compare the perturbed and the unperturbed conditional stationary points at the same coarser argument, using (19.13), and then change the coarser argument, using (19.14). Inserting the free increment adds at most $C_S r_q$. We obtain the recurrence

$$A_{i-1} \le (1 + C_0) A_i + C_S r_q + 2\delta_V, \qquad A_s \le 2\delta_V, \tag{19.15}$$

which also holds for the images under the majorants, since it is obtained by composing majorants. After the finite conversion between the original free coordinates and the coordinates centered at the joint stationary point is included in C_0 and C_S, we may take

$$C_{\mathrm{seq},J} = 2(1 + C_S)(1 + C_0)^{J+1}\Big(1 + \sum_{j=0}^{J-1} (1 + C_0)^j\Big).$$

Indeed, iterating (19.15), we find

$$A_i \le 2\delta_V (1 + C_0)^J + (C_S r_q + 2\delta_V) \sum_{j=0}^{J-1} (1 + C_0)^j,$$

which is at most $C_{\mathrm{seq},J}(2\delta_V + r_q)$. The condition of part (3) therefore leaves half of each margin unused. The same bound applies to all Picard reference points and solution balls used in the construction from the coarsest scale downward. In particular, no gradient is evaluated outside the domains already reached.

Step 6: zero increments. At $q = 0$, the stationarity at the coarsest scale and the successive stationarities at the finer scales give the joint gradient equation. By uniqueness of its branch, this chain is the joint stationary point; Step 5 shows that the chain stays in the required domains.

Step 7: the order of choices. For $\delta_V = 0$ we first choose r_q by the condition of part (3). On the fixed larger unperturbed products, we then choose the perturbed product and the bound on the perturbation so that the same condition holds, and all later radii are chosen inside that product. Decreasing r_q changes only the terms of positive degree in q, and the image at $q = 0$ is the joint stationary point for every coarse field in the domain; hence no later reduction of the coarse-field radius follows. Finite minima and maxima over the initial segments preserve the dependence of the constants. □

19.3 Comparison of the regional and torus stationary points

We now compare the regional problem with the torus problem at a nonzero coarse field. Recall that $F_R(c, z; \xi) = E_{d_0}(\Psi_R(c, z; \xi))$ is the regional objective of Theorem 18.12, and that the torus objective is the effective classical action of the torus reconstruction with the coarse field extended by zero. For a target v of the torus we write $z_T(v)$ for the torus stationary point at v, and P for the restriction from the torus free list to the regional list.

Theorem 19.4. *Fix the larger domains of Theorem 18.12, an odd $M \geq 3$, $J \geq 1$, $1 \leq s \leq J$, $m \geq 4$, a depth $d_0 \geq 0$, and a union Ω of output blocks; positions are in output units. Use a smaller fixed product of $(c, z; \xi)$ on which the gap, inverse, and image margins of that theorem hold, with the previously frozen coordinates fixed. Write*

$$F_R = E_{d_0} \circ \Psi_R(c, z; \xi), \qquad F_T = E_{d_0} \circ \Psi_T(c \oplus 0, z_L, z_H), \qquad (p, h) = z_T(c \oplus 0),$$

put

$$a_T^0 = \Psi_T(c \oplus 0, p, h), \qquad \widehat{a}_R = \Psi_R(c, p; \xi), \qquad d_a = \widehat{a}_R - a_T^0,$$
$$J_R = \Psi_{R,z}(c, p; \xi), \qquad J_T = \Psi_{T,z_L}(c \oplus 0, p, h),$$

and let $r_R = F_{R,z}(c, p; \xi)$ be the regional gradient at the restricted torus stationary point. Then the following statements hold.

1. *(Gradient and response.) Let z_R be the regional stationary point. Then*

$$r_R = (J_R - J_T)^{\mathsf{T}} E'_{d_0}(a_T^0) + J_R^{\mathsf{T}} \int_0^1 E''_{d_0}(a_T^0 + u d_a) d_a \, du,$$
$$\mathcal{A}_R(z_R - p) = -r_R, \qquad \mathcal{A}_R = \int_0^1 F_{R,zz}(c, p + u(z_R - p); \xi) \, du.$$

The first term of r_R is the chain-rule contribution of the coarse constraints omitted in the regional problem. With $a_R = \Psi_R(c, z_R; \xi)$, for every free label or fine link i in Ω,

$$|(r_R)_i| + |(z_R - p)_i| + |(a_R - a_T^0)_i| \leq C_J(\|c\|_\infty + \|\xi\|_\infty) e^{-c_J \operatorname{dist}(i, W)},$$

each summand being read on its own list. These three differences have factorial boundary-localized coefficient bounds, as in Lemma 18.15. In particular, for a fixed input x and a fixed output e in Ω, their differentiated coefficient series are bounded by $C_J e^{-c_J[\operatorname{dist}(e,W)+\operatorname{dist}(e,x)]}$.

2. *(Full output.) Let $u_*(c,\xi) = T_M^s \exp a_R$ be the full output of the s averaging steps, including the values of the coarse links which are not constrained in Ω. It lies in the common torus target chart on this product. The bounds of part (1) on Ω, including those with a fixed input, remain true if $c \oplus 0$ is replaced by $\operatorname{Log} u_*$ and a_T^0 by the torus stationary field a_T^* at the target $\operatorname{Log} u_*$. All derivatives through u_*, including those through z_R, are included.*
3. *(Minimized action.) Let $V_R(c;\xi) = B_s F_R(c, z_R; \xi)$. There are fixed $\rho_0(J), a_W, \alpha_W, A_J^{\mathrm{cl}} > 0$ such that*
$$\mathcal{X}^{\rho_0,\mathrm{cl}}_{\Omega,a_W,\alpha_W}\big(V_R - E_{d_0+s}(c \oplus 0)\big) \le A_J^{\mathrm{cl}}.$$
This is the seminorm of Definition 18.1 with the displayed constant classical radius and rates; it includes all degrees $l \ge 1$. The constant term of the difference is kept in the full action.
4. *(Newly frozen coordinates.) For the newly frozen coordinates ξ, at their positions and with their density,*
$$D_\xi z_R = -F_{R,zz}^{-1} F_{R,z\xi}, \qquad \sum_f |(D_{\xi_f} z_R)_e| \le C_J e^{-a_W \operatorname{dist}(e,W)},$$
$$\|F_{R,z\xi}\|_{a_W} + \|F_{R,zc}\|_{a_W} \le C_J.$$
5. *(Hessians.) The constrained Hessians at the two stationary points satisfy*
$$\big|\big[F_{R,zz}(c, z_R; \xi) - P F_{T,zz}(c \oplus 0, z_T) P^{\mathsf{T}}\big]_{ef}\big| \le C_J e^{-a_W[\operatorname{dist}(e,f)+\operatorname{dist}(e,W)+\operatorname{dist}(f,W)]}.$$
The order-l coefficient tensors of this difference, with every coarse-field and free argument in the connecting network and any root in Ω fixed, are bounded by $(l+2)! C_J^{l+2}$ at fixed exponents.
6. *(Successive minima, inverse square roots, and Haar disintegration densities.) The statements of part (5) hold for each conditional partial minimum, on a smaller product of the coarser coordinates about the joint stationary point, with the exact normalization M^i at scale i. The inverse square roots of these Hessians and the nonconstant coefficients of the logarithms of the Haar disintegration densities satisfy the corresponding boundary-localized comparisons, with any index fixed. Scalar determinants and Haar disintegration densities which are not rooted at a label in Ω are kept as exact quantities.*

All constants have the dependence of Section 19.1 and do not depend on the later widths.

The theorem gives no inverse on fixed boundary coordinates and no rank estimate for the boundary terms at a nonzero coarse field.

Proof. We pose both problems on the torus free list by interpolating between the torus objective and the augmented regional objective. The two objectives then differ by one

inserted factor localized near H, and all estimates follow from the response of the interpolated stationary point to this factor and from the exponential decay of the inverse Hessian.

Step 1: one coordinate list. We write $z = (z_L, z_H)$ for the torus free list and set

$$\widetilde{F}_R(c, z; \xi) = F_R(c, z_L; \xi) + \frac{1}{2}|z_H|^2, \qquad F_t = (1-t)F_T + t\widetilde{F}_R, \quad 0 \le t \le 1, \qquad D = \widetilde{F}_R - F_T. \tag{19.16}$$

Since its minimum is zero, the added auxiliary quadratic does not change the regional value. Theorem 18.12 gives a positive gap at the identity for the Hessian of this interpolation, for all its principal blocks, and for its Schur complements. We reduce the construction product by a fixed amount so that the coefficient variation of each of these Hessians satisfies the condition of Lemma 19.1(2), uniformly in t. This is possible since the variation is at most $Q_J(\|c\| + \|z\| + \|\xi\|)$, and the gap at the identity of the interpolation is at least the minimum of the regional gap, the torus gap, and 1. All straight segments of fine fields used below then lie strictly inside the larger classical chart.

We retain a split resolvent margin for the later perturbation argument. Choose a common intrinsic exponent $b_{\mathrm{ref}} > 0$ and a constant $C_{0,J}$ such that every flat principal and scale Schur reference K_i^b has resolvent norm at most $C_{0,J}/(\lambda_J + t)$ at this exponent, including the factors M^i at the scale stages. When the larger unperturbed products are fixed, reduce them once so that their conditional matrices $K_{0,i}$ satisfy

$$C_{0,J}\|K_{0,i} - K_i^b\|_{b_{\mathrm{ref}}} \le \lambda_J/8$$

on those products, uniformly over the finitely many stages. We decrease the unperturbed reserve c_J if necessary so that $c_J \le b_{\mathrm{ref}}$. These choices use only the unperturbed constructions at fixed J and precede the incoming rates, perturbation threshold, and later widths.

Step 2: localization of the difference of the reconstructions. We use the comparison of the nonlinear words in Theorem 18.12. At common internal coarse values and common regional free values, we set

$$d(c, z; \xi) = \Psi_R(c, z_L; \xi) - \Psi_T(c \oplus 0, z_L, z_H).$$

On fine links in Ω, its defining words vanish outside the fixed interface band. The prescribed values on H can differ, and their difference is a bounded source on H with the separate coefficient bounds of the reconstruction charts. The difference is supported in H together with that band, hence in H_{L_J}; the two extensions need not agree on H. Its coefficient tensors have the corresponding finite-range bounds, rooted at any index. To check the statement about fine links in Ω at nonzero arguments, consider an internal eliminated-edge equation at the coarsest intermediate scale. On the two sides

it has the same endpoint blocks, the same coarse value, and the same free values, so by uniqueness on the common local branch its solution is the same. We repeat this down the s intermediate scales. Only equations meeting a block of H can differ, and the union of their at most J stencils is contained in H_{L_J}. This argument keeps the values of the coarse links across the boundary of the block region as functions of the common free values; it imposes no value on an omitted coarse constraint.

Step 3: the inserted difference. The difference in (19.16) is

$$D = \int_0^1 E'_{d_0}(\Psi_T + vd)[d]\, dv + \frac{1}{2}|z_H|^2. \tag{19.17}$$

Every derivative of the integral either differentiates d, whose fine position stays in H_{L_J}, or leaves such a factor undifferentiated. In the latter case the classical tensor of Theorem 10.11, which is bounded at every root, connects that position to every differentiated chart argument. A derivative in a coarse field or in a free variable in Ω therefore cannot disconnect the difference factor from the network. The auxiliary quadratic has only indices in H, and any connected contribution from it to an external index in Ω passes through an index in H and is bounded by (19.2). This verifies the hypotheses of Lemma 18.15 for the whole inserted difference, at every order and with any external root.

Step 4: the gradient formula and the bounds on values. Torus stationarity says that $J_T^{\mathsf{T}} E'_{d_0}(a_T^0) = 0$. Adding and subtracting $J_R^{\mathsf{T}} E'_{d_0}(a_T^0)$ in $F_{R,z}(c, p; \xi) = J_R^{\mathsf{T}} E'_{d_0}(\widehat{a}_R)$, and applying the fundamental theorem of calculus on the complex segment from a_T^0 to $\widehat{a}_R$, we obtain the formula for r_R. The difference $J_R - J_T$ is supported in the construction band, in its regional input indices and its fine output indices. Its product with the gradient of the action on the fine links is kept: torus stationarity makes only the projection of this gradient onto the torus free directions vanish. By the classical bounds, we have

$$\|E'_{d_0}(a_T^0)\|_\infty + \|d_a\|_\infty \le C_J(\|c\|_\infty + \|\xi\|_\infty);$$

for the first summand we used the bound on the torus stationary point, and for the second the word comparison of Step 2 and the same bound for (p, h). Contracting the two terms of r_R with their localized sources and using (19.2), we obtain

$$|(r_R)_i| \le C_J(\|c\|_\infty + \|\xi\|_\infty) e^{-c_J \delta(i)}. \tag{19.18}$$

Subtracting the regional gradient equations at z_R and at p and integrating along the segment between them, we obtain $\mathcal{A}_R(z_R - p) = -r_R$. The segment lies in the convex larger free box, and its averaged Hessian is the positive regional Hessian at the identity plus a coefficient perturbation satisfying the condition of Lemma 19.1(2). By that lemma, the inverse has entries bounded by $C_J e^{-b_J \operatorname{dist}(e,i)}$. Convolving this bound with (19.18)

and using $\delta(e) \le \delta(i) + \operatorname{dist}(e,i) + L'_J$, we obtain the bound on $z_R - p$, at a fixed smaller exponent. For the fine field we have the identity

$$a_R - a_T^0 = d_a + \int_0^1 \Psi_{R,z}(c, p + v(z_R - p); \xi)(z_R - p)\, dv. \tag{19.19}$$

The first term is supported in H_{L_J}, and the second is the product of a finite-range chart kernel, without boundary weight, with $z_R - p$. This proves the bound on fine links in Ω. No decay is asserted at a fine link deep in H.

Step 5: the coefficient bounds. We now prove the coefficient bounds directly, using the interpolation (19.16). On a common smaller product of parameters, the stationary point z_t of F_t is obtained by the implicit iteration with the inverse of the free Hessian at the identity, which converges coefficientwise. The radius condition and the bound on the inverse times the gradient follow from Theorem 18.12, and the scalar comparison equation is (19.3). Differentiating in t, we obtain

$$\dot z_t = -F_{t,zz}^{-1} D_z(c, z_t; \xi). \tag{19.20}$$

This expression contains exactly one inserted difference from (19.17), and its convergent majorant is (19.4). A further derivative in an input may hit the inverse, the inserted difference, or its argument z_t; in each case the joined network still contains the inserted difference and the index of the new input. We apply Lemma 18.15 and integrate from $t = 0$ to $t = 1$. Since the endpoints are z_T and $(z_R, 0)$, their difference on the regional list has factorial boundary-localized coefficient bounds, rooted at every index. Reading (19.19) as an identity of convergent majorant series, we obtain the corresponding bounds for the fine field, and the same argument applied to the formula for r_R gives its bounds. Keeping one input x fixed and summing over the remaining indices, we obtain the decay with a fixed input stated in part (1).

Step 6: the full output. The composition $T_M^s \exp \Psi_R$ is holomorphic on the common larger chart, by the construction in Theorem 18.12. At the stationary point it satisfies

$$\| \operatorname{Log} u_* \|_\infty \le C_J(\|c\|_\infty + \|\xi\|_\infty).$$

The internal coordinates of $\operatorname{Log} u_*$ are c, and its other coordinates are the values of the coarse links which are not constrained in Ω. These are analytic functions of $(c, z; \xi)$, whose differentiated series compose the coefficient series of the chart words with the series of the stationary point from Step 5. For instance, for any analytic direction v the first derivative is

$$D_v \operatorname{Log} u_* = D_c \mathcal{T}\, D_v c + D_z \mathcal{T}\, D_v z_R + D_\xi \mathcal{T}\, D_v \xi, \qquad \mathcal{T} = \operatorname{Log}(T_M^s \exp \Psi_R).$$

Since higher derivatives are compositions of these factors, all derivatives through the stationary point are included. We reduce the parameter radius so that the segment from $\operatorname{Log} u_*$ to $c \oplus 0$ lies in the common torus target chart. If $\mathcal{A}_T(v)$ denotes the torus stationary fine field at the target v, then

$$a_T^* - a_T^0 = \int_0^1 D\mathcal{A}_T(c \oplus 0 + t(\operatorname{Log} u_* - (c \oplus 0)))[\operatorname{Log} u_* - (c \oplus 0)]\, dt. \tag{19.21}$$

The difference of targets is supported on coarse links which are not internal to Ω. By the same implicit equation on the torus list, the lower bound for the torus constrained Hessian, the chart bounds, and the classical tensors give coefficient bounds without boundary weight for the response of $\mathcal{A}_T$. Each term of (19.21) with a root in Ω therefore passes through a coarse link outside Ω, and its composed network, including the derivatives of u_*, visits H_{L_J}. Lemma 18.15 and the finite word bounds then give the same amplitude and fixed-input bounds as before. The same integral with $\mathcal{A}_T$ replaced by the torus free stationary point z_T bounds $p^* - p$ on the regional free labels, where $(p^*, h^*) = z_T(\operatorname{Log} u_*)$. Thus $z_R - p^* = (z_R - p) - (p^* - p)$ satisfies the same bounds. For the new residual gradient, we subtract its value at p and integrate $F_{R,zz}$ along the segment from p to p^*. A Hessian without boundary weight multiplies this boundary-localized displacement, so the residual satisfies the same bounds. Its formula follows again from torus stationarity, now at the fixed target $\operatorname{Log} u_*$. These arguments are identities of convergent series in all variables, so they also give the fixed-input bounds at the full output. A representative in complementary forest coordinates, if needed, can use forest words of fixed depth based at the regional vertices and the coarse roots. These words change only the construction stencil outside Ω, their coefficient series are among the chart bounds, and the comparison in Ω is unchanged.

Step 7: the minimized action. Let $f_t(c;\xi) = F_t(c, z_t; \xi)$. By stationarity and Lemma 18.8, we have

$$\partial_t f_t = D(c, z_t; \xi). \tag{19.22}$$

At the endpoints, $B_s f_1 = V_R$ and $B_s f_0 = E_{d_0+s}(c \oplus 0)$. The second identity follows by iterating the recurrence $E_{d+1}(c) = M \min_z E_d(b(c,z))$ which defines the effective classical action: by Lemma 18.8 the successive minima equal the joint minimum, and the product of the s factors M is B_s. A nonconstant derivative of the right side of (19.22) has the network structure checked in Step 3. Therefore, for $k \geq 1$ and a root i in Ω,

$$\sum_{i_2,\dots,i_k} e^{c_J \mathfrak{t}(i,i_2,\dots,i_k)} |D^k[B_s(f_1 - f_0)](0;\xi)_{i,i_2,\dots,i_k}| \leq k! C_J^{k+1} e^{-c_J \delta(i)}, \tag{19.23}$$

where the factor $B_s \leq M^J$ is included in C_J. For a scalar series $f(c) = \sum_\nu f_\nu c^\nu$ we have, as in (18.2),

$$\sum_{|\nu|=k} \frac{\nu_i}{k} |f_\nu| e^{a\mathfrak{t}(\nu)} = \frac{1}{k!} \sum_{i_2,\dots,i_k} |D^k f(0)_{i,i_2,\dots,i_k}| e^{a\mathfrak{t}(i,i_2,\dots,i_k)}. \tag{19.24}$$

Indeed, the multiset obtained from ν by removing one occurrence of i has $(k-1)!/[(\nu_i - 1)!\prod_{j\neq i}\nu_j!]$ ordered listings, and $D^k f(0)$ evaluated on any of them is $\nu! f_\nu$. Fix $a_W, \alpha_W < c_J/4$, and then $\rho_0 > 0$ in the smaller construction domain with $C_J\rho_0 < 1/4$. Inserting (19.23) into (19.24), we bound the regional seminorm by

$$\sum_{k\geq 1} \rho_0^{k-2} C_J^{k+1} < \infty.$$

This proves part (3), including degree one. The value $B_s(f_1 - f_0)(0;\xi)$ is never subtracted in (19.22); it remains in the full action.

Step 8: derivatives in the newly frozen coordinates. Differentiating the regional gradient equation in ξ and using invertibility of the Hessian, we obtain $D_\xi z_R = -F_{R,zz}^{-1} F_{R,z\xi}$. The mixed derivative has exactly two terms,

$$F_{R,uv} = \Psi_{R,u}^{\mathsf{T}} E''_{d_0}(\Psi_R)\Psi_{R,v} + E'_{d_0}(\Psi_R)\Psi_{R,uv}, \tag{19.25}$$

and the bounds of Theorem 18.12 on the larger products control both terms for $(u,v) = (z,\xi)$ and $(u,v) = (z,c)$. An index of ξ is at a fine position outside Ω or in its fixed interface stencil. Contracting it with the free inverse and summing over the labels of ξ, we obtain the row sum $C_J e^{-a_W\delta(e)}$ by (19.2). This proves both bounds on the mixed matrices and the bound on $D_\xi z_R$, with no change of the density of the inputs.

Step 9: the Hessians. We compare the endpoints of (19.16) at their stationary points. Before any elimination, the total derivative is

$$\frac{d}{dt} F_{t,zz}(c, z_t; \xi) = D_{zz}(c, z_t; \xi) + F_t^{(3)}(c, z_t; \xi)[\dot z_t]. \tag{19.26}$$

Both terms contain the inserted difference, by (19.17) and (19.20), and all terms of (19.25), including the one with the gradient of the action, are part of these tensors. For two matrix roots in Ω, Lemma 18.15 gives the three distances in the Hessian bound of part (5), and at degree l in additional coarse-field and free arguments it gives the bound $(l+2)!C_J^{l+2}$ after C_J is increased. For example, the corresponding coefficient series of the matrix is dominated on radius R by

$$\sum_{l\geq 0} \frac{(l+2)!}{l!} C_J^{l+2} R^l = \frac{2C_J^2}{(1-C_J R)^3}, \qquad C_J R < 1.$$

The same majorant with a fixed input gives every version rooted at an input.

Step 10: successive minima. We restrict to smaller products for the initial segments before this comparison is used, following the construction of Lemma 19.3(1) uniformly in t. For an initial segment I, we take a solution radius r_I about the joint stationary point

and a smaller radius η_I for the deviation of the coarser coordinates. The principal inverse has bound I_J and the mixed tensors have bound C_J, so at the joint stationary point the inverse times the conditional gradient is at most $I_J C_J \eta_I$. We require $I_J C_J r_I < 1/8$ and $I_J C_J \eta_I < r_I/8$ within the margin of the chart, uniformly in t. Then the conditional Newton map is a contraction on the solution domain. We reduce the radii of the coarse field and of ξ so that $\sup_t \|z_t(c;\xi)\|_{\mathrm{coeff}} < \min_I \eta_I/8$. Then a common product $\|y\|_{\mathrm{coeff}} < \eta_I/2$ of coarser coordinates lies in the allowed domain for every t. On this product the conditional response is $\dot z_I = -F_{t,II}^{-1} D_I$ at fixed y, so the argument of Step 5 applies before a partial minimum is taken. Since there are finitely many initial segments, a common choice is possible, and this is the smaller product in part (6). At such a partial minimum, Lemma 18.8 gives

$$f_{yy} = F_{yy} - F_{yI} F_{II}^{-1} F_{Iy}, \qquad D^3 f[\eta_1, \eta_2, \eta_3] = D^3 F[V_{\eta_1}, V_{\eta_2}, V_{\eta_3}].$$

Differentiating the Schur formula in t replaces one factor by its derivative, which contains the inserted difference; an inverse contributes $-F_{II}^{-1} \dot F_{II} F_{II}^{-1}$, and evaluation at a moving stationary point contributes its response, which also contains the inserted difference. Each resulting network keeps all external roots and a visit to H_{L_J}. At scale i the formula is multiplied by the normalization M^i of the action, and a finite composition over $i < J$ changes only C_J.

Step 11: inverse square roots, and fixing versus eliminating. We apply (19.7) to the Hessians of Step 10. By the common gap and the resolvent condition, the differences of the inverse square roots have integrable boundary-localized coefficient bounds, rooted at every index. To compare $(K_{LL}^T)^{-1/2}$ with $((K^T)^{-1/2})_{LL}$, we set $C = K_{LL}^T \oplus K_{HH}^T$ and apply the resolvent identity to $K^T - C$ before integrating the resolvents. Each off-diagonal factor connects the two sides of the boundary, and hence gives the same boundary-localized estimate rooted in Ω. This also treats the difference between eliminating and fixing the torus free coordinates outside the regional list. For a free matrix T written in blocks with respect to the regional and the remaining torus coordinates, (19.9) expresses $(T^{-1})_{LL} - A^{-1}$ through the Schur complement $D_0 - CA^{-1}B$ on the remaining coordinates, which has the gap of Theorem 18.12. The factors B and C pass through the remaining coordinates and keep the visit to H_{L_J}, also after T is replaced by $T + t$. The same identity inside a larger Schur formula for one scale treats elimination instead of fixing.

Step 12: logarithms of the Haar disintegration densities. In the fixed coordinates, the Haar disintegration density of one intermediate scale is that of Lemma 18.7:

$$c_{\mathrm{Haar}}^f \frac{\prod_{e\ \mathrm{nonforest}} j_H(\Gamma_e)}{\prod_c \det D_{X_{e_c^*}} \mathsf{C}_{b,c}(\Gamma)}, \qquad j_H(X) = \mathrm{sinc}^2(|X|/2), \tag{19.27}$$

where e_c^* is the eliminated edge of the constraint at the coarse link c; the Haar factors of the solved eliminated edges are included in the numerator. At the common zero

the local factors of the numerator equal 1 and the local constraint determinants equal M^{-6}. By the word coefficients of fixed depth and the bounds on the implicit chart, there exists a uniform smaller radius on which each factor, divided by its nonzero value at zero, has nonconstant part with absolute coefficient row sum less than $1/2$. The series $\log(1+x) = \sum_{k\geq 1}(-1)^{k+1}x^k/k$ therefore converges absolutely, with the attached local networks. We compose these logarithms with the conditional stationary points and the inverse square roots. The words for fine links in Ω agree off the interface band, and the prescribed values on H remain bounded sources. Thus every difference has an output in H_{L_J}, and the derivatives of the other factors stay joined to it. Logarithmic matrix factors are treated by (19.8). A nonconstant scalar logarithmic coefficient has a differentiated index in Ω at which its trace cycle can be rooted, so the rooted sums above bound it. Pure scalar determinants, Haar disintegration densities, and traces over H have no such index and are kept as their exact finite values. All choices involved only the fixed construction data of Section 19.1, which proves the stated dependence of the constants. □

19.4 A gauge transformation fixing prescribed vertices

On the torus, Theorem 13.2 brings the reconstructed field into a small neighborhood of the identity by a gauge transformation which depends only on the coarse field. On a block region this gauge transformation must not change the field at the vertices to which frozen coordinates are attached. A frozen coordinate is stored as its based transport $U(\sigma_e)a_e$: the transport along a path σ_e from its basepoint to a link e, times the frozen value a_e of that link (Lemma 18.7). Under a gauge transformation G the frozen value transforms as $a_e^G = G_v a_e G_w^{-1}$, where v, w are the endpoints of e. We therefore multiply the logarithm of the torus gauge transformation by a cutoff which vanishes near H. To avoid a clash with the block region Ω, we write $\Omega^{\mathbb{T}}_{d_0,s}$ for the gauge transformation of Theorem 13.2, applied to a composition of s averaging steps at depth d_0.

Lemma 19.5. *Fix M, J, and the geometry of a composition of $s \leq J$ averaging steps as above. Let the prescribed protected set contain all vertices of H, every fine endpoint and every basepoint of each based transport of a newly or previously frozen coordinate, and all endpoints required in finer-lattice representations of these transports. Assume that its protected vertices outside H lie in the fixed interface band $\mathcal{B}$, in output units. Let $0 \leq \chi \leq 1$ be fixed by the geometry, zero on H and its neighborhood of width two blocks, one outside its neighborhood of width three blocks, and zero at every prescribed protected vertex. Define*

$$k(c) = \operatorname{Log} \Omega^{\mathbb{T}}_{d_0,s}(c \oplus 0), \qquad G^{\Omega}(c) = \exp(\chi k(c)).$$

There are $u_J, A_J, a_G > 0$ such that the following statements hold on $\|c\|_\infty < u_J$.

1. *The maps k and G^{Ω} are holomorphic, periodic, and equivariant under constant global color rotations. At real data they take values in $\mathfrak{su}(2)$ and $\mathrm{SU}(2)$, respectively, and $\|k(c)\|_\infty \leq$*

$A_J\|c\|_\infty$. Their order-l absolute coefficients are bounded by $l!C_J^{l+1}$, with the connecting-network weight at exponent a_G and with the volume-normalized column of every fixed input. Replacing the volume normalization of a column for a fine output by counting measure costs at most the factor $M^{3s} \le M^{3J}$.

2. *At fixed geometry G^Ω depends only on c, not on the free coordinates or the frozen coordinates. It is exactly I at $c = 0$, at the coarse roots, and at all protected vertices, also for complex c.*
3. *Consequently, for every reconstruction U in the chart before gauge transformation,*

$$(T_M^s U^{G^\Omega(c)})_{\text{internal}} = (T_M^s U)_{\text{internal}}, \qquad (U^{G^\Omega(c)})(\sigma_e) a_e^{G^\Omega(c)} = U(\sigma_e) a_e$$

for every based transport of a frozen coordinate. A frozen link across the boundary of the block region with both fine endpoints protected is also unchanged.

4. *The gauge transformation is applied after the reconstruction in the rooted spanning-forest coordinates. It does not change the free coordinates, the support restrictions, the Haar disintegration density, or the determinant of the normalization of the fluctuation variables.*

The constants have the dependence of Section 19.1 and do not depend on the later widths or on the size of the protected set. The existence of a large-field decomposition whose protected vertices satisfy these hypotheses is a geometric hypothesis, not a conclusion of the lemma.

Proof. We take the torus gauge transformation of Theorem 13.2 for each $s \le J$, with a common smaller domain of targets. Extending the target by zero on the coarse links outside Ω deletes coefficients from its majorant. After a construction constant A is increased, the gauge transformation minus the identity has absolute row series at most

$$U(t) = \frac{At}{1 - At};$$

here and below this includes the connecting network and the versions with a fixed input. Theorem 13.2 also provides the logarithm of the gauge transformation. To check the domain condition, we fix $u_J \le U_T$ inside the larger target domain with $Au_J < 1/4$. This is the case $Q_T = 0$ of (19.1), and it gives $u_J < r_s$, a positive denominator, and the fixed intermediate chart margins for every $s \le J$. The convergent matrix logarithm is bounded by

$$\sum_{r \ge 1} \frac{U(t)^r}{r} = \log(1 - At) - \log(1 - 2At) \le \frac{At}{1 - 2At} \le 2At \qquad (0 \le t \le u_J). \tag{19.28}$$

In the first inequality, we wrote the difference of logarithms as $\log(1 + At/(1 - 2At))$ and used $\log(1 + x) \le x$ for $x \ge 0$. Products join coefficient networks. Fixing one input differentiates this majorant series, and on a further fixed smaller radius we obtain order-l tensors bounded by $l!C_J^{l+1}$, for an output row or for the volume-normalized column of

any input. The same bounds hold for $k(c)$, and in particular $\|k(c)\|_\infty \le A_J \|c\|_\infty$. The fine mesh in output units is M^{-s}, so the volume-normalized column of a fine output carries the factor M^{-3s}. Replacing it by counting measure multiplies the bound by the reciprocal, at most M^{3J}; no factor depending on the depth or the volume occurs.

At fixed geometry, multiplication by $\chi(v) \in [0,1]$ can only decrease an absolute coefficient row. With $L(t) = \sum_{r\ge1} U(t)^r/r$, exponentiating χk gives the coefficientwise majorant $\exp L(t) = (1-At)/(1-2At)$. This series and its fixed-input derivative series converge on a fixed smaller radius and give the asserted factorial coefficient bounds for G^Ω. The numerical bound $L(t) \le 2At$ in (19.28) bounds values only and is not used in this coefficient comparison. Periodicity and global color equivariance hold for the torus gauge transformation and its logarithm by Theorem 13.2, and multiplication by the fixed scalar cutoff and exponentiation preserve them. For real targets the logarithm of the compact gauge transformation lies in $\mathfrak{su}(2)$, and its exponential lies in $\mathrm{SU}(2)$; the complex functions are their holomorphic continuations with values in $\mathfrak{sl}_2(\mathbb{C})$ and $\mathrm{SL}(2,\mathbb{C})$.

The torus gauge transformation is I at $c = 0$ and at each coarse root, so its logarithm vanishes at these points. At every other protected vertex $\chi = 0$ by hypothesis. Hence $G^\Omega = I$ at all these points, identically as a holomorphic function and not only at real arguments.

The transport along a path σ from v to w transforms as

$$U^G(\sigma) = G_v U(\sigma) G_w^{-1},$$

since all intermediate vertex factors cancel. A based transport $U(\sigma_e)a_e$ therefore transforms only at its basepoint and at the far fine endpoint of e. Both values of the gauge transformation there are I, which implies the second identity in part (3). If both fine endpoints of a frozen link across the boundary of the block region are protected, the gauge transformation also leaves its value unchanged.

For the coarse output, every based loop holonomy in the centered average (4.3) transforms by conjugation at its initial coarse root, and its reference path transforms at its two coarse endpoints. On the branch of the logarithm used here, the logarithm commutes with conjugation, term by term in its power series. Thus one averaging step is covariant, with the gauge transformation acting only at the coarse endpoints. Iterating s steps cancels the intermediate gauge factors and leaves only the gauge transformation at the two coarse roots of the output link, where it is I. This proves the first identity in part (3), also at complex data. No exceptional value of the Borel extension of T_M occurs inside these charts.

Finally, the gauge transformation acts on a field already reconstructed from its free coordinates in the rooted spanning-forest coordinates, and it changes neither these coordinates nor the integration variables. Hence the support restrictions, the Haar disintegration density, and the determinant of the normalization of the fluctuation variables remain the

same functions of the original variables. The cutoff enters only as a bounded fixed multiplier; neither the size of its support nor a derivative in its geometric parameters enters any bound. This proves that the constants do not depend on the size of the protected set or on the later widths, under the stated hypothesis on the protected vertices. □

19.5 The gauge-transformed reconstruction and its input columns

We now apply $G^{\Omega}(c)$ to the regional reconstruction and compare the result with the gauge-transformed torus reconstruction of Theorem 13.2. Let $a_R^{\mathrm{raw}}(c,q;\xi)$ be the logarithm of the regional reconstruction before gauge transformation, built from the successive regional conditional stationary points and constrained inverse square roots, and let a_T^{raw} be the corresponding torus reconstruction. For a fine link $e=(v,w)$ and a logarithmic gauge field k, we write

$$H_e^{\chi}(a,k) = \mathrm{Log}\big(e^{\chi(v)k(v)}e^{a_e}e^{-\chi(w)k(w)}\big).$$

Then $\Phi_R = H^{\chi}(a_R^{\mathrm{raw}},k(c))$ is the logarithm of the regional reconstruction transformed by $G^{\Omega}(c)$, and $\Phi_{\mathbb{T}} = H^{1}(a_T^{\mathrm{raw}},k(c))$ is the gauge-transformed torus reconstruction of Theorem 13.2.

Theorem 19.6. *On the fixed products of Theorem 19.4 and Lemma 19.5, build the reconstruction from the free coordinates with the successive regional conditional stationary points and constrained inverse square roots, with small newly frozen coordinates ξ. There are fixed larger construction radii and positive rates such that, on every smaller product of coarse fields and fluctuation increments satisfying the domain conditions,*

$$\Phi_R(c,q;\xi) = \Phi_{\mathbb{T}}(c\oplus 0, q\oplus 0)|_{\Omega} + \Delta(c,q;\xi),$$

where $q\oplus 0$ uses the same scale indices on the regional list and sets the remaining torus increments to zero. The following statements also hold.

1. *All terms have convergent majorant series in all variables. The correction Δ has factorial coefficient bounds with a root in Ω, a connecting network through every input, and a visit to H_{L_J}. In particular, let $\boldsymbol{R}$ be a radius profile on a smaller construction product, let $a>0$ be a fixed network exponent, and let $\Delta_{e,\nu}$ be the Taylor coefficients of Δ_e in its analytic variables, namely the coarse field, the increments q, and the newly frozen coordinates ξ. For a fixed input x, the differentiated series*

$$\mathcal{D}_{e,x}(\boldsymbol{R}) = \sum_{\nu:\nu_x\geq 1} \nu_x |\Delta_{e,\nu}| \boldsymbol{R}^{\nu-\mathbf{1}_x} e^{a\mathfrak{t}(\{e\}\cup\operatorname{supp}\nu)},$$

   with the measure conventions of Section 19.1, satisfies

$$\mathcal{D}_{e,x}(\boldsymbol{R}) \leq C_J e^{-a_W[\operatorname{dist}(e,W)+\operatorname{dist}(e,x)]}.$$

   Unlike $C_{e,x}$ in part (4), this series does not contain the factor R_x.

2. *At $q = 0$, the dependence of Δ on the newly frozen coordinates satisfies, in the coefficient norm in c,*

$$\|\Delta_e(\cdot, 0; \xi) - \Delta_e(\cdot, 0; 0)\|_{\text{coeff}} \le C_F \|\xi\|_\infty e^{-a_W \operatorname{dist}(e,W)}, \qquad \Delta(0,0;0) = 0.$$

3. *At radius s_q for the fluctuation increments, the absolute coefficient row sum of the terms of Δ of positive degree in q is at most $C_{\Delta,J} s_q$. The rows of the coarse-field terms near the boundary and all rows in the free variables are only bounded by finite constants depending on J; no contraction factor M^{-J} is asserted for them.*
4. *(Input columns.) Let $R_y \le K_* \rho$ be a construction profile, and choose $a_1, b_1 > 0$ with $b_1 > \alpha_{\text{bd}}$ and with $a_1 + b_1$ smaller than a decay exponent for which the full reconstruction has coefficient bounds without boundary weight. Define*

$$C_{e,x}(\boldsymbol{R}) = \sum_\nu \nu_x |\Phi_{R,e,\nu}(\xi)| \boldsymbol{R}^\nu e^{a_1 \mathfrak{t}(\{e\} \cup \operatorname{supp} \nu)},$$

where $\Phi_{R,e,\nu}(\xi)$ are the Taylor coefficients of Φ_R at the fine output e. Then $C_{e,x}(\boldsymbol{R}) \le D_J R_x e^{-b_1 \operatorname{dist}(e,x)}$, and

$$\sum_e e^{-\alpha_{\text{bd}} d_{\text{old}}(e)} C_{e,x}(\boldsymbol{R}) \le K_J \rho \, e^{-\alpha_{\text{bd}} d_{\text{out}}(x)},$$
$$K_J \le C_{M,J} D_J K_* e^{\alpha_{\text{bd}} C_J} \sum_{l \ge 0} (l+1)^3 e^{-(b_1 - \alpha_{\text{bd}}) l}.$$

Here d_{old} and d_{out} are the distances to the complements of the specified old and output position lists, respectively, both expressed in output units, and we assume that, for every summation label e and every input x,

$$d_{\text{out}}(x) \le d_{\text{old}}(e) + \operatorname{dist}(e,x) + C_J,$$

with a buffer C_J depending only on the fixed construction geometry. The sum runs over the full list of old output labels (the fine labels), at their creation-scale density. For an input among the free coordinates the same statement holds with its own radius R_x in place of $K_* \rho$ in the last bound. For a kernel from inputs to outputs, the column of a fixed input carries the volume of the output cells divided by the volume of the cell of that input. The same calculation applies to the profile $R_y = 2\rho$ within the auxiliary construction ball and to the smaller spatially varying radius profiles of Definition 18.1. These column bounds are different from the bounds on the image under the reconstruction majorant in Lemma 19.7.

The constants have the dependence of Section 19.1, are uniform in the depth and in the shape of Ω, and do not depend on the later widths. No equality with a perturbed incoming constrained problem is asserted.

Proof. We compare the successive regional and torus reconstructions before applying the gauge transformation with cutoff, and then estimate the differentiated coefficient series.

Step 1: the domain of the successive substitutions. We take a common larger construction product as in Theorem 19.4, with radii for coarse fields and free coordinates at most U_T and Q_T from (19.1). Then the torus reconstruction, its gauge transformation, and all column series below are evaluated with $u + v < r_s$ and denominator at least $1/2$, and the smaller product keeps the intermediate classical and Haar-density margins. For the finitely many conditional problems at the intermediate scales, we use the smaller parameter domains of Step 10 of the proof of Theorem 19.4. We choose the radius of the fluctuation increments so that every successive substitution lies strictly inside these domains. Such a radius exists: by Lemma 18.8, at $q = 0$ the successive conditional stationary points are the joint stationary point. Each conditional stationary point and each inverse square root has a convergent majorant series without boundary weight on a larger product. If A_i bounds the deviation of the coarser coordinates from the joint stationary point after the scales above i have been reconstructed, then by these series we have

$$A_{i-1} \le (1 + C_0)A_i + C_S s_q, \qquad A_s = 0, \tag{19.29}$$

on a fixed smaller free ball, where the constants are maxima of the rows of the conditional derivatives and of the inverse square roots on the larger products. The same recurrence holds in the coefficient norms. Iterating it at most J times, we obtain $A_i \le C_S s_q \sum_{j=0}^{J-1}(1 + C_0)^j$. Taking s_q smaller than a fixed fraction of every domain margin divided by this finite sum places the successive product inside the domains. This is the case $\delta_V = 0$ of Lemma 19.3(3), and this choice does not reduce the radius of the coarse field.

Step 2: one scale of the reconstruction. On the original list of free coordinates, the reconstruction at scale i is

$$\Gamma_i\big(c_{i+1}, a_i(c_{i+1}; \xi) + K_i(c_{i+1}; \xi)^{-1/2} q_i; \xi\big). \tag{19.30}$$

Here a_i is the conditional stationary point of the partial minimum after the finer scales have been eliminated, K_i is its constrained Hessian at scale i, and Γ_i is the local inverse chart of the block averaging constraint. The action at this scale is M^i times the partial minimum of the objective in input units, so K_i includes exactly the factor M^i. The variable q_i is the fluctuation increment, and no coupling is absorbed into K_i.

Step 3: the reconstructions before gauge transformation. On each common list the comparison of the stationary points is given by Theorem 19.4. To compare inverse square roots, we extend the regional matrix to the full list by its direct sum with a principal free block of the torus matrix on the complementary coordinates. Both summands have the gap. The internal difference is the difference of the regional and torus Hessians at nonzero coarse field, estimated in Theorem 19.4(5). The removed off-diagonal blocks of the torus matrix have their two roots on opposite sides of W, so they are boundary-localized. The identity (19.7) then gives the comparison on the common list, with every coarse-field and

free argument. When a list of finer coordinates is eliminated on one side and fixed on the other, the identity (19.9) inserts a chain through that list, as in Step 11 of the proof of Theorem 19.4, and that chain visits H_{L_J}. Thus the statement concerns the regional matrix itself, not the torus problem with coordinates deleted.

We subtract the regional and the torus versions of (19.30), with the torus free inputs outside the regional list set to zero. First we change the chart words at the same arguments; their difference lies in the fixed interface stencil. Then we change the conditional stationary point and the inverse square root, using the boundary-localized differences just proved. Finally we change their coarser arguments. The difference of an analytic function at two arguments is its derivative integrated along the common segment, that is, a tensor without boundary weight applied to a boundary-localized difference of arguments. At the coarsest scale these are all the terms. Each descent by one scale adds the boundary-localized difference from the scale above as one more difference of arguments. By induction over at most J scales, the difference $a_R^{\mathrm{raw}} - a_T^{\mathrm{raw}}$ is a convergent boundary-localized series. The values of the torus reconstruction on the complementary outputs, which can be nonzero at zero complementary free input, are joined by networks without boundary weight from their output in H to their inputs in Ω. Such networks cross W, and they provide the visit to H_{L_J} at the next substitution. No sum of sources over the volume of H without decay occurs.

Step 4: the gauge transformation. We apply the same torus gauge transformation $k(c)$ to both fields and cut it off only on the regional side. After the construction radius is chosen, all arguments of H_e^{χ} lie in one fixed larger identity chart, and the difference is

$$\begin{aligned} \Delta_e = {} & H_e^{\chi}(a_R^{\mathrm{raw}}, k) - H_e^{\chi}(a_T^{\mathrm{raw}}, k) \\ & + H_e^{\chi}(a_T^{\mathrm{raw}}, k) - H_e^{1}(a_T^{\mathrm{raw}}, k). \end{aligned} \tag{19.31}$$

The first line contains $a_R^{\mathrm{raw}} - a_T^{\mathrm{raw}}$ as a factor, after the derivative in a is integrated. The second line vanishes when both endpoint values of the cutoff equal 1, so its output root lies in a fixed interface band of width three blocks, including the buffer for the endpoints of fine links. Its other factors have the torus and gauge coefficient bounds of Theorem 13.2 and Lemma 19.5. These facts imply the boundary-localized estimate for both lines of (19.31). A coarse-field derivative which hits a gauge factor appends the network of that factor to the existing network and does not remove the visit to H_{L_J}. The torus term without the cutoff is $\Phi_{\mathbb{T}}$. This proves the decomposition and its factorial coefficient bounds.

Step 5: the cutoff at first order. The contribution of the cutoff can be read off at first order. Let $k_1 = Dk(0)c$. The cutoff part of the linearized correction on the link (v, w) is the difference of $(1 - \chi)k_1$ between its endpoints, which equals

$$(1 - \chi(v))(k_1(w) - k_1(v)) + (\chi(v) - \chi(w))k_1(w).$$

Both terms are contained in (19.31). In particular the second term, which contains the gradient of the cutoff, is not removed by treating the gauge transformation as constant in the target.

Step 6: the local logarithms. The local logarithms in this argument have uniform complex coefficient margins. Indeed, in a submultiplicative matrix norm the exponential series are dominated by e^t, and the logarithm of $I + X$ is dominated by $\sum_{l\ge 1} t^l/l$ on $\|X\| \le t < 1$. We take the rows of the reconstruction before gauge transformation and of the gauge transformation small enough that the product lies in such a disc with a fixed margin. Composition of majorants and the attached networks then bound every derivative of H_e^{χ}, with constants independent of $\chi \in [0,1]$.

Step 7: fixed inputs and the newly frozen coordinates. Fix an input x in the boundary-localized series of the reconstruction and keep its position while summing over the other indices. The connected network contains e, x, and a visit to H_{L_J}, so by the larger decay exponent and Lemma 18.15, we have $\mathcal{D}_{e,x}(\boldsymbol{R}) \le C_J e^{-a_W[\delta(e)+\operatorname{dist}(e,x)]}$. At $q = 0$ the dependence on ξ satisfies the coefficient identity

$$\Delta_e(c,0;\xi) - \Delta_e(c,0;0) = \int_0^1 \sum_f \xi_f D_{\xi_f} \Delta_e(c,0;t\xi)\, dt. \tag{19.32}$$

The derivatives in ξ come from its analytic input slots. The bound on their sum follows from part (4) of Theorem 19.4, the finite compositions of charts, and the fact that the gauge transformation does not depend on ξ. Integrating their coefficient series in c in (19.32), we obtain the bound $C_F\|\xi\|_\infty e^{-a_W\delta(e)}$ of part (2). At $c = q = \xi = 0$ the unperturbed stationary points vanish and both gauge transformations are the identity, so $\Delta(0,0;0) = 0$.

Step 8: terms of positive degree in q. If a convergent majorant series in all variables is bounded on a larger fixed free radius r_Q, then, for $s_q \le r_Q/2$, its terms of positive total degree in q are at most s_q times a fixed bound for its derivative majorant on the larger product. Applying this to (19.31), we obtain the bound $C_{\Delta,J} s_q$ of part (3). The rows near the boundary and the rows in the free variables are bounded by the corresponding convergent majorants without boundary weight, with no factor M^{-J}.

Step 9: the input columns. Fix the input x in the differentiated coefficient series. Removing one power of its radius R_x and using the column bound with any input fixed, we see that the connecting network contains a path from e to x. Assigning b_1 of the larger decay exponent to this path gives

$$C_{e,x}(\boldsymbol{R}) \le D_J R_x e^{-b_1 \operatorname{dist}(e,x)} \tag{19.33}$$

on every smaller construction profile in the statement; since the majorant has nonnegative coefficients, we may restrict to that profile before summing. A free input is included,

since it is an input of (19.30) and of every later composition. By hypothesis the distances satisfy

$$d_{\mathrm{out}}(x) \le d_{\mathrm{old}}(e) + \mathrm{dist}(e,x) + C_J,$$

where the additive constant is a fixed buffer. For an incoming list D_{in} whose complement lies in H up to the fixed stencil, with $d_{\mathrm{old}}(e) = d_{D_{\mathrm{in}}}(e)/B_s$, this condition follows from Lemma 19.8 after the incoming distance and the buffer are divided by B_s; we do not identify the incoming and the current fixed complements. Since $B_s \ge 1$, the condition also holds when d_{old} is measured in input units. Hence

$$\begin{aligned}\sum_e e^{-\alpha_{\mathrm{bd}} d_{\mathrm{old}}(e)} C_{e,x}(\boldsymbol{R}) &\le D_J R_x e^{\alpha_{\mathrm{bd}} C_J} e^{-\alpha_{\mathrm{bd}} d_{\mathrm{out}}(x)} \sum_e e^{-(b_1-\alpha_{\mathrm{bd}})\,\mathrm{dist}(e,x)} \\ &\le C_{M,J} D_J R_x e^{\alpha_{\mathrm{bd}} C_J} e^{-\alpha_{\mathrm{bd}} d_{\mathrm{out}}(x)} \sum_{l\ge 0} (l+1)^3 e^{-(b_1-\alpha_{\mathrm{bd}})l}.\end{aligned}$$

Using $R_x \le K_* \rho$, we obtain the bound on K_J; keeping R_x gives the version for a free input. The sum includes every old output label at its density; restricting it to a sublist only decreases it. For a kernel from inputs to outputs it is multiplied by the volume of the fine output cells divided by the volume of the cell of the fixed input, as in Definition 4.6. The colors and the finitely many scale indices enter $C_{M,J}$, not a factor of the lattice volume. Setting $R_y = 2\rho$ is allowed within the auxiliary ball since $K_* \ge 2$, and the smaller spatially varying radius profile is another restriction of the same nonnegative coefficient series. This completes the proof. □

19.6 Construction radii and bounds on the reconstruction majorant

The next lemma collects the conditions on the radii under which the reconstruction maps a product domain strictly inside the analytic domain used at the next step, in the following sense. For a map with a convergent Taylor series, the absolute coefficient row sum of the Taylor series, evaluated at the radii of the product domain, bounds the image of the domain under the majorant of the map. For the reconstruction we call this bound the image under the reconstruction majorant. For $c \ge 0$ we write S_c for this row sum with the weight $e^{c\ell}$, where ℓ is the length of the connecting network of a monomial including its output; thus S_0 is the unweighted row sum. A bound $S_c < \rho/2$ is stronger than a bound on the values of the map, and it is the hypothesis needed to substitute the reconstruction into a function whose coefficients are controlled at radius ρ. The lemma is applied twice, with the quantum radius ρ and with the classical radius ρ_{cl}.

Lemma 19.7. *Fix the constants of the unperturbed constructions before the later choices of the boundary-layer width, the erosion width, the widths of the protected neighborhoods, and the bound β_{rec} on newly frozen coordinates.*

1. *(Construction radius.) Let $v_{\mathrm{free},J} > 0$ be a free construction radius, distinct from the density constant v_J, with*
$$Q_J v_{\mathrm{free},J} < \lambda_J/64, \qquad I_J Q_J v_{\mathrm{free},J} < r_{z,J}/64.$$
There is a radius $R_{\mathrm{raw}} > 0$, inside both the chart of the block averaging constraint and the chart of Theorem 11.6, which may be chosen below
$$\min\Big\{\frac{\min(r_{\Gamma,J}, r_E)}{64G_J}, \frac{\lambda_J}{64Q_J}, \frac{r_{z,J}}{64I_J Q_J}, \frac{v_{\mathrm{free},J}}{64C_{\mathrm{lift},J}}\Big\}.$$
Here G_J and $r_{\Gamma,J}$ are the bound and the radius of the finite constraint words, r_E is the larger radius of the torus action, and $C_{\mathrm{lift},J}$ bounds the block-constant lift and the coarse-field lift, including all embeddings for the initial segments. If
$$C_{\mathrm{lift},J}[K_* \max(\rho, \rho_{\mathrm{cl}}) + r + \beta_{\mathrm{rec}} + q_{\mathrm{raw}}] < R_{\mathrm{raw}}/8,$$
where r is the radius of the small-link domain B_r and q_{raw} is the radius allowed for the fluctuation increments before gauge transformation, then all images of the reconstruction before gauge transformation lie in these fixed larger charts, and their real free Hessians have gap at least $\lambda_J/2$, with the complex inverse margins. No factor M^{-J} is required of the lift.
2. *(Zero fluctuations.) For each $\rho_\bullet \in \{\rho, \rho_{\mathrm{cl}}\}$, use its own spatially varying radius profile $\phi_\bullet$, equal to the boundary radius $\rho_{\partial,\bullet}$ at labels within distance w_{bd} of H and to $\rho_\bullet$ elsewhere, the outer profile $K_*\phi_\bullet$, and the outer boundary radius $R_{\partial,\bullet} = K_*\rho_{\partial,\bullet}$. For a full renormalization group step, $s = J$ and $B = M^J$, assume the torus contraction inequality (the first inequality below) and impose the four inequalities*
$$B^{-1}Z_\bullet(K_*\rho_\bullet) \le \rho_\bullet/16, \quad C_{\Delta,\bullet}C_{a,\bullet}R_{\partial,\bullet} \le \rho_\bullet/16,$$
$$C_{\Delta,\bullet}C_{a,\bullet}e^{-a_W w_{\mathrm{bd}}/2}K_*\rho_\bullet \le \rho_\bullet/16, \qquad C_{F,\bullet}\beta_{\mathrm{rec}} \le \rho_\bullet/16,$$
where $Z_\bullet$ is the classical row majorant of Theorem 13.2, $C_{\Delta,\bullet}$ and $C_{F,\bullet}$ are the constants of Theorem 19.6, and $C_{a,\bullet}$ is a summation constant fixed in the proof. These constants are evaluated on the larger auxiliary construction ball, before the radii and widths are chosen. The sum of the four left sides bounds the row sum S_0 at $q = 0$ by $\rho_\bullet/4$.
3. *(Fluctuation increments.) For a radius s_q of the fluctuation increments, the increment of S_0 is bounded by*
$$W_\bullet(s_q) = \frac{C_{T,\bullet}s_q}{1 - C_{T,\bullet}(K_*\rho_\bullet + s_q)} + C_{\Delta,\bullet}s_q.$$
Require the denominator to be at least $1/2$ and $W_\bullet(s_q) \le \rho_\bullet/8$ for both radii. The same rule applies to the product in the jointly normalized coordinates u, with its finite-composition free radius and its own denominator, which includes β_{rec} if it occurs in that majorant. The products for the successive substitution must lie in this joint product.

4. *(Spatial weight.) The resulting unweighted absolute row sum satisfies* $S_0 \le 3\rho_\bullet/8$. *If* $S_c \le C_J\rho_\bullet$ *for a fixed* $c > 0$, *then there is a fixed* $0 < \vartheta < 1$, *common to both radii and to the finitely many initial segments, such that*

$$S_{\vartheta c} \le S_0^{1-\vartheta} S_c^{\vartheta} \le \rho_\bullet (3/8)^{1-\vartheta} C_J^{\vartheta} < \rho_\bullet/2.$$

Thus, for both radii, the image under the reconstruction majorant, with connecting-network weight at one positive exponent, is less than half of the radius.

All constants and thresholds have the dependence of Section 19.1 and do not depend on the later widths. For a composition of $s < J$ *averaging steps, the conclusion of part (4) requires the torus contraction inequality with* $B_s = M^s$ *in place of* B, *which must be checked separately for that composition; the finiteness of the constants at fixed* J *does not give it.*

Proof. We choose the construction radius, bound the unweighted row sum at zero fluctuation and its increment, and then add the spatial weight by interpolation.

Step 1: the construction radius. We choose the finite word and lift constants on the larger products of Theorem 18.12 and Lemma 19.3. We increase $C_{\mathrm{lift},J}$ so that it bounds the block-constant lift of the target, the coarse-field lift, the extensions by zero and by the small newly frozen coordinates, and each of the finitely many embeddings for initial segments. Since a local lift uses only its block stencil of fixed depth, its row and input columns have one finite coefficient bound, independent of the number of components and of the later interface widths. Let $v_{\mathrm{free},J}$ satisfy the two strict inequalities in part (1), and let R_{raw} lie below the listed bounds and below the common radii of the local Haar-density chart and of the compact-overlap chart. The lift inequality then places all images strictly inside the larger inverse and torus action charts, their free arguments inside the radius $v_{\mathrm{free},J}$, and their stationary points inside the solution radius $r_{z,J}$. Indeed, the variation of the free Hessian is bounded by the sum of its contributions from the free radius and from the lifted arguments, which is at most

$$Q_J v_{\mathrm{free},J} + Q_J R_{\mathrm{raw}} < \lambda_J/32.$$

Enlarging the fixed lift constant before the radii are chosen accounts for any finite number of such types of arguments. The displacement of the stationary point is bounded by the corresponding inverse times gradient, which is less than $I_J Q_J (v_{\mathrm{free},J} + R_{\mathrm{raw}}) < r_{z,J}/32$. The real gap λ_J at the identity therefore implies a real gap at least $\lambda_J/2$ on all these products, with room for the complex margins. The term $E'_{d_0}\Psi_{zz}$, which contains the gradient of the action, is included in the bound on the variation of the Hessian in Theorem 18.12. The conditional stationary points are those of Lemma 19.3.

Step 2: the row sum at zero fluctuation. We carry out the following calculation for each $\rho_\bullet$, with its own profile and constants. The construction radii satisfy $K_*\rho_\bullet \le U_T$ and

$s_q \le Q_T$, so $K_*\rho_\bullet + s_q < r_s$ and all intermediate margins hold by (19.1); these domain checks precede each rational majorant. At $q = 0$ we use Theorem 19.6. By Theorem 13.2, the torus term has absolute row at most $B^{-1}Z_\bullet(K_*\rho_\bullet)$. We split the regional correction into its value at $\xi = 0$ and its increment in ξ. By Theorem 19.6(2), the latter is bounded by $C_{F,\bullet}\beta_{\mathrm{rec}}$ in the coefficient norm in the target. The former vanishes at zero target, and integrating its differentiated series with a fixed target input bounds it by

$$C_{\Delta,\bullet}\sum_x R_x e^{-a_W[\delta(e)+\mathrm{dist}(e,x)]}, \qquad R_x = (K_*\phi_\bullet)(x),$$

where $C_{\Delta,\bullet}$ is increased to include the fixed normalization of the derivative. Terms with $\delta(x) < w_{\mathrm{bd}}$ have $R_x = R_{\partial,\bullet}$, and their sum is at most $C_{a,\bullet}R_{\partial,\bullet}$, where $C_{a,\bullet}$ bounds the sum of the exponentials. For the other terms, by the conventions for endpoints, we have

$$\delta(e) + \mathrm{dist}(e,x) \ge \delta(x) - L'_J \ge w_{\mathrm{bd}} - L'_J.$$

We use half of the exponent for this inequality and sum the other half using the density bound. After $e^{a_W L'_J/2}$ is included in the fixed constant $C_{a,\bullet}$, these terms are at most $C_{a,\bullet}e^{-a_W w_{\mathrm{bd}}/2}K_*\rho_\bullet$. This bounds the row at $q = 0$ by the sum of the four terms of part (2). Since each of them is at most $\rho_\bullet/16$, the row is at most $\rho_\bullet/4$. All constants in this calculation were evaluated on the larger unperturbed auxiliary ball, before w_{bd} or the smaller boundary radius was chosen.

Step 3: terms of positive degree in the increments. For positive degree in the free coordinates, the torus row is bounded by

$$\frac{C_{T,\bullet}s_q}{1 - C_{T,\bullet}(K_*\rho_\bullet + s_q)},$$

which is the majorant of Theorem 13.2. The row of the correction of positive degree in q is at most $C_{\Delta,\bullet}s_q$, by Theorem 19.6(3). Adding the two, we obtain $W_\bullet(s_q)$, and under the two conditions of part (3) the increment is at most $\rho_\bullet/8$. Combining this with Step 2, we obtain the absolute coefficient row bound

$$S_0 \le 3\rho_\bullet/8. \tag{19.34}$$

The denominator cannot be discarded: its geometric series contains all higher degrees in the free coordinates and in the target.

Step 4: the jointly normalized coordinates. For the joint coordinate u, we substitute $z = z_0 + K_0^{-1/2}u$ into the maps in the original coordinates before taking the majorant. The successive increments are recovered from z by

$$q_i = K_i(c, z_{>i}; \xi)^{1/2}\big(z_i - a_i(c, z_{>i}; \xi)\big),$$

which inverts the unperturbed insertion at scale i. The factor $K_i^{1/2} = K_i K_i^{-1/2}$ has the same larger coefficient bounds. At $u = 0$ all these increments vanish, since the chain at zero fluctuation is the joint stationary point. By finite composition of majorants, there exists a joint radius for which the resulting majorant of the increments is at most Q_T. We take the product of u inside this radius and inside the solution domains of the initial segments. Its target argument is at most U_T, so (19.1) also verifies the torus domain and the denominator for this composition. The finite composition has a rational majorant of the same kind for its increment, with its own constants and argument; in particular, a contribution of the newly frozen coordinates to that argument remains in its denominator. Requiring this majorant to be at most $\rho_\bullet/8$ gives (19.34) for the joint product as well. The products for the successive substitution are restricted to the preimage of this product and to the domains of Lemma 19.3. This restricts a coefficient series which is already bounded.

Step 5: the spatial weight. For one output row, we write its terms as $b_\nu \geq 0$ and let ℓ_ν be the length of the attached network, including the output root. For finite partial sums, by Hölder's inequality with exponents $1/(1-\vartheta)$ and $1/\vartheta$, we have

$$\sum_\nu b_\nu e^{\vartheta c \ell_\nu} = \sum_\nu b_\nu^{1-\vartheta} (b_\nu e^{c\ell_\nu})^\vartheta \leq \Big(\sum_\nu b_\nu\Big)^{1-\vartheta} \Big(\sum_\nu b_\nu e^{c\ell_\nu}\Big)^\vartheta ,$$

and passing to increasing partial sums gives the inequality for the convergent series. Using $S_c \leq C_J \rho_\bullet$ and (19.34), we obtain the bound in part (4). The function $\vartheta \mapsto (3/8)^{1-\vartheta} C_J^\vartheta$ is continuous at $\vartheta = 0$, with value $3/8 < 1/2$. We fix $\vartheta \in (0,1)$ at which its value is below $1/2$ for both radii and for the finitely many initial segments. This proves both weighted bounds on the image under the reconstruction majorant at the same positive exponent. Because the weighted row bound is a bound of the unperturbed construction, this choice of exponent uses no later perturbative estimate.

Step 6: shorter compositions. For $s < J$, Step 1 and all estimates for finite compositions still apply, with $B_s = M^s$. The first inequality of part (2), however, becomes $B_s^{-1} Z_\bullet(K_* \rho_\bullet) \leq \rho_\bullet/16$, which follows only from a separate contraction inequality for that composition. This is the restriction for $s < J$ in the statement. □

19.7 Perturbations of the incoming action

The incoming action of a renormalization group step on a block region is the effective classical action plus a perturbation, defined on the list of variable labels of the previous step. This list and the current block region play different roles; in particular, the protected vertices of the gauge transformation alone do not determine the boundary of the incoming list. We first compare the distance to the boundary of the incoming list with the distance to the current boundary.

Lemma 19.8. *Fix $1 \le s \le J$, $B_s = M^s$, a list D_{in} of incoming positions, and a block region Ω. Use the periodic graph metric, rescaled linearly on positions of coordinates introduced at finer lattices, and freeze all components of a label at one position together. Write $\pi_s x = x/B_s$. Suppose that every position $x \notin D_{\mathrm{in}}$ lies in H up to the fixed chart stencil:*

$$\operatorname{dist}(\pi_s x, \Omega^c) \le L_{\mathrm{buf},J}.$$

Here $L_{\mathrm{buf},J}$ and the fixed buffer $c_{\mathrm{end},J}$ for the convention on link endpoints depend only on the construction geometry, and are fixed before the later widths. Let $d_{D_{\mathrm{in}}}(i)$ be the distance of i to the complement of D_{in}, in input units, and $d_{\mathrm{current}}(e)$ the distance of e to H, in output units. Then for every $i \in D_{\mathrm{in}}$ and every position e of a label in Ω,

$$d_{D_{\mathrm{in}}}(i) \ge B_s d_{\mathrm{current}}(e) - B_s \operatorname{dist}(e, \pi_s i) - C_{\mathrm{buf},J}, \qquad C_{\mathrm{buf},J} = \max_{1 \le s \le J} B_s (L_{\mathrm{buf},J} + c_{\mathrm{end},J}). \tag{19.35}$$

The same conclusion holds with $\operatorname{dist}(e, W)$ in place of $d_{\mathrm{current}}(e)$ after the fixed endpoint buffer is enlarged. It also holds if H is enlarged by additional blocks.

Proof. Suppose that the complement of D_{in} is nonempty, and choose a position $x \notin D_{\mathrm{in}}$ reached by a shortest path from i to this complement; its length is $d_{D_{\mathrm{in}}}(i)$. The scaled path has length $d_{D_{\mathrm{in}}}(i)/B_s$, including the position of x at its own lattice; scale indices and colors give no extra distance. By the triangle inequality and the hypothesis, we have

$$\begin{aligned} d_{\mathrm{current}}(e) &\le \operatorname{dist}(e, \pi_s x) + L_{\mathrm{buf},J} + c_{\mathrm{end},J} \\ &\le \operatorname{dist}(e, \pi_s i) + d_{D_{\mathrm{in}}}(i)/B_s + L_{\mathrm{buf},J} + c_{\mathrm{end},J}. \end{aligned}$$

Multiplying by B_s, we obtain (19.35). The endpoint buffer covers the difference between the distance to the positions in H and the distance to the interface W. Enlarging H can only decrease its distance from a fixed position in Ω, so additional blocks of H preserve both the hypothesis and the bound. If D_{in} has no complement, the finiteness of the boundary seminorm forces the nonconstant boundary part of the incoming perturbation to vanish, by the convention of Definition 18.1, and there is no incoming boundary dependence to transport. If D_{in} is empty there is no incoming root. □

The constant incoming radius in the next theorem is the radius produced by freezing, in the following form of Lemma 18.9. We start with a classical output profile ϕ of interior radius r_c on a set D of variable labels, keep $I \subset \{i \in D : d_D(i) \ge s_{\mathrm{er}}\}$ with $s_{\mathrm{er}} \ge \max(2, w_{\mathrm{bd}})$, and freeze $F = D \setminus I$, which contains the zone of reduced radius. For an analytic function f and frozen values $c^\sharp$, we write $T_{c^\sharp} f(v) = f(v \oplus c^\sharp) - f(0 \oplus c^\sharp)$. For $|c_j^\sharp| \le \eta \phi(j)$ with $\eta \le 1/4$, Lemma 18.9 implies

$$\phi|_I \equiv r_c, \qquad \mathcal{X}_I^{r_c}(T_{c^\sharp} f) \le 2 e^{-\alpha_{\mathrm{cl}}(s_{\mathrm{er}}-1)} \mathcal{X}_D^{\phi}(f). \tag{19.36}$$

The seminorms here have the classical normalization and the stated network and boundary rates. The identity $\phi|_I \equiv r_c$ holds because every remaining position lies outside the zone of reduced radius, and it is needed for the seminorm with constant profile on the left. The frozen values become fixed real parameters, not new variables of radius r_c. Applying (19.36) to the boundary correction produced at the previous step, with $D_{\mathrm{in}} = I$, gives the incoming seminorm at the next step. A new classical boundary-completion difference of the torus action must in addition satisfy its own bound in the seminorm with constant profile, by the separate statement on such differences in Lemma 18.9; erosion alone does not bound such a difference at an additional component of H. The theorem below assumes the bound on the incoming seminorm. That the regions and frozen values of a large-field decomposition satisfy its hypotheses is verified in the construction of that decomposition in Section 21.

Theorem 19.9. *Fix the domains, the protected geometry, the radius R_{raw}, the conditions on the image under the reconstruction majorant for both radii, and the products for the initial segments of Lemmas 19.3, 19.5, and 19.7, with $s = J$; compositions of $s < J$ averaging steps are treated at the end of the statement. Fix K_*, classical input rates $a_{\mathrm{cl}}, \alpha_{\mathrm{cl}} > 0$, and $r_c = \rho_{\mathrm{cl}}$. Let $b = (\xi, b_{\mathrm{rec}})$, where the newly frozen coordinates ξ are small and the previously frozen coordinates b_{rec} are arbitrary in their allowed real set.*

The incoming action. *Let $E_{\mathrm{in}}(a; b) = E_{d_0}(\iota_0 a) + P(a; b)$ be holomorphic and real at real arguments in its variable input a, with b_{rec} fixed, where ι_0 extends a by zero. Fix its incoming list D_{in} of variable labels, the positions of these labels at the lattices where they were introduced, and their cell volumes. The incoming seminorm is the seminorm $\mathcal{X}^{r_c}_{D_{\mathrm{in}}, a_{\mathrm{cl}}, \alpha_{\mathrm{cl}}}$ of Definition 18.1, with the constant profile $\phi_{\mathrm{in}} \equiv r_c$ on every label of D_{in} at which Φ_0 below is substituted; the labels of ξ are fixed parameters of this seminorm. The spatially varying radius profiles are used only for the output. Assume that the complement of D_{in} lies in H up to the fixed stencil, as in Lemma 19.8 (H may contain additional blocks), and that, in input units, for every position e of a label in Ω and every incoming position i,*

$$d_{D_{\mathrm{in}}}(i) \geq B_s d_{\mathrm{current}}(e) - B_s \operatorname{dist}(e, i/B_s) - C_{\mathrm{buf},J}, \qquad B_s = M^s,$$

where the positions on the right are in output units and the fixed buffer includes the chart stencils. If D_{in} has no complement, the nonconstant boundary part of the incoming perturbation is zero. All images of Φ_0 and all connecting segments lie strictly inside the ball of the incoming seminorm. A difference of two perturbations uses the same incoming list, weights, and profile.

The exterior extension. *If the unperturbed regional objective uses the extension ι_ξ, which inserts the newly frozen coordinates into their slots while all previously frozen torus slots remain zero, define the classical boundary-completion difference and the adjusted perturbation*

$$S^{\mathrm{cl}}_\xi(a) = E_{d_0}(\iota_\xi a) - E_{d_0}(\iota_0 a), \qquad \overline{P} = P - S^{\mathrm{cl}}_\xi,$$

and assume $\mathcal{X}^{r_c}_{D_{\mathrm{in}},a_{\mathrm{cl}},\alpha_{\mathrm{cl}}}(\overline{P}) \le 2\sigma_*$. *If the reference objective already uses the extension by zero, take* $S^{\mathrm{cl}}_{\xi} = 0$. *All constants of* S^{cl}_{ξ} *remain in the full classical action. The corresponding difference for the effective interaction, if the reference extension is changed there, is kept with the exact sign of the constant term in Lemma 18.9.*

The objective. *Let* z_0 *be the unperturbed joint stationary point,* $K_0 = F_{0,zz}(c, z_0; \xi)$, *and* $S_0 = K_0^{-1/2}$, *and put*

$$\begin{aligned} F_0(c,z;\xi) &= E_{d_0}(\iota_{\xi}\Psi_R(c,z;\xi)),\\ A_0(c,u;\xi) &= \Psi_R(c, z_0 + S_0 u;\xi),\\ \Phi_0(c,u;\xi) &= \mathrm{Log}[(\exp A_0(c,u;\xi))^{G^{\Omega}(c)}],\\ \mathcal{F}_{\lambda}(c,u;b) &= F_0(c, z_0 + S_0 u;\xi) + \lambda\overline{P}(\Phi_0(c,u;\xi);b), \qquad 0 \le \lambda \le 1, \end{aligned}$$

and $\mathcal{Q}_{\lambda}(c,z;b) = \mathcal{F}_{\lambda}(c, S_0^{-1}(z - z_0); b)$. *The perturbation is evaluated on the gauge-transformed reconstruction* Φ_0, *and the unperturbed Hessian of* $\mathcal{F}_{\lambda}$ *in* u *at* $u = 0$ *is* I. *Initial segments, the conditional stationary points* $a_{\lambda,I}$, *and the Hessians* $K_{\lambda,i}$ *refer to* $\mathcal{Q}_{\lambda}$, *in the original free coordinates.*

Then the following statements hold.

1. *(Incoming derivatives.) If the inputs at which* $\overline{P}$ *is evaluated have absolute coefficient row sums at most* $\kappa\rho_{\mathrm{cl}}$, *with* $0 < \kappa < 1$, *then for every* $j \ge 1$,

$$\|D^j\overline{P}\|_{\mathrm{root}} \le \frac{j!}{(1-\kappa)^{j+1}}(2\sigma_*)\rho_{\mathrm{cl}}^{2-j},$$

   with the incoming network and boundary weights, and with any differentiated input as root.

2. *(Stationary points.) There exist* $\sigma_{0,J}, Q_{0,J} > 0$ *and a fixed smaller domain of* u *such that the following holds for every* $0 \le \sigma_* \le \sigma_{0,J}$, *every* $0 \le \lambda \le 1$, *and every product of increments with* $\max_i \|q_i\|_{\infty} \le Q_{0,J}$ *whose substitutions stay in that domain. Every initial segment of the original free coordinates has a unique holomorphic stationary point of* $\mathcal{Q}_{\lambda}$ *in the domains of Lemma 19.3, and the inequalities of Lemma 19.3(2) on the preconditioned gradient and Hessian hold, not only a spectral bound. The stationary points are real at real data, the real free Hessians satisfy*

$$\frac{1}{2}\lambda_J I \le K_{\lambda,i} \le \Lambda_J I, \qquad \|u_{\lambda}\|_{\mathrm{coeff}} \le C_J\sigma_*\rho_{\mathrm{cl}},$$

   with the exact factors M^i *included in* $K_{\lambda,i}$, *and for every initial segment* I *and every* $y \in \mathcal{T}_I$,

$$\|a_{\lambda,I}(c,y;b) - a_I(c,y;\xi)\|_{\mathrm{coeff}} \le C_J\sigma_*\rho_{\mathrm{cl}}.$$

   The quantity δ_V *of Lemma 19.3 satisfies* $\delta_V \le I_0 C_P\sigma_*\rho_{\mathrm{cl}}$, *with constants* I_0, C_P *depending only on the fixed data, and* $\sigma_{0,J}, Q_{0,J}$ *are chosen so that the condition of Lemma 19.3(3) holds for all initial segments. The weighted complex resolvents are bounded by* $C_J/(\lambda_J + t)$ *for* $t \ge 0$ *at the allocated working rates of part (4).*

3. *(Differences.) The differences from $\lambda = 0$ of the stationary points, the Hessians, their inverses and inverse square roots, and the successive reconstructions have convergent boundary-localized coefficient bounds in all variables, including every coarse-field input in Ω and every fluctuation increment; their networks carry the incoming boundary dependence. These differences are $O_J(\sigma_*)$, and the displacements of stationary points are $O_J(\sigma_*\rho_{\mathrm{cl}})$ on the fixed product. For example, at fixed coarser coordinates y,*

$$\partial_\lambda z_{I,\lambda} = -\mathcal{Q}^{-1}_{\lambda,II} V_I,$$

where V_I is the I-component of the gradient of $z \mapsto \overline{P}(\Phi_0(c, S_0^{-1}(z - z_0); \xi); b)$. Along the successive chain this derivative contains the additional term $-\mathcal{Q}^{-1}_{\lambda,II}\mathcal{Q}_{\lambda,II^c}\partial_\lambda z_{I^c}$ and the full derivative $(\partial_\lambda K^{-1/2}_{\lambda,i})q_i$. The function $V = \overline{P} \circ \Phi_0$ satisfies $\|V_u\| \le C_J\sigma_*\rho_{\mathrm{cl}}$ and $\|V_{uu}\| \le C_J\sigma_*$; the term $\overline{P}'\Phi_{0,uu}$ is kept in the second derivative.

4. *(Output rates.) The estimates of part (3) hold at any fixed positive output rates $a_{\mathrm{out}}, \alpha_{\mathrm{out}}$ with*

$$a_{\mathrm{out}} + \alpha_{\mathrm{out}} < c_J / C_{\mathrm{geom}}, \qquad a_{\mathrm{out}} + \alpha_{\mathrm{out}} < B a_{\mathrm{cl}} / C_{\mathrm{geom}}, \qquad \alpha_{\mathrm{out}} < B\alpha_{\mathrm{cl}} / C_{\mathrm{geom}},$$

where C_{geom} is fixed before J, the rates, and the later widths: it depends only on the dimension, the block geometry, and the allocation of exponents, not on J or on the construction radii. Fixed stencil buffers depending on J affect the amplitudes C_J, not the coefficients of the distances. In particular, the perturbation and every external argument stay in one connected coefficient network.

5. *(Two perturbations.) For two perturbations $\overline{P}_0, \overline{P}_1$ as above, the bounds of parts (2) and (3) on the differences hold with σ_* replaced by $\mathcal{X}^{r_c}_{D_{\mathrm{in}}, a_{\mathrm{cl}}, \alpha_{\mathrm{cl}}}(\overline{P}_1 - \overline{P}_0)$. The corresponding minimized full actions $V_0^{\mathrm{out}}, V_1^{\mathrm{out}}$ satisfy a Lipschitz bound in the output seminorm with constant K_J^{cl}, namely* (19.51).

6. *(The full action.) The outgoing full action is $M^s\mathcal{F}_1(c, u_1; b)$, and on the connected chart*

$$\mathcal{F}_1(c, u; b) = E_{\mathrm{in}}(\Phi_0(c, u; \xi); b).$$

This identity uses the equality of classical actions on compact gauge overlaps only for the torus term, together with the cancellation of the exact classical boundary-completion difference. It does not assert that $\overline{P}(\Phi_0)$ equals $\overline{P}(A_0)$, and it uses no gauge identity for an incoming branch.

7. *(Frozen coordinates.) All perturbed estimates differentiate the coarse-field and free variables at fixed real $b = (\xi, b_{\mathrm{rec}})$; no derivative of a perturbed quantity in ξ or b_{rec} is asserted, and the unperturbed estimates in ξ of Theorem 19.4 are unchanged. If the incoming coefficients and the charts are Borel (respectively continuous) functions of the real parameter b, then the stationary points, the matrix functions, and the minimized values are Borel (respectively continuous) in b.*

All constants have the dependence of Section 19.1; they do not depend on the later widths, the number of preceding steps, the shape of Ω, the depth, or the smaller enclosing and fluctuation radii chosen later. For a composition of $s < J$ averaging steps, the same statements hold, with B_s in place of B, whenever the separate conditions of Lemma 19.7 for that composition hold; no repeated reduction of radii is used. The theorem is a local analytic statement and does not compare probability densities.

Proof. We extract the derivatives of the incoming perturbation from the incoming seminorm and transport its boundary dependence to the output. We then construct the stationary points with Lemma 19.3, first jointly and then for the initial segments. The remaining steps treat the differences, two perturbations, the full action, and the dependence on the frozen coordinates.

Step 1: conventions. All functions in this proof are considered at a fixed real $b = (\xi, b_{\mathrm{rec}})$ in the allowed set, including the newly frozen coordinates ξ. Every estimate is uniform over this set, and the supremum over it is taken after the sums over degrees. Only the coarse field in Ω, the free coordinates, and the interpolation parameter are differentiated, and the labels of ξ are not roots of the incoming seminorm.

Step 2: derivatives of the incoming perturbation. We write $r_c = \rho_{\mathrm{cl}}$ and $\overline{P}(a; b) = \sum_\nu p_\nu(b) a^\nu$, where every multi-index runs over D_{in}, with the positions of its labels at the lattices where they were introduced. Since $\phi_{\mathrm{in}}(i) = r_c$ for every such label, we define, for each degree k,

$$A_k(b) = r_c^{-2} \sup_{i \in D_{\mathrm{in}}} e^{\alpha_{\mathrm{cl}} d_{D_{\mathrm{in}}}(i)} \sum_{|\nu|=k} \frac{\nu_i}{k} |p_\nu(b)| r_c^k e^{a_{\mathrm{cl}} \mathfrak{t}_{\mathrm{in}}(\nu)}.$$

By hypothesis, $\sup_{b \text{ real}} \sum_{k \geq 1} A_k(b) \leq 2\sigma_*$. This uses the full input radius also at the incoming boundary; a reduced radius near the boundary appears only in the output product. By (19.36), the incoming action produced by freezing has this profile when the hypotheses of Lemma 18.9 on freezing the zone of reduced radius and on the frozen values hold. We consider inputs whose absolute coefficient row sums are at most κr_c, and fix the first differentiated input label i. In degree $k \geq j$, summing over the other $j-1$ ordered differentiated labels gives the factor

$$\frac{\nu_i}{k} (k)_j, \qquad (k)_j = k(k-1) \cdots (k-j+1),$$

and the remaining input powers are bounded by $\kappa^{k-j} r_c^{k-j}$. Keeping the original incoming network keeps all differentiated roots and all contracted input labels in it. Therefore the rooted derivative of order j is at most

$$r_c^{2-j} \sum_{k \geq j} A_k (k)_j \kappa^{k-j} \leq (2\sigma_*) r_c^{2-j} \frac{j!}{(1-\kappa)^{j+1}},$$

where we used $\sum_{k\geq j}(k)_j \kappa^{k-j} = j!/(1-\kappa)^{j+1}$, which follows by differentiating the geometric series j times. Any differentiated root can be chosen first, so this proves part (1), with the incoming network and the boundary weight of its root. Degree one is included. The constant coefficient p_0 does not appear in these derivatives and is not restricted.

Step 3: the normalized objective and the perturbing gradient. Let A_0, Φ_0, and $\mathcal{F}_\lambda$ be as in the statement, on the joint product of Lemma 19.7. The image of this product under the reconstruction majorant, with weight at one fixed positive exponent of the connecting network, is less than $r_c/2$, so part (1) applies with a fixed $\kappa < 1$, for example $\kappa = 1/2$. At $u = 0$ we have

$$D_u F_0(c, z_0 + S_0 u; \xi)\big|_{u=0} = 0, \qquad D_u^2 F_0(c, z_0 + S_0 u; \xi)\big|_{u=0} = S_0^{\mathsf{T}} K_0 S_0 = I. \tag{19.37}$$

The first identity is the joint stationarity, and the second uses the symmetric inverse square root on the branch connected to the identity. The coefficients of this function, and those of z_0, Ψ_R, and G^Ω, are bounded on a larger product by the unperturbed results above.

Let $V = \overline{P} \circ \Phi_0$. By the chain rule, we have

$$V_u = \sum_i \overline{P}_i(\Phi_0)(\Phi_0)_{i,u}, \tag{19.38}$$

$$V_{uv} = \sum_{i,j} \overline{P}_{ij}(\Phi_0)(\Phi_0)_{i,u}(\Phi_0)_{j,v} + \sum_i \overline{P}_i(\Phi_0)(\Phi_0)_{i,uv}. \tag{19.39}$$

By part (1) with $j = 1, 2$, together with the fixed rows and volume-normalized columns of the chart, we obtain

$$\|V_u\| \leq C_P \sigma_* r_c, \qquad \|V_{uu}\| \leq C_P \sigma_*. \tag{19.40}$$

The term $\overline{P}'\Phi_{0,uu}$ in (19.39) contributes $C_J \sigma_* r_c$, which is included in $C_P \sigma_*$ since r_c is fixed. We note that the perturbation need not have zero gradient at $u = 0$.

These bounds hold at all orders, as coefficient bounds with spatial weights. Let $B_J(t) = C_J t/(1 - C_J t)$ majorize the increment series of the chart in a fixed displacement direction, on a fixed larger domain. After division by the factorials of the derivatives, part (1) and the chain rule over partitions are bounded by the coefficients of

$$2\sigma_* r_c^2 \Big\{ \frac{1}{1 - \kappa - B_J(t)/r_c} - \frac{1}{1-\kappa} \Big\}. \tag{19.41}$$

Fix $t_* > 0$, a fixed multiple of $\min(r_c, 1)$, with $B_J(t_*) \leq (1-\kappa) r_c/2$. By nonnegativity of its coefficients, the coefficient of degree j of (19.41) is at most $C_J \sigma_* r_c^2 t_*^{-j}$, and restoring $j!$ gives the factorial bounds $j! C_J^{j+1} \sigma_* r_c^{2-j}$, with constants depending on the fixed radius. Fixing a coarse-field or free input uses the column version of the same composition, with the cell volume of that input. Thus all derivatives used here satisfy coefficient bounds on the product.

Step 4: transport of the incoming boundary dependence. A rooted input monomial carries its incoming network and a path from its chosen input root to the complement of D_{in}. The incoming list and its complement are those used in $A_k(b)$. By hypothesis the complement of D_{in} lies in H up to the fixed stencil, so Lemma 19.8 implies (19.35) with its fixed buffer, and hence the comparison assumed in the statement. We scale these paths by B^{-1} to output units and join every network of the chart at its fine input label. The union is connected and contains every external coarse-field and free argument. If the input root lies in Ω, its path to the complement of D_{in} reaches H after at most one additional leg of fixed length. If it lies in a newly removed region, the chart branch joining it to a root in Ω already reaches the boundary. Additional components of H can only shorten the required distance to the boundary.

To make this precise, let ℓ_0 be the length of the incoming network in input units, d_0^{in} the distance of the chosen root to the complement of D_{in}, and ℓ_β the lengths of the branches of the chart and of the free inverse in output units. Let A be the set of external positions and e any root in Ω. There exists a constant C_{dim}, depending only on the dimension and on the comparison of elementary paths, and fixed before J, such that

$$\begin{aligned} a_{\mathrm{out}}\mathsf{t}(A) + \alpha_{\mathrm{out}}\delta(e) \le C_{\mathrm{dim}}(a_{\mathrm{out}}+\alpha_{\mathrm{out}})\Big(\ell_0/B + \sum_\beta \ell_\beta\Big) \\ + C_{\mathrm{dim}}\alpha_{\mathrm{out}} d_0^{\mathrm{in}}/B + (a_{\mathrm{out}}+\alpha_{\mathrm{out}})L'_J(k+1). \end{aligned} \tag{19.42}$$

Indeed, the scaled incoming network and the chart branches alone join all external positions, and adding the scaled path to the complement of D_{in} also reaches the boundary. The first network bounds $\mathsf{t}(A)$, and the second bounds the distance of e to the boundary; this gives the separate coefficients of ℓ_0 and d_0^{in} in (19.42). Here k is the number of attached input factors, and the last term accounts for their fixed displacements by the stencil. To see why C_{dim} depends only on the dimension, we take shortest paths in the graph metric and their connected union. Using a tree on the external vertices increases the length by at most a factor two, by traversing each edge of a Steiner tree twice. Replacing segments by the fixed paths in coordinate order increases it only by the fixed comparison constant of the three coordinate directions. Scaling is exact, and neither operation depends on the number of scales. An offset depending on the scale changes only the additive term with L'_J, whose exponential $e^{CL'_J(k+1)}$ is absorbed in the factorial amplitude C_J^{k+1} on the fixed construction domain. More explicitly, we choose the working radii so that the larger unperturbed radii are at least ζ times the corresponding working radii, for a fixed $\zeta > 1$. Then a monomial of degree k gains the factor ζ^{-k}. We reduce c_J so that $e^{c_J L'_J} \le \zeta^{1/4}$, and the accumulated offset factors $e^{c_J L'_J(k+1)}$ are absorbed by these factors. This choice is made before the later profiles and widths, and it does not change C_{geom}.

We take $C_{\mathrm{geom}} \ge 8C_{\mathrm{dim}}$, increased according to the fixed allocation of exponents among the external network, the route to the boundary, and the internal sums, and we

keep part of the remaining exponent in each chart branch for its density sum $S_J(\varepsilon)$. Under the three strict inequalities of part (4), the incoming factors $e^{a_{\mathrm{cl}}\ell_0}$ and $e^{\alpha_{\mathrm{cl}}d_0^{\mathrm{in}}}$, together with the exponent c_J of the unperturbed branches, dominate the output network and boundary weights in (19.42), and a positive part of the exponent is left for the summations. The exponent in the bound on the image under the reconstruction majorant from Lemma 19.7 is included in the choice of c_J before these rates are specified. The allocation is applied to the whole network, so the exponent is not divided by the Taylor order or by the number of scales. This proves the boundary-localized versions of (19.40) and (19.41) at every allowed output rate.

Step 5: the joint stationary point. We now verify the domain conditions, working first in u near zero. By the unperturbed bound on the third derivative and (19.37), we have

$$\|D_u^2 F_0(c, z_0 + S_0 u; \xi) - I\| \le C_1 \|u\|_{\mathrm{coeff}}.$$

Fix $u_0 > 0$ inside the joint product with $C_1 u_0 < 1/8$, and fix $\sigma_{0,J} > 0$ with $C_P \sigma_{0,J} < 1/8$ and $C_P \sigma_{0,J} r_c < u_0/8$. Then $u \mapsto u - D_u \mathcal{F}_\lambda$ is a coefficient contraction with factor at most $1/4$ on the domain of radius u_0, and it maps the ball of radius $u_0/2$ into itself. Picard iteration gives a unique holomorphic joint stationary point, and from the fixed point inequality we obtain

$$\|u_\lambda\|_{\mathrm{coeff}} \le 2 C_P \sigma_* r_c. \tag{19.43}$$

The stationary point is real at real data, since $\mathcal{F}_\lambda$ is real at real arguments and the stationary point is unique.

Step 6: initial segments in the original coordinates. To treat initial segments, we return to the original free coordinates by the invertible affine map $u = S_0^{-1}(z - z_0)$ at fixed c and ξ. The pullback is

$$\mathcal{Q}_\lambda(c, z; b) = F_0(c, z; \xi) + \lambda \overline{P}\left(\mathrm{Log}[(\exp \Psi_R(c, z; \xi))^{G^{\Omega}(c)}]; b\right). \tag{19.44}$$

All subscripts referring to initial segments refer to this expression, with the original lists of scales. Because the affine map and its inverse have fixed coefficient bounds, (19.40) holds in the original coordinates with larger fixed constants. We take the solution domain of every initial segment from Lemma 19.3 small enough that its image under this affine map stays in the domain of radius u_0.

At an unperturbed conditional stationary point $a_I(c, y; \xi)$, the preconditioned perturbed gradient is

$$A_I^{-1} \mathcal{Q}_{\lambda,I}(c, a_I, y; b) = \lambda A_I^{-1} V_I(c, a_I, y; b),$$

whose coefficient norm is at most $I_0 C_P \sigma_* r_c$. This holds uniformly for every $y \in \mathcal{T}_I$, not only at the joint stationary point, since all these conditional reference points lie in the

image of the same product under the reconstruction majorant. If δ_V is defined for the pullback of V as in Lemma 19.3, the same calculation yields

$$\delta_V \le I_0 C_P \sigma_* r_c. \tag{19.45}$$

Across a conditional displacement of size r_I, the derivative bound is at most

$$\|A_I^{-1}(\mathcal{Q}_{\lambda,II} - A_I)\| \le I_0(C_1 r_I + C_P \sigma_*). \tag{19.46}$$

We first take r_I with $I_0 C_1 r_I < 1/8$, and then reduce $\sigma_{0,J}$ so that, for every initial segment,

$$I_0 C_P \sigma_{0,J} < 1/8, \qquad I_0 C_P \sigma_{0,J} r_c < r_I/8.$$

These inequalities are stronger than the two inequalities required in Lemma 19.3(2). We also require that the error of the real Hessian is less than $\lambda_J/8$. The coefficient resolvent condition is imposed at the allocated working rates of Step 4, using the unperturbed resolvents as references, as detailed in Step 8 below. The larger construction products, their radii, and the unperturbed half of the resolvent margin are fixed first; after J and these spatial rates are fixed, all perturbative constants in this condition are fixed before $\sigma_{0,J}$ is decreased and before the later widths and enclosing radii are chosen. Then Lemma 19.3 applies on each domain $\mathcal{T}_I$ of coarser coordinates, and its estimate (19.13) implies that, for every such y,

$$\|a_{\lambda,I}(c,y;b) - a_I(c,y;\xi)\|_{\mathrm{coeff}} \le 2\lambda I_0 C_P \sigma_* r_c \le C_J \sigma_* r_c. \tag{19.47}$$

This is the conditional bound of part (2), with one common $C_J \ge 2I_0 C_P$, and it holds before any moving coarser coordinates are substituted. The mixed coefficient bounds in the original coordinates follow from (19.41) and the affine inverse; together with the free inverse they verify (19.14) on the same products.

Step 7: successive substitution. The recurrence (19.15), with the conditional and matrix-function bounds just obtained, gives a constant $C_{\mathrm{seq},J}$ for a fixed rough bound on the size of the perturbation. Fix $Q_{0,J} > 0$ and, if necessary, reduce $\sigma_{0,J}$ further, so that

$$C_{\mathrm{seq},J}(2I_0 C_P \sigma_{0,J} r_c + Q_{0,J}) < \frac{1}{2}\varepsilon_{\mathrm{tube}}, \qquad Q_{0,J} \le r_c,$$

where the conversion between the original and the normalized coordinates is included in the minimal margin. The bound (19.45) verifies the condition of Lemma 19.3(3) for every y. The recurrence bounds every conditional reference point and every Newton iterate, not only the final solution, so the hypothesis on the image under the reconstruction majorant holds throughout the construction. This proves the statements on stationary points in part (2), for all initial segments simultaneously, on the product of increments.

Step 8: the Hessians. The unperturbed real Hessian in the original coordinates is at least $7\lambda_J/8$ on these products, since its variation from the Hessian at the identity is at most $\lambda_J/8$ by Theorem 18.12, and the perturbation changes it by less than $\lambda_J/8$. Its principal blocks and Schur complements have the same lower bound, since for a symmetric matrix $H \geq \lambda I$

$$v^{\mathsf{T}}(H_{yy} - H_{yI}H_{II}^{-1}H_{Iy})v = \min_{x}(x,v)^{\mathsf{T}}H(x,v) \geq \lambda|v|^2,$$

as in (18.6). After the normalization by $M^i \geq 1$, we obtain $K_{\lambda,i} \geq \lambda_J I/2$. The upper bounds on the tensors and on the inverses give a common upper bound Λ_J on the same product.

The complex resolvent condition is used at an allocated working exponent b_{w}, with strict reserve for the network and boundary weights of part (4). This exponent is smaller than b_{ref} and is within the transported incoming-rate allocation of Step 4. For each flat reference K_i^b, including the factor M^i when present, the unperturbed bounds give

$$\|(K_i^b + t)^{-1}\|_{b_{\mathrm{w}}} \leq \frac{C_{0,J}}{\lambda_J + t} \qquad (t \geq 0).$$

Put $L_i = K_{\lambda,i} - K_i^b$. At each fixed coarser argument on the conditional products, the fixed-reference Picard bounds of Steps 5 and 6 give the coefficient displacement of the conditional center. Together with Step 4 and the unperturbed mixed tensor bounds, they bound the perturbative matrix difference at b_{w} by $C_{P,b_{\mathrm{w}},J}\sigma_*$. For a Schur block, telescope its defining product and use the principal inverses already constructed. This estimate is obtained before successive substitution. Since $b_{\mathrm{w}} < b_{\mathrm{ref}}$, monotonicity preserves the unperturbed half-margin on the fixed products. Fix the perturbative constants at the working rates and then reduce $\sigma_{0,J}$ so that

$$C_{0,J}C_{P,b_{\mathrm{w}},J}\sigma_{0,J} \leq \lambda_J/8.$$

The two halves give $C_{0,J}\|L_i\|_{b_{\mathrm{w}}} \leq \lambda_J/4$ at every stage. With $R_i^b(t) = (K_i^b + t)^{-1}$, the ordered Neumann expansion

$$(K_{\lambda,i} + t)^{-1} = \sum_{n\geq 0}[-R_i^b(t)L_i]^n R_i^b(t)$$

converges in the coefficient norm at this same working exponent and gives $4C_{0,J}/[3(\lambda_J + t)]$. The bounds with an analytic input fixed follow by inserting the differentiated tensor in this normally convergent series on a fixed smaller product. Thus the inverse uses the intrinsic decay of the unperturbed resolvent and the allocated working decay of the incoming perturbation.

Step 9: the differences carry the perturbation. It remains to prove that the differences carry the incoming boundary dependence, including through the moving coarser arguments. At fixed y, differentiating the gradient equation of an initial segment, we obtain

$$\partial_\lambda z_{I,\lambda} = -\mathcal{Q}_{\lambda,II}^{-1} V_I. \tag{19.48}$$

The free inverse just constructed is a coefficient series at the allocated working rates without boundary weight, and V_I is the boundary-localized series of Steps 3 and 4. The majorant of the product is (19.4), and it is $O_J(\sigma_* r_c)$; integrating in λ proves the bound on the difference of stationary points. Let Z_λ be the stationary point at which a Hessian is evaluated, and let H denote here this Hessian of $\mathcal{Q}_\lambda$. Its total derivative is

$$\dot{H} = V_{zz} + \mathcal{Q}_\lambda^{(3)}[\dot{Z}_\lambda],$$

which is $O_J(\sigma_*)$ and boundary-localized. For a set L of finer eliminated coordinates, the Schur block of scale i is $S = H_{ii} - H_{iL} R H_{Li}$ with $R = H_{LL}^{-1}$, and its derivative is

$$\dot{S} = \dot{H}_{ii} - \dot{H}_{iL} R H_{Li} - H_{iL} R \dot{H}_{Li} + H_{iL} R \dot{H}_{LL} R H_{Li}. \tag{19.49}$$

Every term has exactly one factor which carries the perturbation, including the term coming from the derivative of the inverse. Multiplication by M^i gives the derivative of $K_{\lambda,i}$. The derivative of the inverse is $-K^{-1}\dot{K}K^{-1}$, and (19.7), or its differentiated integral, gives the derivative of the inverse square root, with integrable majorant $C_J t^{-1/2}(\lambda_J + t)^{-2}\|\dot{K}\|$. These identities prove the stated bounds on all differences of matrix functions.

Along the successive chain, the derivative in (19.48) becomes

$$\dot{z}_I = -\mathcal{Q}_{\lambda,II}^{-1}(V_I + \mathcal{Q}_{\lambda,II^c}\dot{z}_{I^c}).$$

An inserted increment has total derivative

$$\frac{d}{d\lambda}[a_{\lambda,i}(c, z_{>i}) + K_{\lambda,i}(c, z_{>i})^{-1/2} q_i] = \partial_\lambda a_{\lambda,i} + D_y a_{\lambda,i}\dot{z}_{>i} + \frac{d}{d\lambda} K_{\lambda,i}^{-1/2} q_i,$$

where the last derivative includes both the explicit change of the objective and the change of the coarser argument. We start at the coarsest conditional stationary point and descend. Each direct derivative carries the perturbation, and each new contribution from the coarser arguments contains a factor which is already known to carry it. By (19.49) and (19.7) this remains true for every inverse square root used at the next scale. Since $\|q_i\|_\infty \le Q_{0,J} \le r_c$, the finite recurrence gives $O_J(\sigma_* r_c)$ for the stationary points and the reconstructed displacements, and $O_J(\sigma_*)$ for their matrix coefficients. Differentiating in a coarse-field or free input fixes the index of that input in these convergent series, and the allocation of Step 4 keeps the perturbation and every external argument in one connected network. This proves part (3) on the product, and together with Step 4 it proves part (4).

Step 10: two perturbations. For two perturbations we interpolate between them. Since the coefficient bounds are convex and the fixed bound $\sigma_{0,J}$ holds for both, every interpolated objective stays in the same domains. Its derivative in the interpolation parameter is given by (19.48) with $V = (\overline{P}_1 - \overline{P}_0) \circ \Phi_0$. We set

$$\Delta_{\mathrm{in}} = \mathcal{X}^{r_c}_{D_{\mathrm{in}},a_{\mathrm{cl}},\alpha_{\mathrm{cl}}}(\overline{P}_1 - \overline{P}_0), \qquad \phi_{\mathrm{in}} \equiv r_c. \tag{19.50}$$

Since both perturbations use the same D_{in}, the same positions and cell volumes, and the same incoming boundary, all the preceding difference estimates are linear in Δ_{in}. We write $\mathcal{Q}_\lambda$ also for the interpolated objective. The derivative of the outgoing values in the interpolation parameter is

$$\partial_\lambda[M^s \mathcal{Q}_\lambda(c, z_\lambda; b)] = M^s(\overline{P}_1 - \overline{P}_0)(\Phi_0(c, u_\lambda; \xi); b).$$

Its nonconstant coefficient networks contain the same incoming difference, also when a derivative hits the stationary point. The fixed ratios of the radii, the composition bound, and (19.24) convert them into

$$\mathcal{X}^{\phi_{\mathrm{cl}},\mathrm{cl}}_{\Omega,a_{\mathrm{out}},\alpha_{\mathrm{out}}}(V_1^{\mathrm{out}} - V_0^{\mathrm{out}}) \le K_J^{\mathrm{cl}} \Delta_{\mathrm{in}}. \tag{19.51}$$

Here the outgoing classical seminorm uses the output profile ϕ_{cl} with interior radius r_c. The seminorm in (19.50) is the incoming seminorm with constant profile. The output seminorm includes degree one. A difference of incoming constants stays in the full value and has zero seminorm. This proves part (5).

Step 11: the full action. We prove the identity of part (6), with its constants. When Ψ_R is written on its regional list, ι_ξ inserts the newly frozen coordinates once; when it is written as a complete fine field, the same insertion is already included. In either notation, the exact identities of Lemma 19.5 at the endpoints imply the equality of complete group fields

$$\exp(\iota_\xi \Phi_0) = (\exp(\iota_\xi A_0))^{G^\Omega(c)},$$

since the basepoint and the fine endpoints of every based transport of a newly frozen coordinate are protected, and the gauge transformation is the identity on the previously frozen extension. For real data both complete fields lie in the common chart of Theorem 11.6: the field before gauge transformation by the choice of R_{raw}, and the gauge-transformed field by the bound on the image under the reconstruction majorant and the bound on the newly frozen coordinates. The gauge transformation is periodic and compact there. Thus Theorem 11.6 applies to the torus classical action, and only to it, and we obtain

$$\begin{aligned} \mathcal{F}_1 &= E_{d_0}(\iota_\xi \Phi_0) + P(\Phi_0; b) - S^{\mathrm{cl}}_\xi(\Phi_0) \\ &= E_{d_0}(\iota_0 \Phi_0) + P(\Phi_0; b) = E_{\mathrm{in}}(\Phi_0; b). \end{aligned}$$

These equalities keep $S^{\mathrm{cl}}_{\tilde{\zeta}}(0)$ as well as all nonconstant coefficients of $S^{\mathrm{cl}}_{\tilde{\zeta}}$; no constant Taylor coefficient has been subtracted. Both sides are holomorphic on the connected product, and they agree on its real open part. Expanding at a real interior point and differentiating the real identity in each coordinate, we find that all Taylor coefficients of the difference vanish. Continuation through overlapping polydiscs in the connected product gives the equality everywhere on it.

If the reference extension of the effective interaction is changed, the corresponding difference is treated by Lemma 18.9. In particular, replacing a resulting interaction $R(v, c)$ by $R(v, c) - R(0, c)$ changes the normalization constant from Λ to $\Lambda - R(0, c)$ and preserves the density; the constant of the extension is not deleted. The perturbation has been evaluated on Φ_0 throughout.

Step 12: dependence on the frozen coordinates. Fix the geometry, the finite lists of labels, and a strictly smaller analytic product, and suppose that the incoming coefficients and the charts are Borel functions of the real parameter b. A finite Taylor partial sum of any chart or incoming function is then jointly Borel in its analytic arguments and b. Since the common coefficient bounds on the larger radius give a geometric tail on the smaller product, uniformly in b, the limits of the series are jointly Borel. For the scalar incoming function this argument is applied to its part of positive degree, and the unrestricted coefficient $p_0(b)$ is kept as a separate Borel summand.

Every finite-dimensional matrix inverse used in a Picard iterate is a quotient of polynomials in its entries with nonzero determinant on the domain, hence Borel there, and each Picard iterate is a composition of such operations and of the jointly Borel functions just obtained. The uniform contraction ratio bounds the distance of the iterates to the stationary point by a geometric sequence, uniformly in b, which implies that the stationary point is jointly Borel. This applies first to the joint problem and then to every conditional problem, at arbitrary coarser arguments in the domains, and the finite successive substitution of these maps is Borel.

For matrix functions we use (19.5) and (19.6). Finite Neumann sums are Borel, and their uniform geometric limit gives the resolvent. On a compact interval of integration inside $(0, \infty)$ the Riemann sums of the integral for the inverse square root are Borel, and the uniform bounds on the gap and the resolvent make the tails at zero and at infinity small, uniformly in the parameters; hence the integral is Borel. The same argument applies to the differences and to the logarithmic factors on their fixed nonvanishing branches. Evaluating the full objective at the stationary point gives Borel minimized values, with the incoming constant restored exactly.

If the coefficients and charts are continuous in b, every finite partial sum, inverse, and Picard iterate in this argument is continuous. The common geometric bounds and contraction ratios make all limits uniform on the smaller products, and the tails of the integrals satisfy the same uniform bounds. The limits and the finite successive

compositions are therefore continuous in b. This proves part (7) without any derivative in ξ or b_{rec}.

Step 13: shorter compositions. For $s < J$ we replace B by B_s in the scaling and use the separate conditions on the radius and on the image under the reconstruction majorant for that composition; the proof for the initial segments is unchanged, with s in place of J. All constants were computed on fixed larger products, before the eventual free, enclosing, and geometric choices. □

SECTION 20

Fluctuation integration and normalization on block regions

In Sections 18 and 19 we set up the averaging steps of one renormalization group step on a block region. There, the coordinates attached to a union Ω of coarse blocks are analytic variables, and the coordinates on the fixed complement of Ω are frozen at real values chosen earlier. Those sections constructed the conditional constrained minimizers of the classical problem on Ω, proved a lower bound on the constrained Hessian independent of the shape of Ω, and controlled the effect of a small perturbation of the classical objective. The goal of this section is to integrate out the normalized fluctuation variables of such a step. We prove that the resulting effective interaction differs from the corresponding torus quantity only by terms that decay exponentially with the distance to the fixed complement, and we keep track of the normalization constant Λ by a separate argument. All estimates are uniform in the shape and topology of Ω, the number of its components, the preceding depth, the number of renormalization group steps already performed, and the values of the frozen coordinates.

Section 20.1 fixes the notation and the coefficient calculus. We then compare the conditional Hessians and Haar densities with their torus counterparts (Section 20.2) and derive the conditional fluctuation potential and its concentration bounds (Section 20.3). We obtain the effective interaction by a cluster expansion (Section 20.4) and control Λ by a separate comparison of real integrals (Section 20.5). Next, we choose the parameters and prove the finite iteration (Theorem 20.14). Finally, we sum the truncation errors for couplings in $(0, \Gamma]$ with any finite Γ (Section 20.7).

We use the norms and the dependence of constants of Section 4, the concentration estimates of Theorem 5.4, and the triangular change of variables and the finite graph inequality of Theorems 12.6 and 12.13. From Section 18 we use the norm with boundary decay, the network estimates, and the substitution identities, and from Section 19 the conditional domains, image bounds, perturbation theorem, and column bounds. The results are used in Section 21, which compares the integrals over the regions of the large-field decomposition with the analytic integrals constructed here, in Section 22, which proves the exponential-moment estimates for blocked actions, and in Section 23, which chooses the parameters.

All statements of this section concern analytic functions on stated domains and real integrals over stated products. We prove in Section 21 that the configurations of the large-field decomposition lie in these domains.

Heuristics. We first explain the orders of magnitude. We write the free logarithmic coordinates of one intermediate scale as $z = z^* + gK^{-1/2}w$, where z^* is the conditional constrained minimizer, K the constrained Hessian, g the coupling, and w the normalized fluctuation variable. Since the classical action enters the density divided by g^2, and its expansion around the minimizer has no linear term and a quadratic term equal to $|w|^2/2$, the remaining classical terms are

$$g^{-2}\,O\big((z-z^*)^3\big) = O(g|w|^3).$$

The Haar disintegration density, the logarithmic determinants of the higher scales, and the incoming effective interaction are not divided by g^2, and their dependence on w starts with a term of order $g|w|$. On fluctuation balls of radius $p \geq 1$, the interaction is therefore small when $g[p^3 + (1+H)p]$ is small, where H bounds the incoming effective interaction; this is the smallness condition of Theorem 20.9. The terms of first order in g are odd under $w \mapsto -w$. Their expectations under a symmetric reference measure vanish, and the fluctuation correction to the effective interaction is of order g^2. The conditional measure with the frozen coordinates held fixed is interacting and need not be symmetric. For this reason, we bound the means of the fluctuation variables separately in Lemma 20.5.

We control the normalization constant by two identities. First, a missing scalar Gaussian coordinate at an intermediate scale with coupling g_i removes one factor g_i from the density. This contributes $\log(1/g_i)$ to the difference between the regional and the torus normalization. Second, fixing coordinates at values c uses

$$e^{\Lambda - R(v,c)} = e^{\Lambda - R(0,c)} e^{-[R(v,c) - R(0,c)]},$$

which moves the value at $v = 0$ into Λ and leaves a centered function. Since the norms of the effective interaction vanish on constants, they cannot control Λ, and we estimate Λ by comparing real integrals.

Finally, fixing the coordinates of a boundary layer affects the boundary part of the effective interaction in two ways. First, the norm of the old boundary discrepancy is bounded by $2e^{-\alpha_{\mathrm{bd}}(s_{\mathrm{er}}-1)}$ times its previous norm, where s_{er} is the width of the frozen layer. Second, fixing coordinates at nonzero values creates a new mixed term from the torus interaction, of size at most a constant times $E\beta_{\mathrm{rec}}/\rho$, where E bounds the torus interaction and β_{rec} bounds the frozen values. The first estimate needs a wide layer, the second needs small frozen values, and neither replaces the other.

Attribution. The architecture used here, namely constrained minimization in a gauge-fixed chart, separation of a background field from normalized fluctuations, and integra-

tion of the fluctuations by a cluster expansion, is Bałaban's renormalization group for lattice gauge theories [18, 19]. We attribute the individual tools where they are used.

Order of the proofs. No conclusion is used before it is proved. In particular, Lemma 20.5 uses only the coefficient, product, and curvature bounds of Lemma 20.3, the density sum (20.1), and Theorem 5.4. It determines the constant C_1 in a hypothesis of Lemma 20.3, and the logarithmic radii of Theorem 20.14 enter it only as a sufficient condition for an inclusion.

20.1 Setting and coefficient calculus

Geometry and labels. Fix an odd integer $M \geq 3$, an integer $J \geq 1$, and $B = M^J$. We consider a composition of s averaging steps, $1 \leq s \leq J$, from a lattice of side $M^s m$ to a lattice of side $m \geq 4$, together with an arbitrary union Ω of blocks of the output lattice. When $s = J$, we speak of a full step; it is one renormalization group step. The intermediate scales are numbered $i = 0, \dots, s-1$. A label is a scalar coordinate: it specifies a direction, a color, an intermediate scale (or the output lattice), and the lattice on which the coordinate was introduced, and it has an assigned position. A fluctuation block is the three-component vector $w_{i,e} \in \mathbb{R}^3$ of normalized fluctuation variables attached to one free link e at one intermediate scale i; it is a single variable of the reference measures below, not three independent ones. Scalar labels and fluctuation blocks are counted separately.

The labels attached to Ω are unfixed: their coordinates are analytic variables. These are the coarse background variable $v = \operatorname{Log} c$ on the output lattice and the free logarithmic coordinates z_i at the intermediate scales. We write Ω^c for the fixed complement of the unfixed positions, W for the boundary (the interface between the unfixed positions and Ω^c), and $\Omega^c_{L_J}$ for the fixed enlargement of Ω^c determined by the construction stencils, as in Lemma 18.15. The fixed complement is denoted H in Section 18 and Section 19: in their notation, $\Omega^c = H$ and $\Omega^c_{L_J} = H_{L_J}$. In this section the letter H denotes instead the bound $E + \mathcal{X}^\rho(f)$ on the incoming effective interaction introduced in Lemma 20.7. All distances are graph distances on the refined position graph of Section 18.2, in units of the output lattice, and network lengths use its periodic ℓ^1 metric, with internal vertices allowed; positions of labels introduced on finer lattices are embedded in these units. We write d_g and t_g for this distance and network length, and d_E, t_E for the periodic Euclidean distance and network length of Definition 4.6. Then

$$d_E \leq d_g \leq \sqrt{3}\, d_E, \qquad \mathsf{t}_E \leq \mathsf{t}_g \leq \sqrt{3}\, \mathsf{t}_E,$$

since $|y|_2 \leq |y|_1 \leq \sqrt{3}|y|_2$ for $y \in \mathbb{R}^3$, applied to each periodic image and to each segment $[p, q]$ of a network, with $y = p - q$. Consequently, a coefficient bound stated

with Euclidean distances and network lengths, at spatial exponent c and boundary exponent c', holds with the graph quantities at exponents $c/\sqrt{3}$ and $c'/\sqrt{3}$. Conversely, a bound stated with the graph quantities implies the Euclidean bound at the same exponents. Every imported Euclidean coefficient bound is converted in this way before the rates of this section are chosen, and the fixed factor $\sqrt{3}$ is included in the geometric constants. Throughout this section, dist and t denote d_g and t_g, as in Section 18.2. The torus seminorm $\mathcal{B}_{\rho,a_{\mathbb{T}}}$ keeps the Euclidean convention of Definition 4.6. For an unfixed label i we write $d_\Omega(i)$ for its distance to Ω^c. We write Ω' for the set of unfixed scalar output labels. Separately, let $\partial_{\mathrm{blk}}\Omega$ be the set of anchors of retained final blocks that share a face with a final block of the fixed complement. This is a geometric set on the output lattice, counted once per anchor, regardless of directions, colors, or the presence of an output link. In particular it includes an isolated retained block, even though that block has no internal coarse bond and contributes no label to Ω'. It is empty when Ω or its fixed complement is empty. We assume the label-density bound

$$\#\{y : R \le \mathrm{dist}(x,y) < R+1\} \le v_J (R+2)^3,$$

where v_J accounts for directions, colors, intermediate scales, and the lattices on which labels are introduced.

Frozen coordinates. The frozen coordinates are written $b = (\xi, b_{\mathrm{rec}})$. Here ξ consists of the coordinates frozen at the end of the preceding step, written in the lattice on which they were frozen, and b_{rec} consists of the older frozen coordinates, each on the lattice on which it was frozen. Throughout this section the frozen coordinates are real and fixed, and only the unfixed background and free variables are differentiated or continued to complex values. The supremum over the frozen values is taken after every coefficient sum and every degree sum. We claim no derivative of a perturbed quantity in ξ or b_{rec}.

Norms. For a function $f(v; b_{\mathrm{rec}}) = \sum_\nu f_\nu(b_{\mathrm{rec}}) v^\nu$ of the unfixed labels, a radius $\rho > 0$, a positive profile $\phi \le \rho$, a spatial exponent $a_{\mathrm{sp}} > 0$, and a boundary exponent $\alpha_{\mathrm{bd}} > 0$, we use the coefficient norm with boundary decay of Definition 18.1, which is the graph-metric variant of (4.11):

$$\mathcal{X}^{\phi}_{\Omega}(f) = \sup_{b_{\mathrm{rec}}\ \mathrm{real}} \rho^{-2} \sum_{k\ge 1} \sup_{i\in\Omega} e^{\alpha_{\mathrm{bd}} d_\Omega(i)} \sum_{|\nu|=k} \frac{\nu_i}{k} |f_\nu(b_{\mathrm{rec}})| e^{a_{\mathrm{sp}} \mathrm{t}(\mathrm{supp}\,\nu)} \phi^\nu.$$

Here $\mathrm{t}(S) = \mathrm{t}_g(S)$ is the ℓ^1 length of a shortest connected network containing the positions in S, internal vertices allowed, and d_Ω is the graph distance, as in Definition 18.1. The supremum over the root i precedes the degree sum, and the supremum over the frozen values follows it. Constants and functions on an empty set of unfixed labels have norm zero, and the degree-one term is included. When Ω^c is empty, a boundary difference has zero nonconstant part and norm zero. We write $\mathcal{X}^{\rho}$ for the norm with the uniform

profile $\phi \equiv \rho$, and $\mathcal{X}^{\mathrm{cl}}$ for the classical version, which has its own radius ρ_{cl}, profiles, and exponents. For a torus function r with $Dr(0) = 0$ we use

$$\mathcal{B}_{\rho,a}(r) = \sum_{k \geq 2} \frac{\rho^{k-2}}{k!} \| D^k r(0) \|_{a,\mathrm{root}}$$

from Definition 4.6. This seminorm does not control the value $r(0)$, which is unrestricted. The three profiles are

$$\phi(i) = \begin{cases} \rho_\partial, & d_\Omega(i) < w_{\mathrm{bd}}, \\ \rho, & d_\Omega(i) \geq w_{\mathrm{bd}}, \end{cases} \qquad \psi_{\mathrm{prof}} = \sqrt{K_*}\phi, \qquad \widehat{\phi} = K_*\phi,$$

where $K_* \geq 2$ is a fixed analytic-radius enlargement factor, $0 < \rho_\partial \leq \rho$, and w_{bd} is the width of the boundary layer with the smaller radius. We call $\widehat{\phi}$ the outer profile, ψ_{prof} the intermediate profile, and ϕ the working profile. A bound on a coefficient tensor is rooted at an external index if it holds with that index fixed and all other indices summed, where for an input index the volume-normalized column factor $a_{\mathrm{out}}^3 / a_{\mathrm{in}}^3$ of Definition 4.6 is included. A coefficient bound with each external index fixed in turn is a bound rooted at every external index. All coefficient bounds concern absolute Taylor coefficients; we never substitute for them a bound on values of a holomorphic function or on an evaluated Hessian.

Admissible data. We work on the products of Lemmas 19.3 and 19.7: the conditional solution neighborhoods of the finitely many stages of the conditional minimization, the smaller neighborhoods of the higher parameters, and the product of sequential free coordinates contained in all of them. On these products, the images under the absolute reconstruction majorant satisfy strict bounds for the classical and quantum radii. A coarse background, a frozen value, or a product of fluctuation balls is called admissible if it lies in these products and satisfies these strict image bounds and the inequality on the conditional forces in Lemma 19.3.

Dependence of constants. Unless stated otherwise, every constant in this section (C_J, c_J, λ_J, radii, and bounds) has the dependence described in item (3) of Definition 4.14. It depends only on M, J, the fixed larger analytic domains and their radius ratios, the spatial and boundary exponents, the label density v_J, and the fixed torus and perturbation bounds. It does not depend on L, γ, m, N, K, the preceding depth d_0, the number of renormalization group steps already performed, the shape or topology of Ω, the number of components of Ω or Ω^c, or the values of the frozen coordinates. It is also independent of the widths chosen later (the width of the boundary layer, the width s_{er} of the frozen layer, the widths of protected neighborhoods, and the size of the cells of the large-field decomposition): every constant is evaluated on the fixed larger domains before these widths are chosen. We assert no bound uniform as $J \to \infty$. Constants in statements about summed errors have the dependence described in item (4) of Definition 4.14.

Density sums and boundary transport. Spatial sums use the label density in units of the output lattice. For $b > 0$ we use

$$S_J(b) = C v_J \sum_{l \geq 0} (l+1)^3 e^{-bl}, \qquad \sup_x \sum_y e^{-b\,\mathrm{dist}(x,y)} \leq S_J(b). \tag{20.1}$$

The constant C accounts for directions, colors, and the finitely many intermediate scales. This is the periodic subset estimate of Lemma 18.15; restricting any of the sets of labels only decreases the sum. Kernels between different meshes keep the volume-normalized column factors of Definition 4.6. For an unfixed root x and a position u in $\Omega^c_{L_J}$ we have

$$d_\Omega(x) \leq d_\Omega(u) + \mathrm{dist}(x,u) + C_J, \tag{20.2}$$

where $d_\Omega(u) = 0$ if $u \in \Omega^c$ and C_J accounts for the fixed enlargement. The weights for network length and for distance to Ω^c are both bounded by one fixed part of the available spatial exponent. The fixed stencil offset in (20.2) contributes a factor e^{bC_J} to the coefficient bound and no factor depending on a later width. We always use the version of Lemma 18.15 with every external index rooted. It performs all contractions with this single allocation of the exponent, independently of the number of vertices and of the Taylor order, instead of reducing an exponent at each contraction.

For a proper nonempty block region, we also use the boundary sum

$$\sum_{u \text{ unfixed}} e^{-c\, d_\Omega(u)} \leq C_J(c) |\partial_{\mathrm{blk}} \Omega|, \qquad c > 0. \tag{20.3}$$

Suppose first that Ω and its fixed complement are nonempty. A shortest route from an unfixed position to the fixed complement crosses an exposed face of a retained final block. The anchor of that block belongs to $\partial_{\mathrm{blk}}\Omega$ and is within a fixed distance C_{face} of the crossing point, in output units. The constant includes the fixed convention for link midpoints and endpoints. Thus each unfixed label u can be assigned to an anchor $a(u) \in \partial_{\mathrm{blk}}\Omega$ with

$$\mathrm{dist}(u, a(u)) \leq d_\Omega(u) + C_{\mathrm{face}}.$$

The density sum (20.1), applied also at these anchor positions, gives

$$\sum_u e^{-c d_\Omega(u)} \leq e^{cC_{\mathrm{face}}} \sum_{a \in \partial_{\mathrm{blk}}\Omega} \sum_u e^{-c\,\mathrm{dist}(u,a)} \leq e^{cC_{\mathrm{face}}} S_J(c) |\partial_{\mathrm{blk}}\Omega|.$$

An anchor need not itself carry a variable; the same density bound applies at every position of the refined graph, after a fixed enlargement of v_J if needed. This proves (20.3), without a regularity or component assumption on the boundary. If Ω is empty there is no label to sum. If its fixed complement is empty, boundary differences vanish and the bound is used only for those zero terms.

We also record the comparison with the interface labels used in the normalization count. For a fixed construction width $w_{\mathrm{band}} \geq 1$, let N_{band} count the scalar labels of the regional step whose positions are within that width of W, and set it to zero when W is empty. Then

$$|\partial_{\mathrm{blk}}\Omega| \leq N_{\mathrm{band}} \leq C_J|\partial_{\mathrm{blk}}\Omega|. \tag{20.4}$$

For the upper bound, a position within w_{band} of W is within $w_{\mathrm{band}} + C_{\mathrm{face}}$ of a boundary-block anchor. The label-density bound on this fixed-radius ball proves the claim. For the lower bound, choose one exposed face of each boundary block and a finest-scale M-block touching that face. There is a finest-scale free edge on the exposed face of this smaller block. Indeed, for the coordinate-ordered tree of Definition 18.6, edges in direction 1 are tree edges only on the line where coordinates 2 and 3 equal those of the root, and edges in direction 2 are tree edges only in the plane where coordinate 3 equals that of the root. On a face normal to direction 1, take an edge in direction 2 with coordinate 3 different from that of the root; on a face normal to direction 2 or 3, take an edge in direction 1 off the root line. Such edges exist since $M \geq 3$. Each lies inside a finest-scale block, so it is not an eliminated edge, which joins two such blocks. Its midpoint is within one input mesh unit, hence within $1/B_s \leq 1$, of a link of W. One fixed color component of this edge is therefore counted by N_{band}. The choices for distinct final blocks are distinct scalar labels. This gives the lower bound, including isolated final blocks. All constants depend only on M, J, v_J and the fixed construction width, not on any later width of an excluded or frozen neighborhood.

Two series. For $0 \leq q < 1$ and integers $j \geq 0$ we have

$$\sum_{k\geq 0}(k+1)(k+2)q^k = \frac{2}{(1-q)^3}, \qquad \sum_{k\geq j}(k)_j q^{k-j} = \frac{j!}{(1-q)^{j+1}}, \tag{20.5}$$

where $(k)_j = k(k-1)\cdots(k-j+1)$. They follow by differentiating $\sum_{k\geq 0} q^k = (1-q)^{-1}$ twice and j times, respectively, on compact subintervals of $[0,1)$. In particular a tensor of order $k+2$ with factorial bound $C^{k+2}(k+2)!$ becomes, after division by $k!$, a summable series of degree-k Hessian coefficients. Additional fixed external indices contribute fixed powers of $k+1$, which are absorbed by passing to one strictly smaller auxiliary product. No smaller radius is chosen at a later renormalization group step.

Coefficient resolution. The following lemma makes precise how the connected networks of coefficients behave under the operations used below. It combines the calculus of coefficientwise majorants of Lemma 5.3 with Definition 18.1. For a tensor V with output index $o(V)$ we write v_i for the cube of the mesh of the lattice of an index i, and $|V|_b$ for the maximum of its output-row norm and its volume-normalized input-column norms at spatial exponent b, as in Definition 4.6.

Lemma 20.1. *Consider a finite family of typed analytic coefficient tensors. Each tensor is supplied with a coefficient resolution whose total variation, weighted by the exponentials of the lengths of its assigned connected networks, satisfies the bounds of Definition 4.6 with each external index fixed in turn on one common larger product. Consider a sum of externally rooted connected contraction diagrams built from these tensors by substitution, contraction at shared indices (represented by equality tensors), finitely many Schur complements of positive constrained free matrices, and positive implicit or Neumann series. Products of factors with disjoint fluctuation supports and no shared index are not connected; they form separate connected components, each with its own network. Assume that every substitution $F \circ G$ is made on a product whose absolute image majorant for G lies strictly inside the coefficient domain of F, that all diagram majorants, including the mesh conversions of part (4), converge absolutely there, and that the inverses and Schur operations satisfy the imported uniform gap and coefficient Neumann conditions on that product. Then the following hold.*

1. *The sum has an exact coefficient resolution indexed by the occurrences of its constituent tensors, its contracted indices, and its derivative partitions. In each connected diagram component, the network of a resolved occurrence is the union of the assigned networks of its constituent occurrences, joined at the shared indices. This union is connected, contains every external position of that component, and*

$$\mathtt{t}(\textit{external positions of the component}) \leq \sum_{\textit{constituent occurrences}} \ell(\textit{assigned network}).$$

2. *The monomial of a resolved occurrence has an exact multi-index. Its fluctuation support is the set of whole fluctuation blocks on which its multi-index is positive. Background positions need not belong to this support, and no enlargement of the support to a connected geometric set is made.*
3. *If one constituent occurrence of a connected diagram component has a network that visits $\Omega^c_{L_J}$, then the union visits $\Omega^c_{L_J}$, and the visit lies in the same connected network as every external position of that component.*
4. *Fix an external root of a connected diagram component. For a vector factor V attached to its parent at an input index j use the counting bound $A_V(j) = (v_j / v_{o(V)})|V|_b$, and if it is attached at its output use $A_V(o(V)) = |V|_b$; for a scalar factor use its counting-root bound. Then the sum over the resolution of the absolute coefficients, weighted by the exponentials of the network lengths, is bounded by the product of these bounds, multiplied at the end by the external normalization v_o / v_{root} when the component has an output o. For a substitution tree the volume ratios cancel exactly and the bound is the product of the norms $|\cdot|_b$, in the row norm and in every volume-normalized column norm. For other diagrams the remaining ratios are kept in the scalar majorant. In particular, a counting scalar outer tensor on an old mesh, rooted at a new input l, carries the factor v_l / v_{old}.*

5. *If a connected network of length ℓ contains the external positions S and the unfixed index i, and visits $\Omega^c_{L_J}$, then $\mathsf{t}(S) \le \ell$ and $d_\Omega(i) \le \ell + L_0$, where L_0 is the fixed constant of the enlargement, and consequently*

$$e^{a\mathsf{t}(S)+\alpha d_\Omega(i)} \le e^{\alpha L_0} e^{(a+\alpha)\ell}.$$

Proof. We first work with finite Taylor polynomials and finite diagrams. For a substitution $U(o;\mathbf{l}_1,\dots,\mathbf{l}_k) = \sum_{j_1,\dots,j_k} T(o;j_1,\dots,j_k)\prod_r S_r(j_r;\mathbf{l}_r)$, the union of the network of T with the networks of the S_r, joined at the indices j_r, connects every external position, so

$$\mathsf{t}(o,\mathbf{l}_1,\dots,\mathbf{l}_k) \le \mathsf{t}(o,\mathbf{j}) + \sum_r \mathsf{t}(j_r,\mathbf{l}_r).$$

We take absolute values before summing. For an output row we sum the inner factors by their rows and then the outer tensor by its row. If a fixed external input belongs to the factor S_r, we sum the other inner factors by their rows, use the input column of S_r, and use the j_r-column of T. Along this path the volume factors multiply to $(v_o/v_{j_r})(v_{j_r}/v_l) = v_o/v_l$, which is exactly the normalization of the column of the composite at l. This proves the cancellation for substitution trees. Products with a common output are treated in the same way: the networks meet at the output, and an input-rooted estimate uses the column of the factor carrying the input and the rows of the others.

For a general connected diagram, we replace every edge outside a spanning tree by two independently summed copies of its index, which only increases the nonnegative sums. We orient the tree from the factor containing the fixed external root and, starting at the leaves, sum each factor over all its indices except the one attached to its parent. A factor attached at an input index j contributes at most its volume-normalized column bound times $v_j/v_{o(V)}$, since the column norm carries the factor $v_{o(V)}/v_j$; this is the counting bound $A_V(j)$. A factor attached at its output contributes its row bound. Finally summing the root factor over all its indices except the fixed root, we obtain the product of the counting bounds, with no count of the internal indices. The external normalization is applied only at the end. In a substitution tree the ratios on the path from the root input to the output multiply to v_l/v_o and cancel against this normalization; in a general diagram they are kept. Connectedness is essential: factors with disjoint supports and no shared index have no tree, and their networks remain separate. A cycle without an external index, such as an undifferentiated trace, is not bounded in this way.

For compositions we use the ordered derivative formula

$$D^N(F\circ G)(0)[u_1,\dots,u_N] = \sum_{n=0}^{N} \frac{1}{n!} \sum_{(B_1,\dots,B_n)} F_n\big[G_{|B_1|}[u_{B_1}],\dots,G_{|B_n|}[u_{B_n}]\big],$$

where $G(0) = 0$, the inner sum is over ordered partitions of $\{1,\dots,N\}$ into nonempty blocks, and $F_n = D^nF(0)$, $G_k = D^kG(0)$. If $G(0) \neq 0$, we write $G = G(0) + \widetilde{G}$ and

apply this formula to $\widetilde{G}$, with F_n replaced by $D^n F(G(0))$; the strict image condition justifies this translation and the infinite sums over the constant terms. Dividing by $N!$, we obtain the coefficient of s^N in $\widehat{F}(\widehat{G}(s))$, where $\widehat{F}, \widehat{G}$ are the absolute majorants. Fixing an external index chooses its branch and then its position in that branch, as in $(\widehat{F} \circ \widehat{G})' = (\widehat{F}' \circ \widehat{G})\widehat{G}'$; no second Taylor factorial occurs. We define the resolution in part (1) by retaining a separate signed occurrence for every summand of this formula, every tuple of contracted indices, and every network refinement of the constituent tensors; grouping occurrences can only decrease the total variation. Its monomial is the product of the constituent monomials, which proves part (2). In a connected component the union of networks contains the visit of a constituent occurrence and is connected, which proves part (3). The diagram bound above, applied to every resolved occurrence, proves part (4) for finite truncations; the gap and Neumann conditions cover the Schur complements, Neumann series, and implicit series. Finally, by the image condition the nonnegative majorant sums converge on the common product. Tonelli's theorem then justifies every grouping, contraction, substitution, and derivative, and the resulting analytic functions agree because their coefficients agree.

For part (5), the network contains every external position, so $\mathrm{t}(S) \le \ell$. A route in the network from i to the visited position $h \in \Omega^c_{L_J}$ has length at most ℓ, and at most L_0 more length reaches Ω^c. We conclude that $d_\Omega(i) \le \ell + L_0$, and adding the two inequalities with weights a and α completes the proof. □

When we apply Lemma 20.1, we sum an internal index by keeping a positive part b of the connecting exponent and using (20.1). We convert a visit to $\Omega^c_{L_J}$ by (20.2) into decay in the distance of every unfixed root to Ω^c. In the applications below, the mixed-mesh contractions are substitutions, chains of matrices on a single lattice, and the composition with the incoming interaction, where the remaining ratio is the fixed factor $\Gamma_J \le M^{3J}$ of Step 4 of the proof of Lemma 20.7; these factors are included in the common majorants.

20.2 Conditional minimizers, constrained Hessians, and Haar densities

We order the intermediate scales from the finest, $i = 0$, to the coarsest, $i = s - 1$. A stage of the conditional minimization is given by an initial segment I of the conditional integrations in this order. At that stage the free coordinates of the scales in I are minimized, with the coordinates $y = z_{I^c}$ of the remaining scales held fixed. The fluctuation increments in the following theorem are the coupling-scaled fluctuation inputs, $\zeta_i = q_i = g_i w_i$ in the notation of Section 19.

Theorem 20.2. *Fix an odd integer $M \ge 3$, an integer $J \ge 1$, $B = M^J$, the larger analytic domains and their strict margins, the label-density bound v_J, and the bounds for the classical and quantum torus norms. Use the conditional solution neighborhoods, the smaller neighborhoods*

of the higher parameters, and the product of sequential free coordinates of Lemma 19.3, and the perturbed objective of Theorem 19.9. In joint coordinates this objective is

$$\mathcal{F}(v,u;b_{\mathrm{rec}}) = F_0\big(v, z_0(v;\xi) + S_0(v;\xi)u;\xi\big) + \bar{P}\big(\Phi_0(v,u;\xi);\xi,b_{\mathrm{rec}}\big), \qquad S_0 = K_0^{-1/2}. \tag{20.6}$$

Here $v = \operatorname{Log} c$ is the coarse background variable, z_0 is the unperturbed joint constrained minimizer, K_0 is its constrained Hessian, u is the joint normalized free variable, and Φ_0 is the unperturbed reconstruction followed by the gauge transformation $G^{\Omega}(c)$ of Lemma 19.5, which depends only on c and is the identity at all protected endpoints. The function $\bar{P} = P - S^{\mathrm{cl}}_{\xi}$ is the incoming perturbation of the classical action with the classical boundary-completion difference S^{cl}_{ξ} subtracted, including its classical constant, as in Theorem 19.9. Assume

$$\mathcal{X}^{\mathrm{cl}}(\bar{P}) \le 2\sigma_*, \qquad 0 < \sigma_* \le \sigma_0,$$

where the preliminary perturbation bound $\sigma_0 > 0$ satisfies the margins of Lemma 19.3 for the preconditioned conditional forces, the Hessians, and the images. Here $\mathcal{X}^{\mathrm{cl}}$ is the incoming classical norm on the incoming set D_{in} of unfixed labels, with the uniform profile ρ_{cl}, as in Theorem 19.9. Assume the inequality on the conditional forces of Lemma 19.3, and assume that the incoming fixed complement lies on the current fixed side, in the sense that for every current unfixed position e and every incoming label i,

$$d_{D_{\mathrm{in}}}(i) \ge B_s d_{\mathrm{current}}(e) - B_s \operatorname{dist}(e, i/B_s) - C_{\mathrm{buf},J}. \tag{20.7}$$

Here $B_s = M^s$, $d_{D_{\mathrm{in}}}$ is measured in input units, $d_{\mathrm{current}} = d_{\Omega}$, i/B_s is the position of i in output units, and $C_{\mathrm{buf},J}$ is a fixed buffer that includes the chart stencils. Assume finally that both images of the incoming functions under the absolute reconstruction majorant, for the classical radius and for the quantum radius, are strictly smaller than half of that radius, as in Lemma 19.7. Derivatives are taken at fixed real (ξ, b_{rec}).

Then the following statements hold for every preceding depth $d_0 \ge 0$, every $1 \le s \le J$, every output side $m \ge 4$, every union Ω of output blocks, and every admissible real value of the frozen coordinates.

1. *Every stage of the conditional minimization has a holomorphic conditional constrained minimizer, and every scale has a positive constrained Hessian $K_i^{\Omega,P}$, $0 \le i < s$, which includes the exact factor M^i of its scale. Writing the unnormalized fluctuation increments as $\zeta_i = g_i w_i$, the free logarithmic coordinates at scale i are*

$$z_i = z_i^*(c_{i+1};b_{\mathrm{rec}}) + K_i(c_{i+1};b_{\mathrm{rec}})^{-1/2}\zeta_i,$$

where c_{i+1} is the reconstruction from the coarser scales, with their fluctuation increments inserted. There are $Q, a_1, \alpha_1, \lambda_J > 0$ and $C_J, \mathcal{L}_{K,J} < \infty$ such that, on the outer profile $\widehat{\phi}$ and for $|\zeta_{i,e}| \le Q$, the real matrices satisfy

$$\tfrac{1}{2}\lambda_J I \le K_i^{\Omega,P} \le \mathcal{L}_{K,J} I, \qquad \|(K_i^{\Omega,P} + t)^{-1}\|_{\mathrm{row,col},a_1} \le \frac{C_J}{\lambda_J + t} \quad (t \ge 0). \tag{20.8}$$

The complex continuation satisfies the same resolvent bound with a fixed larger C_J.

2. *Adjoin to the regional problem, as identical independent auxiliary variables with unit Hessian, the free labels of the matched torus problem that are absent from it, so that both problems have the same sets of free labels. Let $K_i^{\mathbb{T},\mathrm{cut}}$ be the restriction of the matched torus Hessian to the unfixed free labels, extended by the identity on the auxiliary labels and by zero on the mixed blocks. If*

$$\Delta_i(v,\zeta;b_{\mathrm{rec}}) = K_i^{\Omega,P} - K_i^{\mathbb{T},\mathrm{cut}} = \sum_{\nu,\kappa} \Delta_{i;\nu\kappa}(b_{\mathrm{rec}}) v^\nu \zeta^\kappa,$$

then

$$\sup_{u \text{ unfixed}} e^{\alpha_1 d_\Omega(u)} \sum_{v',\nu,\kappa} |\Delta_{i;uv',\nu\kappa}(b_{\mathrm{rec}})|\, \widehat{\phi}^\nu Q^{|\kappa|} e^{a_1 \mathfrak{t}(u,v',\mathrm{supp}\,\nu,\mathrm{supp}\,\kappa)} \le C_J. \tag{20.9}$$

The transposed bound holds, and so do the bounds rooted at any unfixed background or free external index, with the volume-normalized column factors of Definition 4.6. The underlying mixed tensors with k additional background or free derivatives have bounds $C_J^{k+2}(k+2)!$ at every external index, on a fixed larger product. The auxiliary blocks have zero defect. If Ω^c is empty, the defect has zero nonconstant part.

3. *The same rooted comparisons with boundary decay hold for the conditional minimizers of every stage, the inverse square roots, the logarithms of the Haar disintegration densities, and the diagonal densities $(\log K_i)_{xx}/2$, after composition with the reconstruction from every value of the coarser fluctuation variables. In particular, let L_i be the negative logarithm of the Haar disintegration density at scale i after its field-independent normalization has been moved into Λ, and put*

$$L_{0,i}(c_{i+1}) = L_i\big(c_{i+1}, z_i^*(c_{i+1})\big), \qquad B_i = L_{0,i} + \tfrac{1}{2}\log\det K_i.$$

The fluctuation-dependent part of the density contains

$$\sum_{i=0}^{s-1} \big[L_i(c_{i+1},z_i) - L_{0,i}(c_{i+1}) + B_i(c_{i+1}) - B_i(\widehat{c}_{i+1})\big], \tag{20.10}$$

where $\widehat{c}_{i+1}$ is the reconstruction with every fluctuation increment equal to zero. These differences start at degree one in ζ, whereas the classical remainders start at degree three. The comparison includes the correction $\log(T_{II}) - (\log T)_{II}$ that arises when the logarithm of a torus matrix T is restricted to the list I of unfixed labels. A torus diagonal density that is absent from the regional problem and has an unfixed external index has a network visiting Ω^c and is summable from that index; its constant part remains an explicit sum over omitted labels.

4. *All constants have the dependence described in item (3) of Definition 4.14, including independence of the later widths. They are evaluated on the fixed larger products before the final radius for the free coordinates is decreased. In particular they do not change at the renormalization group steps following the creation of a new component of* Ω^c.

Proof. Steps 1 and 2 verify that the incoming perturbation satisfies the hypotheses of Theorem 19.9 on all parameter domains. Steps 3 to 5 construct the conditional minimizers by a contraction argument that is uniform in the higher parameters, and check that every sequential substitution stays in the admissible domains. Steps 6 to 9 compare the regional and torus quantities, first without and then with the perturbation. Step 10 treats the matrix functions and the Haar densities, Step 11 the triangular determinant, and Step 12 the dependence of the constants on the frozen values.

We fix the real frozen value $b = (\xi, b_{\mathrm{rec}})$ and write $\mathcal{Q}_\theta = F_0 + \theta V$, where $V = \bar{P} \circ \Phi_0$ and $0 \le \theta \le 1$; here θ is an interpolation parameter. Returning from u to $z = z_0 + S_0 u$ is an invertible affine change of variables at fixed v. In the free logarithmic coordinates, the objective is

$$\mathcal{Q}_\theta(v,z) = F_0(v,z;\xi) + \theta \bar{P}\big(\mathrm{Log}[(\exp \Psi_R(v,z;\xi))^{G^{\Omega}(v)}];\xi, b_{\mathrm{rec}}\big),$$

where Ψ_R is the reconstruction before the gauge transformation. We use only this change of variables; we do not need the incoming perturbation to take the same value at the reconstruction before and after the gauge transformation.

Step 1: the incoming hypotheses. The incoming analytic labels form the set D_{in}, with their positions on the lattices where they were introduced and their volume factors. On this set the incoming profile is uniformly ρ_{cl}; the coordinates ξ are fixed parameters, and the spatially varying profiles are output profiles. The strict bounds on the image under the reconstruction majorant place Φ_0, on every admissible stage, inside this uniform input ball with a margin of half the radius. The same holds for every segment between two compared images, since coefficientwise a convex combination is bounded by the larger of the two absolute image bounds. In particular, the input jet bounds of Theorem 19.9 apply before any conditional minimization, on all its parameter neighborhoods.

Step 2: the incoming boundary comparison. For example, the inclusion of fixed complements used in Theorem 19.9 implies (20.7) as follows. Let h be an incoming fixed position nearest to i. A path from e to the current fixed complement can first go to i/B_s, then follow the scaled image of a shortest path from i to h, of length $d_{D_{\mathrm{in}}}(i)/B_s$, and finally cross the fixed buffer between the incoming and the current fixed complements, whose length is included in $C_{\mathrm{buf},J}/B_s$. Multiplying by B_s, we obtain (20.7). This argument uses no regularity or component assumption on the boundary. We keep (20.7) as a hypothesis on the geometry; choosing small radii does not establish it.

In particular, if $\alpha_{\mathrm{out}} \le B_s \alpha_{\mathrm{cl}}$ and a chart branch has spatial rate $b > \alpha_{\mathrm{out}}$, then

$$e^{\alpha_{\mathrm{out}} d_{\mathrm{current}}(e)} e^{-\alpha_{\mathrm{cl}} d_{D_{\mathrm{in}}}(i)} e^{-b\,\mathrm{dist}(e,i/B_s)} \le e^{\alpha_{\mathrm{out}} C_{\mathrm{buf},J}/B_s} e^{-(\alpha_{\mathrm{cl}}-\alpha_{\mathrm{out}}/B_s) d_{D_{\mathrm{in}}}(i)} e^{-(b-\alpha_{\mathrm{out}})\,\mathrm{dist}(e,i/B_s)}.$$

This is the transport of the input boundary weight used in the perturbation bound. Input network lengths are divided by B_s when expressed in output units. Column normalizations remain the ratios of the cubed mesh sizes of their output and input labels. Local rates may be chosen below the finite minimum of these bounds over $1 \le s \le J$; the rates returned after a full step use $s = J$ and $B_s = B$. If there is no incoming boundary, the incoming nonconstant boundary function is zero.

Step 3: conditional minimizers. For each stage I (an initial segment of the conditional integrations, with $y = z_{I^c}$ fixed), let $a_I(v, y)$ be the unperturbed conditional minimizer. By Lemma 19.3, there exist a fixed solution neighborhood, a smaller neighborhood of the higher parameters, and an invertible matrix $A_I = F_{0,II}(v, a_I, y)$. Let I_0 be a common bound for the coefficient norms of the inverses A_I^{-1} on the fixed larger neighborhoods. Using the uniform incoming jet bound with $j = 1$ and the fixed rows of the chart derivatives, we obtain, at every admissible higher parameter y and not only at the joint minimizer,

$$\|V_I(v, a_I, y; b)\|_{\mathrm{coeff}} \le C_P \sigma_* \rho_{\mathrm{cl}}, \qquad \delta_V \le I_0 C_P \sigma_* \rho_{\mathrm{cl}}, \tag{20.11}$$

where δ_V is the bound on the preconditioned conditional forces of Lemma 19.3. The constant C_P is evaluated on the larger products at the preliminary bound σ_0 and includes the conversion from z to u. The jet bound with $j = 2$ and the chain rule, including the term $\bar{P}' \Phi_{0,zz}$, give a uniform bound $C_P \sigma_*$ on the mixed second derivatives. The real gap, the complex coefficient margins, the inequality $\delta_V \le r_I/4$, where r_I is the radius of the solution neighborhood, and the derivative inequality below are then the hypotheses of Lemma 19.3. On that neighborhood the map

$$h \longmapsto h - A_I^{-1} \mathcal{Q}_{\theta,I}(v, a_I + h, y)$$

has derivative norm at most $1/2$ and value at zero of norm at most $r_I/4$. Hence it maps the closed ball of radius $r_I/2$ into itself, and its successive iterates converge: the difference of the iterates $n+1$ and n is at most 2^{-n} times the first difference. The same bounds on absolute coefficients hold for the analytic iterates, which gives normal convergence on every smaller product and a holomorphic limit. Uniqueness follows by subtracting two fixed point equations. Since the objective is holomorphic and real at real arguments, the minimizer is real at real data. The real Hessian and complex resolvent margins are those of Theorem 19.9; its weighted resolvent bounds rest on the exponential conjugation method of Combes and Thomas [61]. Taking the finite minimum over $s \le J$ and over the stages fixes λ_J and Q, and taking the finite maximum fixes $\mathcal{L}_{K,J}$ and the bound on the inverses. The factors M^i belong to these matrices before the extrema are taken.

Step 4: sequential substitution. For the sequential construction we use the inequality

$$C_{\mathrm{seq},J}(2\delta_V + Q) < \tfrac{1}{2}\varepsilon_{\mathrm{tube}}, \tag{20.12}$$

where $\varepsilon_{\mathrm{tube}}$ is the minimal margin of the parameter and solution neighborhoods of Lemma 19.3. By the contraction bound, the displacement from $a_I(v, y)$ is at most $2\theta\delta_V$, for every admissible y. The uniform mixed coefficient bounds and the bound on the free inverses give a finite common Lipschitz constant D_J of the conditional minimizers in y, and $\|K_i^{-1/2}\| \le C_{S,J}$. Let A_i be a bound for the deviations of the already reconstructed coarser coordinates from the unperturbed joint chain. The next insertion satisfies

$$A_{i-1} \le (1 + D_J)A_i + 2\delta_V + C_{S,J}Q, \qquad A_s = 0. \tag{20.13}$$

Iterating, we find that the total deviation is at most $\max\{1, C_{S,J}\}\sum_{k=0}^{J-1}(1 + D_J)^k(2\delta_V + Q)$. We choose $C_{\mathrm{seq},J}$ larger than the coefficient of this finite expression and than every fixed embedding constant of the stages. Then (20.12) keeps every substituted coarser argument in the admissible domains, even after the deviation is doubled. The mixed bounds and the constant $C_{\mathrm{seq},J}$ are fixed before the later widths. In particular the preliminary bound σ_0 must satisfy the same inequality with $\delta_V \le I_0 C_P \sigma_0 \rho_{\mathrm{cl}}$.

Step 5: dependence on the coarser coordinates. We explain why this construction controls coefficients when the coarser coordinates move. Differentiating the stationary equation at fixed y, we obtain

$$\partial_\theta z_I = -\mathcal{Q}_{\theta,II}^{-1} V_I. \tag{20.14}$$

If y moves, the right side has the additional term $-\mathcal{Q}_{\theta,II}^{-1}\mathcal{Q}_{\theta,II^c}\partial_\theta y$. A sequential insertion also has the term $(\partial_\theta K_i^{-1/2})\zeta_i$. All these terms are included in Theorem 19.9, and (20.13) allows their evaluation at every value of the coarser coordinates. At zero free input, conditional uniqueness identifies the sequential chain with the joint minimizer. Decreasing Q therefore does not change the admissible profile of the coarse background.

Step 6: the unperturbed boundary comparison. We use matched reconstruction formulas on the unfixed labels. Away from the fixed construction enlargement of Ω^c, the formulas defining the common unfixed outputs, the block axial gauge equations, and the choices of eliminated edges coincide. Their unique admissible solutions on the unfixed outputs therefore coincide there. This does not assert that the extended fields agree inside a component of Ω^c. The prescribed values in Ω^c are separate bounded sources; a source deep inside a component of Ω^c need not be small at its own position. For the torus action composed with two reconstructions $\Psi_R = \Psi_{\mathbb{T}} + d$, the exact difference is

$$F_R - F_{\mathbb{T}} = \int_0^1 DE_{d_0}(\Psi_{\mathbb{T}} + \tau d)[d]\, d\tau \tag{20.15}$$

on the common unfixed variables. If auxiliary missing variables are kept, their separate auxiliary quadratic form is kept as a term rooted in Ω^c. Every differentiated coefficient of the integral contains either a derivative of a changed formula or the factor d attached to an action tensor. The action and chart tensors on the larger domain are the tensors of Theorem 19.9, and their contractions with a changed formula are networks covered by Lemma 18.15. Rooting at any unfixed external index connects that index to the change. For example, the second derivative is

$$D_z^2(E_{d_0} \circ \Psi) = \Psi_z^{\mathsf{T}} E''_{d_0}(\Psi)\Psi_z + E'_{d_0}(\Psi)\Psi_{zz}.$$

Both terms are present: stationarity in z does not make $E'_{d_0}(\Psi)$ vanish. Differentiating (20.15) produces derivatives falling on E_{d_0} as well as derivatives falling on d; the former remain connected to the inserted change. Summing a bounded source in Ω^c from an unfixed root is justified by (20.1) and (20.2). This proves factorial bounds with a visit to Ω^c for the difference before minimization, rooted at every external index.

Step 7: minimization, Schur complements, and restriction. We pass to the conditional minimizers through their stationary equations. A force carrying a visit to Ω^c is multiplied by the free inverse, as in (20.14). The coefficientwise majorant series of the implicit equation converges on the admissible products: if Y denotes the majorant of the solution without the visit, the variation carrying the visit has the form $H(x, Y)/(1 - A(x, Y))$, where $A \le 3/4$ after the auxiliary radius has been fixed. This follows by substituting the majorant of the variation into the differentiated fixed point equation and summing $\sum_{n\ge 0} A^n$. The visit and all fixed external indices are kept. For a partial minimum the exact second derivative is the Schur complement

$$\mathcal{Q}_{yy} - \mathcal{Q}_{yI}\mathcal{Q}_{II}^{-1}\mathcal{Q}_{Iy}. \tag{20.16}$$

We subtract two such expressions by replacing the three factors of the product one at a time. An inverse difference is $A^{-1} - B^{-1} = -A^{-1}(A - B)B^{-1}$, so each summand keeps a factor with a visit to Ω^c. Only constrained free blocks are inverted. Positivity passes to the Schur complement by minimizing the positive quadratic form over the coordinates in I.

A separate correction compares restriction with elimination. Let A be a single torus free matrix, and let R and H be the lists of unfixed and of missing labels (in this paragraph R and H denote lists of labels). Block elimination gives

$$(A^{-1})_{RR} - A_{RR}^{-1} = A_{RR}^{-1}A_{RH}\big(A_{HH} - A_{HR}A_{RR}^{-1}A_{RH}\big)^{-1}A_{HR}A_{RR}^{-1}. \tag{20.17}$$

To check this identity, we solve $Ax = (f_R, 0)$, first for x_R in terms of x_H and then for x_H. Each term on the right of (20.17) passes through a missing index. Its coefficient network from an unfixed root therefore reaches Ω^c, and the part of the exponential decay not

used for the network weight sums over that index. Adding this correction to the regional comparison, we obtain the unperturbed defect at each stage. This operation compares restrictions of one torus matrix; it does not identify a regional problem with a torus problem whose complement is set to zero.

Step 8: from factorial bounds to coefficient bounds. The bounds just obtained for the tensors of order $k+2$, at every external index, are $C_J^{k+2}(k+2)!$. Dividing by the Taylor factorials and using (20.5), we find that on a fixed smaller auxiliary radius h the summed matrix coefficients are at most

$$C_J^2 \sum_{k\ge 0} (k+1)(k+2)(C_J h)^k = 2C_J^2 (1 - C_J h)^{-3}.$$

We choose the outer background and free products inside this radius and do not change them later. Since any index may be fixed before the sums are taken, we may fix a background or free input, which proves the column versions.

Step 9: adding the perturbation. We insert the unperturbed regional matrix at its own chain of coarser arguments. The defect in (20.9) is the sum of three terms: the change of the objective and of the minimizer at a common coarser argument, the change of that argument, and the unperturbed regional–torus defect. The first term has the rooted perturbation bound of Theorem 19.9, with its visit to Ω^c. The second term is the integral of an unperturbed matrix derivative against the difference of the coarser reconstructions, which carries a visit to Ω^c; both are defined on the same products by the statement on the sequential product in Lemma 19.3, and the network joins the new index to the visit. The third term was treated in Steps 6 to 8. The sum satisfies (20.9) for fixed smaller $a_1, \alpha_1 > 0$. The real matrices are symmetric, which gives the transposed bound with the same constants. Rooting each contraction at the specified background or free index gives the other bounds, with its volume factor. The auxiliary blocks are identical throughout and have zero difference; no matrix element rooted purely at an auxiliary label is assigned a boundary decay.

Step 10: matrix functions and Haar densities. For positive matrices, integrating the scalar resolvent and applying the resolvent identity, we obtain the ordered identities of holomorphic functional calculus (see [27])

$$A^{-1/2} - B^{-1/2} = -\frac{1}{\pi} \int_0^\infty t^{-1/2} (A + t)^{-1} (A - B)(B + t)^{-1} \, dt, \tag{20.18}$$

$$\log A - \log B = \int_0^\infty (A + t)^{-1} (A - B)(B + t)^{-1} \, dt. \tag{20.19}$$

Indeed $A^{-1/2} = \pi^{-1} \int_0^\infty t^{-1/2} (A + t)^{-1} \, dt$ and $\log A = \int_0^\infty [(1 + t)^{-1} I - (A + t)^{-1}] \, dt$ hold for positive numbers, hence for real symmetric positive matrices by orthogonal diag-

onalization. The common complex resolvent margins extend these identities holomorphically. The coefficient majorants of the integrands are $C_J t^{-1/2}(\lambda_J + t)^{-2}$ and $C_J(\lambda_J + t)^{-2}$, which are integrable at both endpoints. We may therefore integrate all contractions and derivatives termwise. Each difference keeps its factor $A - B$.

The logarithm of the Haar disintegration density is a sum of logarithms of the nonvanishing Haar factors of finitely many local formulas and of the determinants of the constraints at the eliminated edges, as in Definition 4.3. On the fixed chart we write each factor as $a(1 + h)$, with its nonzero value a at the base point and a fixed strict coefficient margin $|h| < 1$; the series $\log(1 + h) = \sum_{k\geq 1}(-1)^{k+1}h^k/k$ gives its absolute derivatives on every smaller chart. The base factors are moved into Λ. Away from the boundary the local formulas agree. In a difference of compositions, a changed local formula, or a changed minimizer, inverse square root, or coarser argument, is a factor carrying a visit to Ω^c. The preceding calculus therefore yields the comparison of the Haar densities at all orders.

A diagonal matrix-logarithm density keeps its index until an external unfixed index is chosen. Its nonconstant derivatives are chains of resolvents with a differentiated matrix inserted. Rooting at that insertion makes the trace sum summable by (20.1). If a torus diagonal density is missing from the regional problem, its network with any unfixed external index must reach the missing index, and the same argument sums over the missing index from the unfixed index. A pure constant has no such index and remains its exact sum over omitted labels.

To compare with the restriction of the torus logarithm, we set $T = K_i^{\mathbb{T}}$ and $C = T_{II} \oplus T_{HH}$, where $I = I_i$ and $H = H_i$ are the lists of unfixed and missing free labels at scale i. Using the integral representation of the logarithm, we obtain

$$\log T_{II} - (\log T)_{II} = \int_0^\infty \big[(T + t)^{-1} - (C + t)^{-1}\big]_{II}\, dt. \tag{20.20}$$

The integrand equals $-[(T + t)^{-1}(T - C)(C + t)^{-1}]_{II}$. Its middle factor connects unfixed and missing labels, so it has a visit to Ω^c, and it has the same integrable bound as (20.19). Thus this correction, composed with every value of the coarser fluctuation variables, is included in the comparison.

Step 11: the triangular determinant. The determinant of the triangular change of variables of Theorem 12.13, or of the identical finite triangular calculation for the present minimizers, is

$$\prod_i g_i^{3f_i} \det K_i(c_{i+1})^{-1/2},$$

where f_i is the number of free blocks at scale i. Adding and subtracting the logarithm of its value at zero fluctuation, we combine the Haar terms into (20.10). Only one

determinant occurs. For an analytic function G on the common product,

$$G(v,\zeta) - G(v,0) = \int_0^1 D_\zeta G(v,\tau\zeta)[\zeta]\, d\tau. \tag{20.21}$$

This keeps every positive degree in ζ. Stationarity and the exact normalization by $K_i^{-1/2}$ cancel the terms of degrees one and two of each classical remainder, so its degree is at least three. Composition with the coarser scales does not lower that degree.

Step 12: constants and measurability. The proof uses only margins on fixed domains, finitely many operations on the stages, (20.1), normally convergent coefficientwise majorant series, and the resolvent integrals above. These give the dependence stated in part (4). A new component of Ω^c changes the set of indices carrying a visit and the frozen values, but no constant. If Ω^c is empty, no formula changes and there is no input carrying a visit. This proves the stated special cases and uniformities.

We also record the regularity in the frozen values needed for finite iterations. If the incoming coefficients and the charts depend on the real value b in a Borel way, then so does every iterate of the contraction in Step 3: finite sums, products, and admissible inverses preserve this property, and a convergent coefficient composition is a limit of its polynomial truncations. The geometric contraction bound is uniform in b, so the coefficients of the limit are Borel. The resolvent integrals for square roots and logarithms are limits of finite Riemann sums with uniformly bounded tails, and preserve this property. With continuous incoming data on a fixed branch, the same uniform convergence gives continuity. None of these arguments differentiates in b. In the finite analytic recursion, the initial torus functions and the local formulas in the identity chart have this regularity, and substitution of a frozen value and the integrals over fixed products below preserve Borel dependence. Thus every coefficient family constructed by the recursion depends on the frozen values in a Borel way. □

20.3 The conditional fluctuation potential

Lemma 20.3. *Use the data and products of Theorem 20.2. Let the incoming effective interaction be*

$$R = r_{d_0}(\,\cdot \oplus 0) + f, \qquad Dr_{d_0}(0) = 0, \quad \mathcal{B}_{\rho,a_{\mathbb{T}}}(r_{d_0}) \le E, \quad \mathcal{X}^{\rho}(f) \le \sigma_* \le \sigma_0,$$

where r_{d_0} is the torus effective interaction at depth d_0, with its torus symmetries, evaluated with the fixed slots set to zero, and f is its boundary part. The value of r_{d_0} at zero is unrestricted. For $0 \le i < s \le J$ set

$$t_{\max} = \max_i g_i = \sqrt{\gamma/(Mm)}, \qquad g_i = t_{\max}\lambda_i, \qquad \lambda_i = M^{(i-s+1)/2} \in [\lambda_*, 1],$$

where $\lambda_* = M^{-(J-1)/2}$. Let F_i be the partially minimized objective at scale i, without the coupling factor and with its exact normalization M^i, and define

$$T_i(c_{i+1},\zeta_i) = F_i\big(c_{i+1}, z_i^* + K_i^{-1/2}\zeta_i\big) - F_i(c_{i+1}, z_i^*) - \tfrac{1}{2}|\zeta_i|^2.$$

For a fixed admissible real coarse background and fixed real frozen values, the conditional fluctuation potential, with its values at zero fluctuation moved into the prefactor, is exactly

$$\begin{aligned} V(w) = {} & \tfrac{1}{2}\sum_i |w_i|^2 + \sum_i g_i^{-2} T_i(c_{i+1}, g_i w_i) \\ & + \sum_i \big[L_i(c_{i+1}, z_i) - L_{0,i}(c_{i+1}) + B_i(c_{i+1}) - B_i(\widehat{c}_{i+1})\big] \\ & + R\big(\operatorname{Log} C(v, (g_i w_i)_i; b_{\mathrm{rec}})\big) - R\big(\operatorname{Log} C(v, 0; b_{\mathrm{rec}})\big), \end{aligned} \tag{20.22}$$

where $C(v,\zeta;b_{\mathrm{rec}})$ denotes the reconstructed configuration on the unfixed labels. Only logarithms of unfixed labels in the identity chart are taken. The Haar disintegration density, the degree-one terms of the incoming interaction, and all determinant terms of the coarser scales occur in (20.22). *The separate prefactor contains all constants of the block averaging constraint and of the Haar measure, the Gaussian powers of the couplings, the values at the minimizers, and the external compact factors.*

There are $A \geq 1$, $a' > 0$, and $C_{V,J}, C_0 < \infty$ with $C_0 \geq 2A^3$, and a fixed radius $s_W > 0$ for the increments ζ_i, such that on the product $|g_i w_{i,e}| \leq s_W$

$$V(w) = \tfrac{1}{2}|w|^2 + \sum_{k\geq 3} t_{\max}^{k-2} P_k(w) + \sum_{k\geq 1} t_{\max}^k Q_k(w), \qquad \|P_k\|_{a',1} \leq A^k, \quad \|Q_k\|_{a',1} \leq \mathcal{L}_V A^k, \tag{20.23}$$

where P_k, Q_k are homogeneous polynomials of degree k in the scalar coordinates of w and $\mathcal{L}_V = C_{V,J}(1 + E + \sigma_0) \geq 1$. For $T_k(w) = \sum_{|\eta|=k} t_\eta w^\eta$ the norm is

$$\|T_k\|_{a',1} = \sup_j \sum_{\eta_j > 0} \eta_j |t_\eta| e^{a' \mathrm{t}(\operatorname{supp}\eta)}.$$

The bounds (20.23) *also hold before the background is evaluated, in the coefficient algebra at the outer profile, with the background positions included in the network length.*

The following inequalities suffice for a common enclosing product. All constants below are computed at the preliminary bound σ_0, before σ_*, β_{rec}, r, and the later widths are fixed. Let $r_{q,U}, r_{q,P}, u_0$ be the radii of the unperturbed and perturbed sequential free products and of the joint product of Lemma 19.3, and $c_{\mathrm{tube},J}$ its fixed conversion constant. For $\rho_\bullet \in \{\rho, \rho_{\mathrm{cl}}\}$ let R_{raw}, $C_{\mathrm{lift},J}$, $s_{\mathrm{aux},\bullet}$, $C_{T,\bullet}$, $C_{\Delta,\bullet}$, and $A_{0,\bullet}$ be the radius of the larger construction domain, the bound on the lifts, the auxiliary radii, the constants of the image increments, and the bound on the image at zero fluctuation in Lemma 19.7. Choose $R_W > 0$ strictly below

$$\begin{aligned} \min\big\{ & s_W/2,\ r_{q,U}/2,\ r_{q,P}/2,\ c_{\mathrm{tube},J} u_0,\ R_{\mathrm{raw}}/(64 C_{\mathrm{lift},J}),\ 1/(4A),\ 1/(16 C_0), \\ & \min_{\rho_\bullet \in \{\rho,\rho_{\mathrm{cl}}\}} \{ s_{\mathrm{aux},\bullet}/2,\ 1/(4C_{T,\bullet}),\ \rho_\bullet/[8(2C_{T,\bullet} + C_{\Delta,\bullet})] \} \big\}. \end{aligned}$$

Impose the margins of the larger construction domain and of the stages in Lemma 19.7 and, for both radii, $A_{0,\bullet} \le \rho_\bullet/4$ *and* $C_{T,\bullet}K_*\rho_\bullet \le 1/4$. *Let* $C_{\mathrm{en},J} \ge 1$ *be a fixed constant (in the application it is the constant of the enclosure estimate Theorem 21.8; nothing else from that section is used), and require*

$$r,\ \beta_{\mathrm{rec}},\ \sigma_*\rho_{\mathrm{cl}} \le \frac{\lambda_* R_W}{6C_{\mathrm{en},J}}, \qquad \delta_{\mathrm{en}} = C_{\mathrm{en},J}(r + \beta_{\mathrm{rec}} + \sigma_*\rho_{\mathrm{cl}}), \qquad R_{\mathrm{en}} = 2\delta_{\mathrm{en}}/\lambda_*, \tag{20.24}$$

where r *is the radius of the small-link domain* B_r *and* β_{rec} *is the bound on the frozen values. Then the whole product*

$$\mathcal{K}_{\mathrm{en}} = \prod_{i,e} \{|w_{i,e}| \le R_{\mathrm{en}}/t_{\max}\}$$

is admissible. On it the absolute coefficient increment of either incoming image is bounded by

$$\frac{C_{T,\bullet}R_{\mathrm{en}}}{1 - C_{T,\bullet}(K_*\rho_\bullet + R_{\mathrm{en}})} + C_{\Delta,\bullet}R_{\mathrm{en}} \le \rho_\bullet/8,$$

the denominator is at least $1/2$, *and the image under the absolute reconstruction majorant at spatial exponent zero is at most* $3\rho_\bullet/8$. *If these bounds are imposed in a weighted coefficient row, the same bound holds in that row. In the alternative provided by Lemma 19.7, the unperturbed image row* $S^0_c \le C_J\rho_\bullet$ *at an exponent* $c > 0$, *larger than the working exponent, gives one fixed positive exponent* ϑc *with*

$$S^0_{\vartheta c} \le (3\rho_\bullet/8)^{1-\vartheta}(C_J\rho_\bullet)^{\vartheta} < (\sqrt{3}/4)\rho_\bullet.$$

For the unperturbed construction, this exponent is fixed before the regional rates. For the perturbed reconstruction, impose the output-rate conditions of Theorem 19.9 at the allocated working rates below this exponent and bound its coefficient difference from the unperturbed reconstruction there. Fix the larger-product difference-row constant $C_{P,\bullet}$ *before the final perturbation bound and require* $C_{P,\bullet}\sigma_*\rho_{\mathrm{cl}} \le \rho_\bullet/64$ *for both radii. The total image row is then less than* $(\sqrt{3}/4 + 1/64)\rho_\bullet < \rho_\bullet/2$ *at those rates; no bound for the perturbed image at the original higher exponent is required. Thus the margin of half the incoming radius is an absolute weighted coefficient bound, not only a bound on values.*

Let C_1 *be the constant of Lemma 20.5, which depends only on* A, a', *and* v_J. *For* $0 < t_{\max} \le t_* < e^{-1}$ *impose separately*

$$C_0 t_*^2 \mathcal{L}_V \le 1/16, \qquad C_1 t_*(\mathcal{L}_V + 2) < \frac{1}{4\sqrt{3}}. \tag{20.25}$$

Then on a neighborhood of the whole real product $\mathcal{K}_{\mathrm{en}}$,

$$\|D^2_w(V - |w|^2/2)\|_{\mathrm{row,col},a'} \le \frac{C_0(R_{\mathrm{en}} + t^2_{\max}\mathcal{L}_V)}{(1 - AR_{\mathrm{en}})^3} \le \frac{8}{27} < \frac{1}{2}. \tag{20.26}$$

If $p(t) = A_{\mathrm{w}} \log(1/t)$*, the products of balls with radii* $p_i \in [p(t_{\max}), p(t_{\max}) + A_{\mathrm{w}}(J-1)(\log M)/2]$ *lie in* $\mathcal{K}_{\mathrm{en}}$ *whenever*

$$t_{\max}\big[p(t_{\max}) + A_{\mathrm{w}}(J-1)(\log M)/2\big] < R_{\mathrm{en}}.$$

The cutoff of the small-field event (4.6) *is the case* $p_i = p(t_{\max})$ *for all* i*; the cutoffs* $p_i = p(g_i)$ *at the individual scales are a separate case. All constants have the dependence described in item (3) of Definition 4.14, and are also independent of the later widths, of the frozen values, and of the individual radii of the fluctuation balls.*

Proof. We keep $b = (\xi, b_{\mathrm{rec}})$ fixed and write $t = t_{\max}$. The data of Theorem 20.2 include the uniform incoming classical profile, (20.7), and (20.11) on all parameter neighborhoods. We choose the radius for the increments ζ below Q; then (20.12) holds at every stage. These are the hypotheses for the perturbed tensors used here, and no derivative in the frozen values is needed.

Step 1: the exact formula. At scale i, the minimum at fixed coarser arguments is $F_i(c_{i+1}, z_i^*)$. With $S_i = K_i^{-1/2}$, Taylor's formula with integral remainder gives

$$g_i^{-2} T_i(c_{i+1}, g_i w_i) = \frac{g_i}{2} \int_0^1 (1-\tau)^2 D_z^3 F_i(c_{i+1}, z_i^* + \tau g_i S_i w_i)[S_i w_i, S_i w_i, S_i w_i]\, d\tau. \tag{20.27}$$

The terms of orders zero, one, and two have been, respectively, subtracted, annihilated by stationarity, and normalized to $|g_i w_i|^2/2$ by $S_i^{\mathsf{T}} K_i S_i = I$. The successive partial minima satisfy $F_{i+1} = M \min F_i$, and the couplings satisfy $g_{i+1}^2 = M g_i^2$, so the values at the minimizers telescope in the exponent. In decreasing order of the scales, the map from w to z is triangular with diagonal blocks $g_i S_i$. This proves the classical part of (20.22) and its Gaussian term, by the same finite algebra as in Theorem 12.13. The Haar disintegration density and the single triangular determinant split as in part (3) of Theorem 20.2. Splitting $R(\operatorname{Log} C)$ at its value at zero fluctuation, we obtain the last two terms. All values removed at zero fluctuation, the Gaussian powers, and the constant Haar densities belong to the prefactor; none of them is set to one.

Step 2: the two series. We fix an auxiliary radius $h_0 > 0$ for the increments ζ, strictly inside every admissible stage product and its joint neighborhood. Theorem 20.2 gives tensors with bounds at every external index on a larger product. Dividing by the Taylor factorials, composing coefficientwise majorants (Lemma 20.1), and using (20.5), we bound the degree-k scalar coefficients, rooted at any free index, by $D_J H_J^k$ for fixed D_J, H_J. An additional multiplicity $\eta_j \le k$ is bounded by 2^k. For an incoming function, the strict image bound gives the jet bound

$$\|D^j R\|_{\mathrm{root}} \le (E + \sigma_0)\rho^{2-j} \frac{j!}{(1-\kappa)^{j+1}}, \qquad \kappa \le \tfrac{1}{2}, \quad j \ge 1, \tag{20.28}$$

at a point whose image under the absolute reconstruction majorant is at most $\kappa\rho$. To verify it, we fix the first differentiated input index. At original degree l, the fixed-index weight in the input norm and the sum over the other $j-1$ differentiated positions give the factor $(l)_j$, with the remaining factor $\kappa^{l-j}\rho^{2-j}$, and the second identity in (20.5) sums the result. The torus seminorm starts at degree two and the boundary norm at degree one; the same estimate bounds both. Constants of R disappear only in the fluctuation difference. The input networks are joined to the reconstruction networks, and a prescribed differentiated index stays fixed. This proves (20.28) in the coefficient algebra, before the background is evaluated.

Consider a monomial of T_i, and let η_j be its degree in the free coordinates of scale j. It has at least three indices at scale i, so $\eta_i \geq 3$ and $\sum_{j\geq i}\eta_j = k \geq 3$. After division by g_i^2 its coupling factor is

$$t^{k-2}\lambda_i^{\eta_i-2}\prod_{j>i}\lambda_j^{\eta_j}.$$

The product of ratios is at most one; the weaker bound λ_*^{-2} would also be an admissible fixed constant. By (20.21), every Haar, determinant, and incoming difference has at least one free index. A term of degree k there has the factor $t^k\prod_j\lambda_j^{\eta_j}$, whose product of ratios is again at most one. The values B_i in (20.22) are evaluated at the coarser reconstructions, and their coefficients in the coarser free variables belong to the same series. Summing over at most J scales, increasing $A \geq \max\{1, 2H_J, 2D_JH_J\}$, and decreasing h_0 if necessary, we obtain

$$\|P_k\|_{a',1} \leq A^k, \qquad \|Q_k\|_{a',1} \leq C_{V,J}(1+E+\sigma_0)A^k.$$

The first quantum coefficient Q_1 includes every degree-one term of the incoming interaction. Only powers of the fixed radii were absorbed in these constants. We choose $s_W < h_0$ with a strict margin in the larger domain. The series are then normally convergent on that radius, at the outer profile as well as after evaluation.

Step 3: the enclosing product is admissible. The three inequalities in (20.24) imply that

$$\delta_{\mathrm{en}} \leq \lambda_* R_W/2, \qquad R_{\mathrm{en}} \leq R_W.$$

For $w \in \mathcal{K}_{\mathrm{en}}$ we have $|\zeta_i| = t\lambda_i|w_i| \leq R_{\mathrm{en}}$. The minimum defining R_W places this whole product strictly inside the unperturbed and perturbed sequential products and the joint neighborhood; the constant $c_{\mathrm{tube},J}$ includes every finite sequential embedding. Indeed, the incoming displacement term is still $2\delta_V$ at the preliminary bound σ_0, and the new free radius is at most $R_{\mathrm{en}} \leq Q$. Then (20.13) implies that $C_{\mathrm{seq},J}(2\delta_V + R_{\mathrm{en}}) < \varepsilon_{\mathrm{tube}}/2$ at every coarser argument. The separate margin of the larger construction domain in Lemma 19.7 includes the background, the frozen values, and the free radius; it places all reconstructions before the gauge transformation in the larger charts of the Haar densities and of the action.

Step 4: the image increments. For either radius, we abbreviate $C_T = C_{T,\bullet}$ and $C_\Delta = C_{\Delta,\bullet}$. By hypothesis, we have $C_T(K_*\rho_\bullet + R_{\mathrm{en}}) \le 1/2$. The rational increment in the statement is therefore at most $(2C_T + C_\Delta)R_{\mathrm{en}} \le \rho_\bullet/8$. Adding the bound $A_{0,\bullet} \le \rho_\bullet/4$ at zero fluctuation, we obtain the bound $3\rho_\bullet/8$ at exponent zero. If these inequalities hold in a weighted coefficient row, each calculation holds in that row. Otherwise apply the following interpolation to the unperturbed image row at such an exponent c, with $S_c^0 \le C_J\rho_\bullet$. For nonnegative coefficient weights b_η and network lengths l_η, Hölder's inequality for finite sums gives

$$\sum_\eta b_\eta e^{\vartheta c l_\eta} \le \Big(\sum_\eta b_\eta\Big)^{1-\vartheta}\Big(\sum_\eta b_\eta e^{c l_\eta}\Big)^{\vartheta}.$$

Passing to increasing finite sums proves the stated interpolation. Its right side, divided by $\rho_\bullet$, tends to $3/8$ as $\vartheta \downarrow 0$. Hence one positive ϑ works for both radii and the finitely many stages of the unperturbed construction. Its exponent is fixed before the regional rates are chosen. At allocated working rates below this exponent and satisfying Theorem 19.9, that theorem bounds the coefficient row of the perturbed-minus-unperturbed reconstruction by $C_{P,\bullet}\sigma_*\rho_{\mathrm{cl}}$ on the same enclosing products. Fixing this constant before the final choice of σ_* and making that bound smaller than the remaining half-radius margin gives the asserted perturbed image bound. No interpolation at the unperturbed exponent is applied to inherited perturbative networks.

Step 5: curvature. For the curvature bound, we fix one derivative at the scalar coordinate j and sum over the second differentiated index. Differentiating a homogeneous monomial of degree k twice gives the factor $k-1$ relative to the norm $\|\cdot\|_{a',1}$. The matrix weight is bounded by the weight of the original network, since the distance between the two differentiated indices is at most the network length. At the radius $\varrho = R_{\mathrm{en}}$ in the variables ζ, the two contributions are bounded by

$$\sum_{k\ge 3}(k-1)A^k\varrho^{k-2} = A^2\big[(1-A\varrho)^{-2}-1\big] \le \frac{2A^3\varrho}{(1-A\varrho)^2},$$

$$t^2\mathcal{L}_V\sum_{k\ge 2}(k-1)A^k\varrho^{k-2} = \frac{A^2t^2\mathcal{L}_V}{(1-A\varrho)^2}.$$

Here we used that on $\mathcal{K}_{\mathrm{en}}$ the coordinates satisfy $|w_j| \le R_{\mathrm{en}}/t$, so that $t^{k-2}(R_{\mathrm{en}}/t)^{k-2} = R_{\mathrm{en}}^{k-2}$ for the classical terms and $t^k(R_{\mathrm{en}}/t)^{k-2} = t^2R_{\mathrm{en}}^{k-2}$ for the others. We enlarge $C_0 \ge 2A^3$ to include the fixed conversion between scalar and three-component block norms. The column bound follows from the symmetry of the Hessian. The weaker denominator $(1-AR_{\mathrm{en}})^{-3}$ in (20.26) applies to both contributions. Since $AR_{\mathrm{en}} \le 1/4$, $C_0R_{\mathrm{en}} \le 1/16$, and $C_0t^2\mathcal{L}_V \le 1/16$, the result is

$$\frac{1/16+1/16}{(1-1/4)^3} = \frac{8}{27} < \frac{1}{2}.$$

All inequalities have strict margins in the charts, so they hold on a neighborhood of the real product, including its faces and corners. The constant C_1 of Lemma 20.5 is determined from A, a', the label density, and the curvature bound just proved, so the second inequality in (20.25) is a separate requirement compatible with the present choices.

Step 6: logarithmic cutoffs. A ball of radius p_i lies in $\mathcal{K}_{\mathrm{en}}$ whenever $tp_i < R_{\mathrm{en}}$. The finite logarithmic offset in the statement bounds every such p_i, since $p(g_i) = p(t) + A_{\mathrm{w}} \log(1/\lambda_i)$ and $\lambda_i \geq \lambda_*$. This proves the inclusion both for the common cutoff and for the cutoffs at the individual scales. All constants were computed at σ_0 on fixed larger products, before any final enclosure quantity or width. The proof involves no derivative in the frozen values, no sum over earlier renormalization group steps, and no dependence on the individual radii of the fluctuation balls. □

Remark 20.4. The incoming boundary function f in Lemma 20.3 is measured in the norm $\mathcal{X}^{\rho}$ with the uniform profile ρ, and (20.28) is stated for this case. For a function measured with a nonuniform profile ϕ, the analogous estimate holds for the rescaled function $\widetilde{R}(x) = R((\phi_i x_i)_i)$: if its degree-wise rooted sum at unit profile is at most $H\rho^2$, then at a point whose image under the absolute reconstruction majorant is bounded by $\kappa\phi$, $0 \leq \kappa < 1$,

$$|D^j \widetilde{R}|_{\kappa,\mathrm{root}} \leq H\rho^2 \sum_{l \geq j} (l)_j \kappa^{l-j} = H\rho^2 \frac{j!}{(1-\kappa)^{j+1}}, \qquad j \geq 1.$$

Thus each differentiated slot carries its own radius ϕ_i. The unscaled form (20.28) does not follow for a spatially varying radius profile. Indeed, fix an unfixed index i at distance d_i from Ω^c. The function $R(v) = H\rho^2 e^{-\alpha_{\mathrm{bd}} d_i} v_i/\phi_i$ has norm H and derivative $H\rho^2 e^{-\alpha_{\mathrm{bd}} d_i}/\phi_i$, which is unbounded as the boundary radius $\phi_i = \rho_\partial$ decreases with d_i fixed. In the coefficient sums of Section 20.4 every differentiated background index is multiplied by its own radius, so no inverse power of the small boundary radius ρ_∂ enters.

Lemma 20.5. *The following statements hold.*

1. *Let $\mathcal{K}$ be a finite product of three-dimensional balls, let $S, \mathcal{W} \subset \mathcal{K}$ be Borel sets, let $\chi : \mathcal{K} \to [0,1]$ be Borel, let e^{-V} be a positive Borel function with $0 < Z_{\mathcal{K}} = \int_{\mathcal{K}} e^{-V}\, dw < \infty$, and let $P > 0$ be a constant prefactor (unrelated to the perturbation P of Theorem 20.2). Set*

$$G = P \int_S \chi e^{-V}\, dw, \qquad \widetilde{F} = P \int_{\mathcal{W}} e^{-V}\, dw, \qquad d\nu_{\mathcal{K}} = Z_{\mathcal{K}}^{-1} \mathbf{1}_{\mathcal{K}} e^{-V}\, dw.$$

   If $\nu_{\mathcal{K}}(\mathcal{W}^c) \leq \delta < 1$, then $G \leq (1-\delta)^{-1}\widetilde{F}$. Nonnegative functions of the coarse background and external factors may multiply both sides. No inclusion between $\mathcal{W}$ and S is needed. A product with no factors has mass one.

2. *Let $\mathcal{K} = \mathcal{K}_{\mathrm{en}}$ be the enclosing product of Lemma 20.3, under its hypotheses with $t_{\max} \le t_*$, at an admissible real coarse background and fixed real frozen values, and let V be the potential* (20.22). *There is a constant C_1, depending only on A, a', and v_J, such that*

$$D_w^2 V \ge I/2, \qquad \sup_j |\mathbb{E}_{\nu_{\mathcal{K}}} w_j| \le C_1 t_{\max}(\mathcal{L}_V + 2),$$

where j runs over the scalar coordinates. For every scalar function F that is 1-Lipschitz for the Euclidean norm and every $v \ge 0$,

$$\nu_{\mathcal{K}}(|F - \mathbb{E}F| \ge v) \le 2e^{-v^2/4}.$$

Let $p(t) = A_{\mathrm{w}} \log(1/t)$, and choose radii $p_i \ge p(t_{\max})$ with $t_{\max} \max_i p_i < R_{\mathrm{en}}$, so that the product $\mathcal{W} = \prod_{i,e}\{|w_{i,e}| \le p_i\}$ is contained in $\mathcal{K}$. If $C_1 t_{\max}(\mathcal{L}_V + 2) \le p(t_{\max})/(2\sqrt{3})$, which holds for all sufficiently small $t_{\max}$ and is one of the requirements on the coupling bound g_* in Theorem 20.14, then

$$\nu_{\mathcal{K}}(\mathcal{W}^c) \le 6\mathsf{b} \exp\{-p(t_{\max})^2/48\}, \qquad \mathsf{b} \le C_J m^3,$$

where b counts all fluctuation blocks of the step, jointly over all components of Ω and all scales. These are means under $\nu_{\mathcal{K}}$ at fixed frozen values; no symmetry of the frozen values is assumed. The constants have the dependence described in item (3) of Definition 4.14 and are independent of the later widths.

3. *Consider the stopping sides $m_t = mB^t$, $t \ge 0$, together with at most one additional side $\eta m B^j$, where η ranges over a fixed finite set of positive ratios (arising from a final composition of fewer than J averaging steps). Suppose that nonnegative errors at these sides satisfy*

$$\delta_t \le C_J m_t^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{M m_t/\gamma}}, \qquad z_t \le C_J m_t^3 e^{-b m_t/\gamma}, \qquad a_{\mathrm{w}}, b > 0,$$

and similarly at the additional side. By part (2), the first bound holds with $a_{\mathrm{w}} = A_{\mathrm{w}}^2/48$ for the comparison errors of this lemma. Then for every fixed $\Gamma \in (0, \infty)$, in particular for every $\Gamma = \gamma_0 \le 1$, there is a minimum side m_0, depending only on Γ, the fixed data, and the finite set of ratios, such that, uniformly for $m \ge m_0$ and $0 < \gamma \le \Gamma$, all errors are at most $1/2$ and

$$\sum_t (\delta_t + z_t) < \infty, \qquad \log \prod_t (1 - \delta_t)^{-1} \le 2 \sum_t \delta_t \le C_\delta.$$

The sums and the logarithm tend to zero as $m \to \infty$, uniformly in $0 < \gamma \le \Gamma$ and in the finite or infinite number of sides. The same conclusion holds for $\epsilon_t = \delta_t/(1 - z_t)$ after increasing m_0. There is one comparison for the whole product at each stopping side, not a separate factor for each component of Ω^c. The minimum side and C_δ have the dependence described in item (4) of Definition 4.14; none of them depends on the number of steps or on the large-field decomposition.

Proof. Step 1 proves part (1). Steps 2 to 6 prove part (2): we first check that the measure is well defined, then interpolate between the Gaussian product and the potential, bound the force of the interaction using fourth moments, integrate the derivative of the means along the interpolation, and finally bound the probability outside the chosen product. Step 7 reduces part (3) to Lemma 20.15.

Step 1: the abstract comparison. The Borel hypotheses make both integrands measurable, and since $0 \le \chi \le 1$ and $0 < Z_{\mathcal{K}} < \infty$, we have $0 \le G, \widetilde{F} \le PZ_{\mathcal{K}} < \infty$. Since $S \subset \mathcal{K}$, we have $G \le PZ_{\mathcal{K}}$. On the other hand

$$\widetilde{F} = PZ_{\mathcal{K}}\nu_{\mathcal{K}}(\mathcal{W}) \ge PZ_{\mathcal{K}}(1-\delta).$$

Dividing by the positive finite number $PZ_{\mathcal{K}}$ gives part (1); the common prefactor cancels before any estimate. Multiplying by nonnegative functions of the coarse background preserves the inequality pointwise. For a product with no factors we use the unit point mass, and the same proof applies.

Step 2: normalizability on the enclosing product. The potential of Lemma 20.3 is real and smooth on a neighborhood of the fixed compact product $\mathcal{K}_{\mathrm{en}}$. Its ball radii $R_{\mathrm{en}}/t_{\max}$ are positive and finite, so the product has positive finite Lebesgue volume. If $V_{\min}$ and $V_{\max}$ are the minimum and maximum of V on $\mathcal{K}_{\mathrm{en}}$, then

$$0 < e^{-V_{\max}} \operatorname{vol}(\mathcal{K}_{\mathrm{en}}) \le Z_{\mathcal{K}_{\mathrm{en}}} \le e^{-V_{\min}} \operatorname{vol}(\mathcal{K}_{\mathrm{en}}) < \infty.$$

Thus the integrand is positive, Borel, and normalizable. The chosen product $\mathcal{W}$ is closed, hence Borel; the comparison in part (1) keeps its Borel hypotheses on S and χ.

Step 3: convexity and concentration. We write $t = t_{\max}$ and $H(w) = V(w) - |w|^2/2$, and interpolate on the same product

$$V_\theta(w) = |w|^2/2 + \theta H(w), \qquad 0 \le \theta \le 1.$$

Each V_θ is real and smooth on the compact product, so the normalization bounds of Step 2 hold throughout the interpolation. By (20.26) the Hessian perturbation is at most $\kappa = 8/27$, so every V_θ has Hessian at least $(1-\kappa)I \ge I/2$; for $\theta = 1$ this is the first assertion. The absolute coefficient bound in (20.26) bounds the exponentially weighted sums over y of the suprema over the product of $|(V_\theta)_{xy}|$, in rows and in columns, by the same fixed constant; the three-component block form follows by including the fixed block conversion in C_0. Fix $0 < b \le a'$ so small that

$$\max\Big\{\sup_x \sum_{y\neq x} (e^{b\,\mathrm{dist}(x,y)} - 1) \sup\|(V_\theta)_{xy}\|,\ \sup_y \sum_{x\neq y} (e^{b\,\mathrm{dist}(x,y)} - 1) \sup\|(V_\theta)_{xy}\|\Big\} \le \tfrac{1}{4}.$$

Such a choice depends only on the fixed weighted bound, since the convexity of $u \mapsto e^u$ gives $e^{bd} - 1 \le (b/a')(e^{a'd} - 1)$ for $b \le a'$. The off-diagonal blocks of the Gaussian

part vanish. Thus all hypotheses of Theorem 5.4, which adapts the Bakry–Émery and Helffer–Sjöstrand methods [8, 110] to products of balls with reflecting boundary, hold with convexity constant $1/2$, on a neighborhood of the finite product; its ball faces and product corners are included in that theorem. It yields the scalar tail $2e^{-v^2/4}$ and the covariance bound

$$|\mathrm{Cov}_\theta(F,G)| \le 4\sum_{x,y} e^{-b\,\mathrm{dist}(x,y)}\|\nabla_x F\|_2\|\nabla_y G\|_2, \tag{20.29}$$

where Cov_θ and $\|\cdot\|_2$ refer to the normalized measure with density proportional to e^{-V_θ} on $\mathcal{K}_{\mathrm{en}}$. These constants do not depend on the number or the radii of the balls.

Step 4: the force. Let $M(\theta) = \max_j |\mathbb{E}_\theta w_j|$, where j is scalar (in this proof $M(\theta)$ is unrelated to the blocking factor M). The tail just obtained implies a universal bound on the fourth moment of $w_j - \mathbb{E}_\theta w_j$, by integrating $\int_0^\infty 4u^3\mathbb{P}(|w_j - \mathbb{E}_\theta w_j| > u)\,du$ against the Gaussian majorant. Hence

$$\|w_j\|_4 \le C_4 + M(\theta).$$

Consider a differentiated classical monomial of degree $k \ge 3$. After fixing its differentiated coordinate, we place two of its remaining $k-1$ factors in L^4 and the other $k-3$ factors in the supremum norm R_{en}/t of the product. Hölder's inequality, which applies also when the two factors are the same scalar coordinate, gives the factor

$$t^{k-2}(R_{\mathrm{en}}/t)^{k-3}(C_4 + M(\theta))^2 = tR_{\mathrm{en}}^{k-3}(C_4 + M(\theta))^2.$$

The coefficient sum with the differentiated index fixed is bounded by A^k, and the geometric sum is at most $C(A)t(1 + M(\theta)^2)$ because $AR_{\mathrm{en}} \le 1/4$. For the quantum terms, including degree one, a direct supremum bound gives

$$\sum_{k\ge 1} \mathcal{L}_V A^k t^k (R_{\mathrm{en}}/t)^{k-1} = \frac{\mathcal{L}_V A t}{1 - AR_{\mathrm{en}}}.$$

Combining the two bounds, we obtain

$$\sup_j \|\partial_j H\|_2 \le C(A)t[\mathcal{L}_V + 1 + M(\theta)^2]. \tag{20.30}$$

Step 5: the means. Differentiating the finite integrals on the fixed compact product, we obtain

$$\frac{d}{d\theta}\mathbb{E}_\theta w_j = -\,\mathrm{Cov}_\theta(w_j, H).$$

Indeed, the derivative of the numerator is $-\int w_j H e^{-V_\theta}$ and that of the denominator is $-\int He^{-V_\theta}$, and their quotient is the displayed centered expression. The integrands and their derivatives are bounded on this finite product, so the differentiation is justified

directly. This is the calculation of Theorem 13.10 on a fixed product, carried out here for the present measure; we do not use the conclusions of that theorem, whose hypotheses concern the torus products. Combining (20.29), (20.30), and (20.1), we obtain a fixed C_1 with

$$\Big|\frac{d}{d\theta}\mathbb{E}_\theta w_j\Big| \le C_1 t[\mathcal{L}_V + 1 + M(\theta)^2]. \tag{20.31}$$

It depends only on A, a', and the label density; the margin $\kappa < 1/2$ has already been imposed. This is the constant in the hypothesis (20.25) of Lemma 20.3.

At $\theta = 0$ the measure is a product of centered truncated Gaussian measures on balls, so every coordinate has mean zero, for every frozen value. All means are continuous in θ. Suppose that M reached the value one, and let θ_1 be the first time at which it does. Integrating (20.31) for each coordinate on $[0, \theta_1]$, where $M \le 1$, would give $M(\theta_1) \le C_1 t(\mathcal{L}_V + 2) < 1/(4\sqrt{3}) < 1$, a contradiction. Inserting $M < 1$ into (20.31) and integrating once more proves $M(1) \le C_1 t(\mathcal{L}_V + 2)$. This argument integrates the inequalities for the individual coordinates before taking the maximum; it does not use any differentiability of the maximum.

Step 6: the probability outside the chosen product. The condition $t \max_i p_i < R_{\mathrm{en}}$ puts the chosen product strictly inside $\mathcal{K}_{\mathrm{en}}$. For the logarithmic radii of Theorem 20.14 this condition follows from (20.47); for other radii it is the explicit inclusion hypothesis. If a fluctuation block lies outside its ball of radius $p_i \ge p(t)$, then some scalar coordinate has absolute value larger than $p(t)/\sqrt{3}$. Since the mean of that coordinate is at most $p(t)/(2\sqrt{3})$ in absolute value, the coordinate deviates from its mean by at least $p(t)/(2\sqrt{3})$. By the scalar tail and a union bound over the three coordinates, the probability that a given block lies outside its ball is at most $6e^{-p(t)^2/48}$. The step has at most $\mathsf{b} \le C_J m^3$ blocks: each of the at most J scales has a fixed finite number of free labels per output block, and removing blocks from the region only decreases this number. This proves the bound on $\nu_{\mathcal{K}}(\mathcal{W}^c)$, with no factor depending on the number of components. The enclosure and curvature hypotheses are used on the whole product $\mathcal{K}_{\mathrm{en}}$, which does not depend on the configuration.

Step 7: summation. Part (3) is the case $C = C_J$, $c = b$, $a = a_{\mathrm{w}}$ of Lemma 20.15, with the ratio B and the finite set of additional ratios, since $\log^2 \sqrt{Mm/\gamma} = z^2$ with $z = (1/2)\log(Mm/\gamma)$. With $p(t_{\max}) = A_{\mathrm{w}} \log \sqrt{Mm/\gamma}$, the bound of part (2) is of the stated form with $a_{\mathrm{w}} = A_{\mathrm{w}}^2/48$, since $6\mathsf{b} \le C_J m^3$. □

20.4 Cluster expansion with boundary-localized coefficients

We now expand the logarithm of the fluctuation integral, keeping two structures apart. Probabilistic independence is determined by the set of fluctuation blocks on which a

monomial depends: two monomials depending on disjoint sets of blocks are independent under a product reference measure, even if they depend on the same background coordinates. Spatial decay is carried instead by a connected network through all positions of the coefficient, background positions included, which may lie far from the fluctuation blocks. Overlapping monomials share a fluctuation block, so their networks meet there, and the union of their networks is connected without any additional connecting path.

The organization into connected polymer activities and a convergent logarithm follows the constructive cluster expansion; see Bałaban [18, 19] for its implementation in lattice gauge theories, Brydges [38] for a general exposition, and Kotecký and Preiss [120] for the abstract polymer criterion. The cancellation of connected graphs against rooted trees used in Theorem 12.6 is Penrose's partition [136]; its construction by generations and parents, and the positive tree recursions used below, are described in [87, Sections 2 and 4.1]. The finite graph inequality is imported in the form of [68, Appendix B, (323), p. 42], through Theorem 12.6; no other result of that paper, which concerns a scalar field theory, is used. We prove directly the features needed here: the two kinds of roots, the exact fluctuation supports, and the visits to the fixed complement.

Complex coupling parameter. In this section we replace the coupling powers in (20.23) by powers of a complex parameter z: the classical powers $t_{\max}^{q-2}$ become z^{q-2} and the other powers $t_{\max}^{q}$ become z^{q}. The incoming functions, the couplings of earlier steps, the ratios λ_i, and the normalized symmetric reference measures on balls are kept fixed. The incoming insertion becomes

$$A_R(z) = R\big(\operatorname{Log} C(v, (z\lambda_i w_i)_i; b_{\mathrm{rec}})\big) - R\big(\operatorname{Log} C(v, 0; b_{\mathrm{rec}})\big).$$

We call the interaction without insertion the sum of all terms of $V - |w|^2/2$ in (20.22) except the incoming insertion, after this substitution. For $p_x > 0$ attached to the fluctuation blocks, with $p_x = p_i$ for a block at scale i, we write $p = \max_i p_i$, and we always assume $p \geq 1$.

Definition 20.6. Let F be an interaction, given with a resolution into scalar monomials

$$U_\lambda = u_\lambda v^{\nu_\lambda} w^{\eta_\lambda}, \qquad |\eta_\lambda| \geq 1,$$

as in Lemma 20.1. A fluctuation index is a whole fluctuation block at its scale and position; a background index is an unfixed scalar background coordinate on the lattice where it was introduced. Write S_λ for the set of fluctuation blocks on which η_λ is positive (the fluctuation support of the monomial) and $k_\lambda = |\nu_\lambda|$ for its background degree. Each monomial carries a connected network through all of its fluctuation and background positions; for a monomial whose coefficient has a visit to $\Omega_{L_J}^c$, the network contains this visit. We write ℓ_λ for the total length of the network, including the visit. No enlargement of S_λ is made. Internal indices are summed, using a fixed part of the exponential decay

rate, before the resolution into monomials, and repeated occurrences keep their own network refinements. For the exponent $s_0 > 0$ set

$$b_\lambda(F) = |u_\lambda(F)|\psi_{\mathrm{prof}}^{\nu_\lambda}\prod_x p_x^{|\eta_{\lambda,x}|}e^{s_0\ell_\lambda},$$

and for $h \geq 0$

$$W_h(F) = \sup_x \sum_{\lambda: x\in S_\lambda} e^{h|S_\lambda|}b_\lambda(F),$$
$$D_h(F) = \sum_{k\geq 1}\sup_i \sum_{\lambda: k_\lambda = k} \nu_{\lambda,i}e^{h|S_\lambda|}b_\lambda(F).$$

In W_h the root x is a fluctuation block, and in D_h the root i is a background index. In D_h the supremum over the root is taken before the sum over the background degree, as in the coefficient norm with boundary decay.

Lemma 20.7. *Fix the admissible larger products and the preliminary perturbation ball of Theorem 20.2 and Lemma 20.3, including both strict margins for the images under the reconstruction majorant and the inequalities on the conditional forces at every stage. Fix the ratio K_* and the profiles $\widehat{\phi} = K_*\phi$ and $\psi_{\mathrm{prof}} = \sqrt{K_*}\phi$. The only restrictions on the rates needed here are a fixed allocation of the exponential decay rate available in the coefficient bounds of the potential and the restrictions on the transport from input to output of Theorem 19.9 and Lemma 18.15; let $s_0 = a + \alpha$ lie strictly below these bounds. Consider the following families of interactions, resolved into monomials as in Definition 20.6: the interaction without insertion, the incoming insertion, the differences between the regional families and the restricted torus families, and the mixed difference of the boundary change and the incoming insertion. Let $H = E + \mathcal{X}^\rho(f)$ and set*

$$\mathfrak{s}(z) = \frac{C_J|z|(p^3 + p + Hp)}{1 - C_J|z|p},$$

for z in the fixed larger radius with $C_J|z|p < 1$, inside both incoming image margins. Then, uniformly in the fixed real frozen values,

$$W_{16}(F) + D_{16}(F) \leq \epsilon_F$$

for each of these families F. One may take $\epsilon_F \leq C_J\mathfrak{s}(z)$ for the family without insertion and for the boundary differences, and

$$\epsilon_A + \epsilon_{\partial A} \leq \frac{C_J|z|Hp}{1 - C_J|z|p} \tag{20.32}$$

for the incoming insertion A and its boundary difference ∂A. In particular the latter bound holds with a visit to Ω^c and with an arbitrary background root. The constants have the dependence described in item (3) of Definition 4.14 and are independent of the later widths; the profiles and the input radii are not decreased at later steps.

Proof. Step 1 records the coefficient resolution of the terms of the potential and its basic bounds. Steps 2 and 3 write out, with every contraction, the resolution in the two typical cases of a classical monomial and of a monomial of the Haar density. Step 4 treats the incoming insertion and the boundary differences. Step 5 converts the coefficient bounds into the bounds on W_{16} and D_{16}, keeping the order of the supremum and the degree sum.

Step 1: the resolution. The tensors of Theorem 20.2, with bounds at every external index, and the coefficient version of Lemma 20.3 are available on the outer profile, before the background is evaluated. By Lemma 20.1, every term of the potential has an exact resolution into monomials carrying connected networks. Rooted at an arbitrary free index, this resolution has convergent majorants in the free degree q, namely

$$C_J^q |z|^{q-2} p^q \quad (q \geq 3) \qquad \text{and} \qquad C_J^q |z|^q p^q \quad (q \geq 1),$$

for the classical terms and for the other terms, respectively. For the incoming insertion the second majorant is multiplied by H. The ratios λ_i have modulus at most one, and J is fixed. For the last assertion the input is (20.28) with $E + \sigma_0$ replaced by H: fixing its first differentiated input and summing over the other inputs gives

$$\|D^j R\|_{\mathrm{root}} \leq H \rho^{2-j} \frac{j!}{(1-\kappa)^{j+1}}, \qquad \kappa \leq \tfrac{1}{2},$$

by applying the factor $(l)_j \kappa^{l-j}$ to the input norm at degree l with that input fixed and summing the geometric series. The constants of R disappear in the fluctuation difference; they are not bounded by H. The composition with every index rooted in Theorem 19.9, with its volume-normalized input columns, keeps a specified external background index as well as a specified free index. At a background root i, the sum of the monomials containing that index is bounded by $\widehat{\phi}(i)$ times the absolute coefficient majorant of $\partial_i F$. This produces the factor $\nu_{\lambda,i}$ in D_h. No division by the smaller boundary radius occurs.

Step 2: a classical monomial. Fix a scale i. By the definition of the partial minimization, $F_i(v, c_{i+1}, y)$ is the perturbed objective $\mathcal{Q}_1$ of the proof of Theorem 20.2, in the free logarithmic coordinates and multiplied by the factor M^i, evaluated with the coordinates of the finer scales at their conditional minimizers, at fixed frozen values. We write this as $F_i(v, c_{i+1}, y) = \mathcal{Q}^{(i)}(\Psi_i(v, c_{i+1}, y))$, where $\mathcal{Q}^{(i)} = M^i \mathcal{Q}_1$, y denotes the free logarithmic coordinates of scale i, $c_{i+1} = C_{i+1}(v, \zeta_{>i})$ is the coarser reconstruction, and Ψ_i maps (v, c_{i+1}, y) to the full list of coordinates $(v, z^*_{<i}, y, z_{>i})$, with the finer coordinates $z^*_{<i}$ at their conditional minimizers. The coefficient bounds for $\mathcal{Q}^{(i)}$ on the common product are those of Theorem 19.9, and those for Ψ_i, which contains the conditional minimizers of the finer stages, are those of Theorem 20.2. The factorization only displays the chain rule; the general term can equally be bounded through the tensors $D^r_y F_i$ of that theorem.

At fixed (v, c_{i+1}) the minimizer z_i^* satisfies $F_{i,y}(v, c_{i+1}, z_i^*) = 0$, and $K_i = F_{i,yy}(v, c_{i+1}, z_i^*)$, $S_i = K_i^{-1/2}$, $z_i = z_i^* + g_i S_i w_i$. Since $S_i^{\mathsf{T}} K_i S_i = I$, Taylor's formula in y on the common coefficient product gives

$$\frac{F_i(v, c_{i+1}, z_i) - F_i(v, c_{i+1}, z_i^*)}{g_i^2} - \frac{|w_i|^2}{2} = \sum_{r \geq 3} \frac{g_i^{r-2}}{r!} \sum_{a_1, \dots, a_r} \sum_{\beta_1, \dots, \beta_r} F^*_{i, a_1 \cdots a_r} \prod_{l=1}^{r} S_i(a_l, \beta_l) w_{i, \beta_l}.$$

The star denotes evaluation at $y = z_i^*$ (not at zero coarser input), and the β_l are scalar labels at scale i. This expression is analytic at $g_i = 0$: stationarity and the exact subtraction of the quadratic term remove the apparent singularity.

We display the term $r = 3$. For a multi-index $\tau = (\nu, \eta_{>i})$ in the background variables and the coarser free variables, we write $[\,\cdot\,]_\tau$ for the coefficient of $v^\nu \zeta_{>i}^{\eta_{>i}}$ after the substitution $c_{i+1} = C_{i+1}(v, \zeta_{>i})$, and set

$$e^{(m)}_{x_1 \cdots x_m; \tau} = [(D^m \mathcal{Q}^{(i)})_{x_1 \cdots x_m}(\Psi_i^*)]_\tau, \qquad P_{x; A; \tau} = [(\partial_{y_A} \Psi_{i,x})^*]_\tau, \qquad s_{a\beta; \tau} = [S_i(a, \beta)]_\tau,$$

where $\partial_{y_A} = \partial_{y_a} \partial_{y_b}$ for $A = (a, b)$, and similarly for longer A. The chain rule gives, for $T_{abc;\tau} = [F^*_{i,abc}]_\tau$,

$$\begin{aligned} T_{abc;\tau} = {} & \sum_{x_1, x_2, x_3} \sum_{\tau_0 + \tau_1 + \tau_2 + \tau_3 = \tau} e^{(3)}_{x_1 x_2 x_3; \tau_0} P_{x_1; a; \tau_1} P_{x_2; b; \tau_2} P_{x_3; c; \tau_3} \\ & + \sum_{x_1, x_2} \sum_{\tau_0 + \tau_1 + \tau_2 = \tau} e^{(2)}_{x_1 x_2; \tau_0} \big(P_{x_1; ab; \tau_1} P_{x_2; c; \tau_2} + P_{x_1; ac; \tau_1} P_{x_2; b; \tau_2} + P_{x_1; bc; \tau_1} P_{x_2; a; \tau_2} \big) \\ & + \sum_{x} \sum_{\tau_0 + \tau_1 = \tau} e^{(1)}_{x; \tau_0} P_{x; abc; \tau_1}. \end{aligned}$$

In particular, the Hessian is

$$F^*_{i,ab} = \sum_{x, x'} \mathcal{Q}^{(i)}_{xx'}(\Psi_i^*) \Psi^*_{i,x,a} \Psi^*_{i,x',b} + \sum_x \mathcal{Q}^{(i)}_x(\Psi_i^*) \Psi^*_{i,x,ab}.$$

Stationarity in y does not imply $(\mathcal{Q}^{(i)})'(\Psi_i^*) = 0$, so the term with $(\mathcal{Q}^{(i)})'$ and the last line of the formula for $T_{abc;\tau}$ cannot be deleted. Let η_i be a multi-index of degree three in the fluctuation variables of scale i. After the substitutions $g_l = z\lambda_l$ and $\zeta_{>i} = z\lambda_{>i} w_{>i}$, the coefficient of $v^\nu w_i^{\eta_i} w_{>i}^{\eta_{>i}}$ in this cubic term is

$$\frac{z^{1 + |\eta_{>i}|} \lambda_i}{6} \prod_{j=i+1}^{s-1} \lambda_j^{|\eta_j|} \sum_{a,b,c} \sum_{\substack{\beta_1, \beta_2, \beta_3 \\ \mathbf{e}_{\beta_1} + \mathbf{e}_{\beta_2} + \mathbf{e}_{\beta_3} = \eta_i}} \sum_{\tau_0 + \tau_1 + \tau_2 + \tau_3 = (\nu, \eta_{>i})} T_{abc; \tau_0} s_{a\beta_1; \tau_1} s_{b\beta_2; \tau_2} s_{c\beta_3; \tau_3}, \tag{20.33}$$

where η_j is the part of the multi-index $\eta_{>i}$ at scale j. The factor $1/6$ also accounts for repeated β's; no further factorial occurs. For each summand we take the networks of its

coefficients and join them at their common indices x and a, and at the coarser arguments. The network of the resulting monomial is this connected union, and its fluctuation support is

$$S_\lambda = \{\text{blocks of } \beta_1, \beta_2, \beta_3\} \cup \{\text{coarser blocks used by } \eta_{>i}\},$$

with repeated blocks counted once. The background positions in ν belong to the network even if they lie outside S_λ. Let $\mathcal{Q}_m^+$, P_m^+, and S^+ be the absolute scalar majorants of the jets and maps above on their common product, including the volume ratios of part (4) of Lemma 20.1. The formula for $T_{abc;\tau}$ and Lemma 20.1 give the cubic majorant

$$\tfrac{1}{6}\big(\mathcal{Q}_3^+(P_1^+)^3 + 3\mathcal{Q}_2^+P_2^+P_1^+ + \mathcal{Q}_1^+P_3^+\big)(S^+)^3,$$

and the same expression with a derivative falling on one factor bounds the sum rooted at a fluctuation or background index. Each product here corresponds to a connected contraction in the formula for $T_{abc;\tau}$, so no unrooted product over an extensive set appears. For general r the rule is the partition formula

$$\partial_{a_1}\cdots\partial_{a_r}(\mathcal{Q}^{(i)}\circ\Psi_i) = \sum_{\pi}\sum_{(x_B)_{B\in\pi}} (D^{|\pi|}\mathcal{Q}^{(i)})_{(x_B)}(\Psi_i)\prod_{B\in\pi}\partial_{a_B}\Psi_{i,x_B},$$

where π runs over the partitions of $\{1,\dots,r\}$. Together with Lemma 20.1, it gives a convergent coefficientwise majorant on a common smaller free product. Since $r \geq 3$, a term of total free degree $q = r + |\eta_{>i}|$ has the coupling power z^{q-2}, and the ratios of the scales have modulus at most one. This proves the cubic starting order before any expectation over the fluctuation variables is taken.

Step 3: a monomial of the Haar density. Let $\Gamma(v, c_{i+1}, y)$ be the chart of solved links at scale i, let $\mathcal{E}_i^\circ$ be its links outside the block axial gauge trees, and let $\mathfrak{c}$ run over the set $\mathfrak{C}_i$ of constraints solved at scale i, with eliminated edges $e_\mathfrak{c}^*$. We write

$$A_\mathfrak{c} = D_{X_{e_\mathfrak{c}^*}}\mathsf{C}_\mathfrak{c}(\Gamma), \qquad L_i = -\sum_{e\in\mathcal{E}_i^\circ}\log j_H(\Gamma_e) + \sum_{\mathfrak{c}\in\mathfrak{C}_i}\log\det A_\mathfrak{c},$$

with $j_H(X) = \operatorname{sinc}^2(|X|/2)$ as in Definition 4.3; only field-independent factors have been removed. The fluctuation-dependent part of L_i at scale i is

$$L_i(v, c_{i+1}, z_i) - L_i(v, c_{i+1}, z_i^*) = \sum_{r\geq 1}\frac{g_i^r}{r!}\sum_{a_1,\dots,a_r}\sum_{\beta_1,\dots,\beta_r} L^*_{i,a_1\cdots a_r}\prod_{l=1}^{r} S_i(a_l,\beta_l)w_{i,\beta_l}.$$

Its linear coefficient is

$$L^*_{i,a} = -\sum_{e\in\mathcal{E}_i^\circ}\sum_{\varsigma=1}^{3}(\partial_\varsigma\log j_H)(\Gamma_e^*)\Gamma^*_{e\varsigma,a} + \sum_{\mathfrak{c}\in\mathfrak{C}_i}\sum_{A,B=1}^{3}(A_\mathfrak{c}^{-1})^*_{BA}(\partial_{y_a}A_\mathfrak{c})^*_{AB},$$

where $(\partial_{y_a} A_{\mathfrak{c}})_{AB} = \sum_{e,\varsigma} (\partial_{X_{e\varsigma}} A_{\mathfrak{c}})_{AB} \Gamma_{e\varsigma,a}$, and all factors are evaluated at the minimizer and at the coarser reconstruction $C_{i+1}(v, \zeta_{>i})$. Taking the coefficient $[\,\cdot\,]_\tau$ of each factor and summing over all allocations of τ gives the coefficients $l_{a;\tau} = [L^*_{i,a}]_\tau$, with every link, constraint, color, integrated coordinate, and multi-index sum displayed. For $|\eta_i| = 1$ the coefficient after the coupling substitution is

$$z^{1+|\eta_{>i}|} \lambda_i \prod_{j=i+1}^{s-1} \lambda_j^{|\eta_j|} \sum_a \sum_{\beta : \mathbf{e}_\beta = \eta_i} \sum_{\tau_0 + \tau_1 = (\nu, \eta_{>i})} l_{a;\tau_0} s_{a\beta;\tau_1}.$$

The trace in $L^*_{i,a}$ is rooted at the index a through the derivative $\partial_{y_a} A_{\mathfrak{c}}$; its coefficient bound sums over $\mathfrak{c}, e, A, B, \varsigma$. It is not the unrooted norm of a sum of logarithmic determinants. The network is the connected union of the networks of the Haar factors, the inverse matrices, and the chart, joined to the network of S_i at a, and the support is the block of β together with the coarser blocks used by $\eta_{>i}$. Lemma 20.1 bounds these coefficients by the products of the majorants of the factors and their derivatives. The series starts at total free degree one, with coupling power equal to the total free degree.

The remaining part of the measure fluctuation in (20.10) is the difference $B_i(c_{i+1}) - B_i(\widehat{c}_{i+1})$, whose fluctuation support may lie entirely in coarser scales; it is not part of the field-independent prefactor. For a coordinate h_γ of the coarser argument, the total derivative is

$$\partial_{h_\gamma} B_i = L^*_{i,h_\gamma} + \sum_a L^*_{i,a} \partial_{h_\gamma} z^*_{i,a} + \frac{1}{2} \sum_{a,b} (K_i^{-1})_{ba} \partial_{h_\gamma} K_{i,ab},$$

where $\partial_{h_\gamma} z^*_i = -K_i^{-1} F^*_{i,y h_\gamma}$ and $\partial_{h_\gamma} K_{i,ab} = F^*_{i,ab h_\gamma} + \sum_{a'} F^*_{i,aba'} \partial_{h_\gamma} z^*_{i,a'}$. The difference equals the convergent coefficient expansion of

$$\int_0^1 \sum_{j=i+1}^{s-1} \sum_{\beta \in I_j} \zeta_{j,\beta} \sum_\gamma (\partial_{h_\gamma} B_i)\big(v, C_{i+1}(v, \tau\zeta_{>i})\big)\, (\partial_{\zeta_{j,\beta}} C_{i+1,\gamma})(v, \tau\zeta_{>i})\, d\tau,$$

since the integrand is the derivative in τ of $B_i(v, C_{i+1}(v, \tau\zeta_{>i}))$; here I_j is the set of unfixed scalar free labels at scale j, and $\partial_{\zeta_{j,\beta}} C_{i+1}$ is evaluated at $\tau\zeta_{>i}$ without an extra factor τ. Each Taylor coefficient of this integral carries the factor $1/(n+1)$ when the remaining integrand has degree n in τ. Likewise, at fixed couplings,

$$dz_i = (\partial_v z^*_i) dv + (\partial_c z^*_i) dc_{i+1} + g_i \{(\partial_v S_i) dv + (\partial_c S_i) dc_{i+1}\} w_i + g_i S_i\, dw_i,$$

and none of these terms may be dropped. The inverse square root S_i is treated as a constituent tensor with the bounds of Theorem 20.2; if it is expanded, (20.18) and the Neumann series of the resolvent around $K_i(0,0)$ give a chain of ordinary matrix products whose coefficients are its network refinements. The comparison of determinant matrices with the same indices also includes the correction (20.20), which is a further constituent tensor with a visit to Ω^c.

Step 4: the incoming insertion and the boundary differences. We write $\mathcal{A}(v,\zeta) = \operatorname{Log} C(v,\zeta;b_{\mathrm{rec}})$. Then

$$R(\mathcal{A}(v,\zeta)) - R(\mathcal{A}(v,0)) = \sum_{n\geq 1} \frac{1}{n!} D^n R(\mathcal{A}(v,0))\big[\mathcal{A}(v,\zeta)-\mathcal{A}(v,0),\dots,\mathcal{A}(v,\zeta)-\mathcal{A}(v,0)\big],$$

and each factor $\mathcal{A}(v,\zeta)-\mathcal{A}(v,0)$ has positive degree in ζ. The coefficient of $v^{\nu}\zeta^{\eta}$ is the sum over n, over the contracted indices $j_1,\dots,j_n$ of the old lattice, and over the allocations of the multi-indices to the n factors with positive free degree in each, of the products of the jet coefficients of R and the coefficients of the factors. No additional multinomial factor occurs, since each coefficient is already a multi-index coefficient. Each such occurrence keeps the union of the old network of R, scaled by B^{-1} in output units, and the attached reconstruction networks, and its fluctuation support is the set of blocks used by η. By the jet bound of Step 1 with $j=1$ at an image bounded by $\rho/2$, the derivative series of R at the image is at most $4H\rho$. The column majorant of the reconstruction with a free index fixed vanishes at zero free radius and is linear in the free radius on the fixed product, so it is at most $C_J|z|p$. Fixing an external input in the old counting convention contributes the fixed volume ratio $\Gamma_J = \max_i v_i/v_{\mathrm{old}} \leq M^{3J}$ between the input mesh and the old mesh. We obtain the incoming bound, linear in H and starting at $|z|p$.

For a difference between the regional and the restricted torus constructions we compare factor by factor, before any expansion of logarithms. In each product of coefficients we use the ordered identity

$$\prod_{r=1}^{m} A_r^1 - \prod_{r=1}^{m} A_r^0 = \sum_{r=1}^{m} \Big(\prod_{l<r} A_l^1\Big)(A_r^1 - A_r^0)\Big(\prod_{l>r} A_l^0\Big),$$

and for the incoming function at two reconstructed arguments C_0, C_1 in the identity chart (here C_0, C_1 denote arguments, not the constants of Lemma 20.3),

$$R(C_1) - R(C_0) = \int_0^1 DR\big(C_0 + s(C_1-C_0)\big)[C_1-C_0]\,ds.$$

Both images under the absolute reconstruction majorant lie in the common product with half the incoming radius, so the whole segment does. Terms involving the incoming boundary function use its incoming boundary weight; torus terms acquire the visit carried by the difference of the reconstructions. Fixed input slots are visits to Ω^c. Changed formulas, minimizers, inverse square roots, and Haar densities are treated by the same identity, with $-A^{-1}(A-B)B^{-1}$ for inverses and (20.18) for inverse square roots. Each term contains one changed factor with its visit to Ω^c. The versions with every index rooted in Theorem 19.9 keep every differentiated background or free index, even when the changed factor is not differentiated; the degree-one terms are therefore included.

We join the incoming networks, scaled by B^{-1}, to the chart networks at their contracted indices. The transport of the route to the fixed complement is exactly (19.42), and

Lemma 18.15 sums the remaining internal indices. We append the resulting route to the network of the monomial. One fixed allocation of the available exponents bounds $e^{s_0\ell_\lambda}$, including this route and the fixed stencil offsets; the offsets contribute a fixed factor in the degree, absorbed on the margin already provided by the construction. The allocation is the same for every order and every contraction, and no exponent is lost at each vertex. The scaled incoming networks and routes are bounded by the inequalities against Ba and $B\alpha$. Every term still contains an incoming factor, so its bound is linear in H and starts at $|z|p$. The arguments of Step 5 apply to this majorant with a visit to Ω^c and give (20.32). Finally, a torus monomial deleted because it uses a missing fluctuation block already has a visit at that block; if it has an unfixed root, its network provides the route to Ω^c.

Step 5: conversion to W_{16} and D_{16}. By Steps 1 to 4, there exist a free radius $V_1 > 0$, strictly inside all image and stage margins, and a common bound A_0 for the coefficientwise majorants of the diagrams on the outer profile $\widehat{\phi}$ and at free radius V_1, including each permitted fixed coefficient index and the volume ratios of part (4) of Lemma 20.1. For the incoming family the bound is A_0H, and for a difference it is linear in the bound of the changed factor. We write the resolved coefficients of free degree q and background degree k as $u_\lambda^0 v^{\nu_\lambda}\zeta^{\eta_\lambda}$, after removing the factor z^{q-2} for the classical terms and z^q for the others; the ratios λ_i have modulus at most one. The mixed factorial identity is

$$\frac{1}{k!\,q!}\sum_{\text{other ordered indices}}\left|D_v^k D_\zeta^q (u^0 v^\nu \zeta^\eta)\right| = \begin{cases} (\eta_l/q)|u^0|, & \text{one free input } l \text{ fixed},\\ (\nu_i/k)|u^0|, & \text{one background input } i \text{ fixed}, \end{cases}$$

for $q \geq 1$ and $k \geq 1$ respectively, and the radii of all inputs multiply these expressions. With $\widetilde{C} = \max\{1, V_1^{-1}\}$, Lemma 20.1 and the finite majorant at V_1 give

$$\sup_l \sum_{\lambda:(k_\lambda,q_\lambda)=(k,q)} \frac{\eta_{\lambda,l}}{q}|u_\lambda^0|\widehat{\phi}^{\nu_\lambda}e^{s_0\ell_\lambda} \leq A_0\widetilde{C}^q, \qquad \sup_i \sum_{\lambda:(k_\lambda,q_\lambda)=(k,q)} \frac{\nu_{\lambda,i}}{k}|u_\lambda^0|\widehat{\phi}^{\nu_\lambda}e^{s_0\ell_\lambda} \leq A_0\widetilde{C}^q.$$

These bounds concern the total variation of the resolution produced by composition of coefficientwise majorants.

Let $\vartheta = K_*^{-1/2} < 1$. Passing from $\widehat{\phi}$ to ψ_{prof} multiplies a term of background degree k by exactly ϑ^k, independently of the positions of its background indices in the spatially varying radius profile. Each term has $|S_\lambda| \leq q$, and selecting a fluctuation block is bounded by the sum of its three scalar multiplicities. At fixed k, q, the preceding bounds therefore contribute at most $3qA_0\widetilde{C}^q\vartheta^k$ for a fluctuation root and $kA_0\widetilde{C}^q\vartheta^k$ for a background root; the latter bound is uniform in the root at each degree. Taking the supremum over the root at each degree and only then summing over k, and using $q \leq 2^q$, we find that the sums in the definitions of W_h and D_h, at fixed q, are at most

$$A_0\widetilde{C}^q e^{hq}\Big(\frac{3q}{1-\vartheta} + \frac{\vartheta}{(1-\vartheta)^2}\Big) \leq \mathsf{A}\mathsf{B}^q, \qquad \mathsf{A} = A_0\Big(\frac{3}{1-\vartheta} + \frac{\vartheta}{(1-\vartheta)^2}\Big), \quad \mathsf{B} = 2e^h\widetilde{C}.$$

Multiplying by $|z|^{q-2}p^q$, $q \geq 3$, or by $|z|^q p^q$, $q \geq 1$, and summing the geometric series, we obtain on $\mathsf{B}|z|p < 1$

$$W_h^{\mathrm{cl}} + D_h^{\mathrm{cl}} \leq \frac{\mathsf{A}\mathsf{B}^3|z|p^3}{1-\mathsf{B}|z|p}, \qquad W_h^{\mathrm{Haar}} + D_h^{\mathrm{Haar}} \leq \frac{\mathsf{A}\mathsf{B}|z|p}{1-\mathsf{B}|z|p}, \qquad W_h^{\mathrm{inc}} + D_h^{\mathrm{inc}} \leq \frac{\mathsf{A}\mathsf{B}H|z|p}{1-\mathsf{B}|z|p}$$

for the classical, Haar-density, and incoming families. The same bounds hold for the differences with a visit to Ω^c, with their majorants. Note that the classical bound starts with $|z|p^3$: the two coupling powers removed by the division by g_i^2 are not restored. For $h = 16$, enlarging the constant to a common C_J and restricting the disc accordingly gives the assertions of the lemma. Choosing the auxiliary disc smaller by this fixed factor keeps it inside the same larger free radius, and neither an input radius nor the ratio K_* changes. Finitely many additional background marks contribute a polynomial factor in k, which is summable since $\sum_k (k+1)^m \vartheta^k < \infty$. The argument never interchanges $\sup_i \sum_k$ with $\sum_k \sup_i$. The bounds at fixed real frozen values are proved first and are uniform, so taking the supremum over the frozen values afterwards preserves them. All coefficientwise majorant series converge on the same fixed larger products, and finite truncations and the absolute majorants justify the displayed sums. □

Lemma 20.8. *Let $\pi = \bigotimes_x \pi_x$ be a finite product of probability measures on fluctuation blocks, each π_x supported in the ball $\{|w_x| \leq p_x\}$ with $p_x < \infty$; these are the radii used in b_λ, W_{16}, and D_{16}. Use the same working rates $a, \alpha > 0$ as in $\mathcal{X}^\phi$, and assume $s_0 \geq a + \alpha$. Consider monomial families as in Definition 20.6, with nonempty supports S_λ and networks through all of their positions, and put $\epsilon = W_{16}(U) + D_{16}(U)$. There is an absolute constant $\epsilon_0 > 0$ such that $\epsilon < \epsilon_0$ implies the following.*

1. *The product expansion followed by the hard-core polymer expansion, with incompatibility $S_\lambda \cap S_\mu \neq \varnothing$, gives a normally convergent logarithm of $\int e^{-\sum_\lambda U_\lambda}\, d\pi$, equal to zero at zero interaction, and this integral does not vanish in the coefficient ball. Neither spatial connectedness of S_λ nor membership of the background positions in S_λ is needed.*
2. *Every resolved term of the logarithm carries the connected union of the networks of its monomials, with no additional length. Its absolute sum rooted at a fluctuation block, with the weight $e^{4|S|}$ where S is the union of the supports of its monomials, is at most $C\epsilon$. After passage from ψ_{prof} to ϕ, the sum over the background degrees of its rooted coefficient suprema is at most $C\epsilon$.*
3. *For one marked family A the same bounds hold with $C\epsilon_A$. Let $U(s,r) = U + sB + rA + srC$, $0 \leq s, r \leq 1$, where B carries the boundary change, A the incoming insertion, and C both (here s, r are interpolation parameters and B, C are families of monomials). Assume that every occurrence in B and C has an assigned network visiting $\Omega^c_{L_J}$, with that visit included in ℓ_λ and in its weighted bound, and that every interpolated family lies in the same fixed small ball.*

Then the mixed derivative $\partial_s \partial_r$ of the logarithm and its four-corner difference are bounded, in both rooted norms after passage of profile, by

$$C(\epsilon_{\partial A} + \epsilon_{\partial} \epsilon_A), \tag{20.34}$$

where $\epsilon_{\partial}, \epsilon_A, \epsilon_{\partial A}$ are the values of $W_{16} + D_{16}$ for B, A, C. A term containing the boundary change keeps a visit to Ω^c, and a term containing both changes keeps an incoming factor. These bounds keep the weight of the network length. In particular, for a difference F of logarithms containing the boundary change, on the working profile,

$$\mathcal{X}^{\phi}(F) \le C_J(\epsilon_{\partial A} + \epsilon_{\partial} \epsilon_A)$$

in the case of two changes, and $\mathcal{X}^{\phi}(F) \le C_J \epsilon_{\partial}$ in the case of one change.

4. *The logarithm and its derivatives in the changes are holomorphic on this ball.*

The combinatorial constants are absolute, with the dependence described in item (1) of Definition 4.14; the constants of the passage of profile, of the density, and of the spatial conversion have the dependence described in item (3).

Proof. The proof follows the standard two-stage cluster expansion; we give the estimates so that the root and the support weights stay visible. We first truncate to finitely many monomials.

Step 1: the product expansion. Let $f_\lambda = e^{-U_\lambda} - 1$. Its absolute coefficient majorant is at most $e^{b_\lambda} - 1 \le 2b_\lambda$ for small ϵ. Indeed $|w_x| \le p_x$ holds π_x-almost surely, so the polynomial bounds defining b_λ bound the integrands on the support of the product measure. The normalized truncated Gaussian measures on balls used later satisfy this hypothesis. We expand the exact identity

$$e^{-\sum_\lambda U_\lambda} = \prod_\lambda (1 + f_\lambda).$$

We group each selected family of distinct indices by the connected components of the graph in which λ, μ are joined when $S_\lambda \cap S_\mu \neq \varnothing$. Different components depend on disjoint sets of fluctuation blocks, so their expectations factor, even if their background parameters coincide. This is an exact hard-core gas whose polymers are unions of fluctuation supports. Spatially disconnected sets may serve as polymers, because compatibility uses only set intersection and the independence of the reference variables.

Step 2: the tree majorant at the first stage. Let $n_\lambda = |S_\lambda|$ and $a_\lambda = 2b_\lambda e^{10 n_\lambda}$. The majorant by rooted trees is the increasing iteration from zero of

$$T_\lambda = a_\lambda \exp\Big(\sum_{\mu : S_\mu \cap S_\lambda \neq \varnothing} T_\mu \Big). \tag{20.35}$$

Every connected selected family has a spanning tree; expanding the exponential supplies the factorials for unordered children, and dropping the distinctness of the indices only increases this sum of nonnegative terms. If $T_\mu \le a_\mu e^{n_\mu}$ for all μ, then the exponent in (20.35) is at most

$$n_\lambda \sup_x \sum_{\mu : x \in S_\mu} a_\mu e^{n_\mu} \le 2\epsilon n_\lambda .$$

For $2\epsilon \le 1$ the candidate $a_\lambda e^{n_\lambda}$ therefore bounds every iterate. Its sum rooted at a fluctuation block is at most 2ϵ. Thus the polymer activities are absolutely summable with the weight $e^{10|S|}$.

Step 3: the second stage. We apply the finite graph inequality of Theorem 12.6 to this hard-core gas; only its bound on alternating sums over connected graphs is imported. At the level of polymers we repeat (20.35), using the weight $e^{4|S|}$ for the output and a factor $e^{|S|}$ of the support weight for the children. The estimate with weight $e^{10|S|}$ bounds the sum over the children by $C\epsilon$ times the size of the parent support. Decreasing ϵ_0 if necessary, we obtain the bound of part (2) with weight $e^{4|S|}$. Repeated polymer occurrences are allowed, as in the finite graph theorem. Thus the input weight is $e^{16|S|}$, the polymer activities have weight $e^{10|S|}$, and the logarithm has weight $e^{4|S|}$.

Step 4: the networks. We keep the resolution into monomials inside each exponential and each polymer. Within a connected family of the first stage, the networks of adjacent factors share a fluctuation position. At the second stage, adjacent polymers share a fluctuation block used by a factor in each of them, so their networks also meet at that position. By induction along a spanning tree at each stage, the union is connected and

$$\ell(\mathcal{N}_{\text{union}}) \le \sum_{\lambda \text{ occurrences}} \ell_\lambda . \tag{20.36}$$

Coincident positions of different color coordinates have distance zero. Copies of the same monomial in an exponential have the same support and network. A visit to Ω^c remains a visit in the union. Thus the network weights multiply, with no extra connecting length at either stage.

Step 5: the background root. Fix a background coordinate i in a coefficient of a product. The identity $\nu_i = \sum_\lambda \nu_{\lambda,i}$ assigns the derivative in i to one monomial occurrence, with its multiplicity. We root the spanning tree of the first stage at this factor and, at the second stage, at the polymer containing it. The estimates for the children just proved bound the remaining part of the expansion by $Ce^{cn_\lambda} b_\lambda$ with $c < 16$, so that the total support weight used is less than $e^{16 n_\lambda}$. At the distinguished factor we use the degree-k term in D_{16} instead of its norm rooted at a fluctuation block. This works even if the background position is not a fluctuation position. The other factors are summed through their intersections of fluctuation supports.

Fixing i and summing over all output degrees at the intermediate profile, we obtain the bound $C \sum_k d_k \le C\epsilon$, where d_k is the degree-k supremum in D_{16} for the distinguished monomial. Indeed, the remaining part of the expansion is summed at its fixed fluctuation root, and its total coefficient majorant there is bounded by the estimates for the children. We thus obtain a bound on $\sup_i \sum_K$ at the intermediate profile, which is not yet the coefficient norm with boundary decay. Let $q_* = K_*^{-1/2} < 1$. At output degree K, passing to the working profile multiplies every coefficient by q_*^K. Thus, taking the supremum separately at each degree,

$$\sum_{K \ge 1} \sup_i \{\text{output coefficients of degree } K \text{ rooted at } i, \text{ at } \phi\} \le C\epsilon \sum_{K \ge 1} q_*^K.$$

This is the required order of operations; a bound on $\sup_i \sum_K$ at the same radius would not imply a bound on $\sum_K \sup_i$. The second half of the ratio between the profiles is used here, once for each local map on the fixed profiles. The factor ν_i / K in the coefficient norm with boundary decay only decreases the multiplicity bound. Repeated copies in an exponential obey the same identity for ν_i, and differentiating the exponential accounts for all possible distinguished occurrences.

Step 6: one and two changes. The tree estimates also hold in the rooted norms with changes. Differentiating (20.35) once gives

$$T'_\lambda = e^{\sum_{\mu \sim \lambda} T_\mu} a'_\lambda + T_\lambda \sum_{\mu \sim \lambda} T'_\mu,$$

where $\mu \sim \lambda$ means $S_\mu \cap S_\lambda \ne \varnothing$. In the norm rooted at a fluctuation block, the last operator has norm at most $C\epsilon < 1/2$, since its incidence factor $n_\lambda \le e^{n_\lambda}$ is bounded by a factor e^{n_λ} of the support weight that is not used in the output bound. Its inverse is a Neumann series with nonnegative terms and norm at most two. Hence a first variation is bounded by the norm of the changed source. Writing $h_\lambda = \sum_{\mu \sim \lambda} T_\mu$, the mixed variation satisfies

$$T_{\lambda,sr} = e^{h_\lambda} a_{\lambda,sr} + e^{h_\lambda} (a_{\lambda,s} h_{\lambda,r} + a_{\lambda,r} h_{\lambda,s}) + T_\lambda h_{\lambda,s} h_{\lambda,r} + T_\lambda \sum_{\mu \sim \lambda} T_{\mu,sr}.$$

Its inhomogeneous terms are a source with both changes, products of the two first variations, and a source with one change times a first variation. Their bounds are $C(\epsilon_{\partial A} + \epsilon_\partial \epsilon_A)$, and the same inverse bounds the mixed variation. The polynomial incidence factors have degree at most two, and $\sup_{n \ge 1} n^2 e^{-n} < \infty$. In the bilinear interpolation, terms containing the family C are bounded by a constant times $\epsilon_{\partial A}$, since the other monomial norms are bounded on the fixed small ball. Integrating the mixed derivative over the unit square, we obtain the four-corner difference, with the same bound. These calculations apply at both stages of the expansion. For a background root, we

first sum the resulting rooted expressions at the distinguished factor at the intermediate profile, with the sequence d_k described above, and then apply the factor q_*^K at each output degree. If the background root lies on a factor different from both changes, the remaining expansion has at most one additional distinguished branch. Its cubic incidence factor is bounded by a further factor e^{n_λ} of the support weight, since $\sup_{n\ge1} n^3 e^{-n} < \infty$; the passages from $e^{16|S|}$ to $e^{10|S|}$ and from $e^{10|S|}$ to $e^{4|S|}$ leave these factors available. The source with both changes keeps its incoming factor, and the product source contains the first variation in the incoming insertion. This proves (20.34) in both rooted norms, including the case of a background root on an unchanged factor.

Step 7: spatial conversion. We keep the joined networks. By the hypothesis on B and C, every term containing the boundary change carries a visit to $\Omega^c_{L_J}$. If a coefficient with unfixed background root i carries such a visit, then by part (5) of Lemma 20.1

$$a\mathrm{t}(\nu) + \alpha d_\Omega(i) \le (a+\alpha)\ell(\mathcal{N}_{\mathrm{union}}) + C_J\alpha.$$

Since $s_0 \ge a+\alpha$, the product of the weights $e^{s_0\ell_\lambda}$ in b_λ dominates $e^{(a+\alpha)\ell(\mathcal{N}_{\mathrm{union}})}$, by (20.36). The fixed buffer is used only at the final visit to Ω^c. The factor ν_i/K in (4.11) is at most the multiplicity of the distinguished index. The bound at the intermediate profile and the degree sum $\sum_{K\ge1} q_*^K$ just proved, multiplied by the fixed factor ρ^{-2} and the buffer constant, give the stated bounds on $\mathcal{X}^\phi$.

Step 8: the logarithm. The bounds on the coefficientwise majorants prove the normal convergence of every resolved series and of the displayed derivatives. For a small multiple of the interaction, the two series are the Taylor expansion of the logarithm of the finite product integral. Their exponential agrees with the integral throughout the strict ball, by the identity theorem in that multiplier. Hence the integral does not vanish there. The uniform absolute bounds allow us to remove the truncations to finitely many monomials and to differentiate termwise in the parameters, and they prove holomorphy in the absolute coefficient norms. We have not used the hypothesis on background supports in the holomorphy theorem of Section 12. □

Theorem 20.9. *Fix the torus rate $a_{\mathbb{T}} > 0$ and the ratio K_* between the profiles $\widehat{\phi} = K_*\phi$ and $\psi_{\mathrm{prof}} = \sqrt{K_*}\phi$. There are geometric constants C_{alloc} and C_g, independent of J, with the following property. Choose $C_*^{\mathrm{geom}} \ge C_g$ and choose J once with*

$$B = M^J \ge B_{\mathrm{geom}}, \qquad \textit{where } B_{\mathrm{geom}} = 256 C_{\mathrm{alloc}}(C_*^{\mathrm{geom}} + 1).$$

After J has been fixed, choose positive rates

$$a = a_{\mathrm{cl}} = a_{\mathrm{sp}}, \qquad \alpha = \alpha_{\mathrm{cl}} = a/16, \qquad m_{\mathrm{rate}} = C_*^{\mathrm{geom}}(a+\alpha), \qquad b_1 = 8C_*^{\mathrm{geom}}\alpha$$

so that

$$m_{\mathrm{rate}} + b_1 < \min(c_{\mathrm{prim},J}, Ba)/C_{\mathrm{alloc}}, \qquad b_1 < B\alpha/C_{\mathrm{alloc}}, \qquad \sqrt{3}\,(a+\alpha) < a_{\mathbb{T}},$$

where $c_{\mathrm{prim},J}$ is the fixed positive reserve for the intrinsic tensors and the unperturbed weighted reconstruction images, in the graph metric of Section 20.1, chosen no larger than the intrinsic exponent c_J of Theorem 19.9. The inherited perturbative networks use the separate inequalities against Ba and Bα from Theorem 19.9; their images satisfy the half-radius bound at the allocated working rates.

Consider a full renormalization group step ($s = J$) on admissible data. Sum the internal indices first, keep networks through all positions of the monomials, and use the exact nonempty fluctuation supports of Definition 20.6 in both expansions. All factors and polymer occurrences that are joined share a fluctuation position; the union of their networks keeps every background index and every visit to Ω^c, and adds no length. Set $p = \max_i p_i \geq 1$, $x = \mathcal{X}^\rho(f)$, and $H = E + x$, and substitute the complex parameter z for the coupling powers as described before Definition 20.6, with the insertion $A_R(z)$. Let Ξ_0 and Ξ_R be the integrals of e^{-U} against the product of normalized symmetric reference measures on balls, for the interaction U without insertion and for U plus the insertion, respectively. For the matched torus potential, with the fixed background slots set to zero, define its restriction by deleting the monomials that use a missing fluctuation block, and adjoin the missing blocks with the identical normalized reference measures.

There are $\epsilon_J, c_{z,J} > 0$ and $C_J < \infty$ such that the following holds if

$$\mathfrak{s}(z) = \frac{C_J|z|(p^3 + p + Hp)}{1 - C_J|z|p} \leq \epsilon_J, \qquad C_J|z|p < 1.$$

The integrals without and with insertion, the restricted torus integrals, and the linearly interpolated integrals do not vanish, and their logarithms are the normally convergent expansions of Lemma 20.8. The regional and restricted families satisfy $W_{16} + D_{16} \leq C_J\mathfrak{s}(z)$; their boundary-difference families satisfy the same bound with networks visiting Ω^c. The comparisons of the nonconstant parts of the logarithms, including the deleted torus terms with an unfixed background index, satisfy

$$\mathcal{X}^\phi\big(\log \Xi_\bullet^\Omega - (\log \Xi_\bullet^{\mathbb{T}})|\big) \leq C_J\mathfrak{s}(z), \qquad \bullet \in \{0, R\},$$

where the bar denotes zero extension of the fixed background slots; constants supported in Ω^c remain separate. The mixed difference of the boundary change and the insertion is bounded by $C_J(\epsilon_{\partial A} + \epsilon_\partial \epsilon_A)$ in the norms of Definition 20.6, and every term keeps an incoming factor. The family extends holomorphically to $z = 0$, and its compared insertion logarithm F satisfies $F(0) = F'(0) = 0$. In particular, if

$$r_z = \frac{c_{z,J}}{p^3 + p + Hp}, \qquad 0 < t_{\max} \leq r_z/2,$$

then

$$\mathcal{X}^\phi\big(\mathsf{D}^\Omega R - (\mathsf{D}^{\mathbb{T}} r_{d_0})|\big) \leq C_J t_{\max}^2 H(p^4 + Hp^2), \qquad \mathsf{D}R = -\log \Xi_R + \log \Xi_0.$$

After the whole boundary layer with reduced radius has been frozen as in Lemma 18.9, the classical and quantum comparisons return the same rates a, α and the same input radii; the torus rate

remains $a_{\mathbb{T}}$. The constants have the dependence described in item (3) of Definition 4.14 and are independent of the later widths. The return of the same profile is asserted only for full steps with $B \geq B_{\mathrm{geom}}$, not for compositions of fewer than J averaging steps.

Proof. The constants C_{alloc} and C_g bound only the fixed contraction with every index rooted and the transport of the input boundary weight in Theorem 19.9 and Lemma 18.15; they include the factor $\sqrt{3}$ of the conversion between Euclidean and graph exponents in Section 20.1, and hence do not depend on J. The torus coefficients, bounded in $\mathcal{B}_{\rho,a_{\mathbb{T}}}$ with Euclidean network lengths, have graph exponent $a_{\mathbb{T}}/\sqrt{3} > a + \alpha$ by the last inequality in the statement. With $\alpha = a/16$ we have $m_{\mathrm{rate}} + b_1 = (25/16)C_*^{\mathrm{geom}} a$, and both restrictions against Ba and $B\alpha$ follow from the lower bound on B. At this fixed J, we decrease $a > 0$ to satisfy the bounds on the exponents of the coefficients of the potential, of the weighted images, and of the torus, including $\sqrt{3}\,(a + \alpha) < a_{\mathbb{T}}$. No constant depending on J is used to choose J. The comparison of the classical boundary networks uses the same allocation of the decay rate and no expansion with respect to a reference product. At zero fluctuation it works as follows. Consider a classical comparison, or the comparison of the pullback terms, with the boundary tensors rooted at every index. At background degree $k \geq 1$, its rooted absolute sum on $\widehat{\phi}$ is bounded by its tensor majorant for fixed J, and that allocation already accounts for the weights of its output network and of its distance to Ω^c. Passing to ϕ gives the factor K_*^{-k}. Summing over the degree, including any fixed polynomial factor for the choice of a distinguished index, we obtain the bound in the coefficient norm with boundary decay. For a pulled-back incoming boundary term, we use its jet majorant at half the radius and its distinguished input columns before this calculation. Thus the classical coefficients are converted without assigning a fluctuation support to a term at zero fluctuation, and these terms never enter either expansion.

We apply Lemma 20.7 at these rates and then Lemma 20.8. The hypotheses of the latter on the rates and on the boundary-change families hold, since Lemma 20.7 uses $s_0 = a + \alpha$ and gives the boundary differences with their networks visiting Ω^c. Restricting a torus family decreases its norms, which are sums of absolute values. For its difference from the full family, every deleted coefficient with an unfixed background root visits a missing fluctuation position and hence Ω^c, and the same lemma applies. Pure background constants without an unfixed index have zero norm with boundary decay and stay outside this comparison. The estimate with two changes implies the comparison of the logarithms with and without insertion. The logarithms and their derivatives in the parameters are determined by the finite identities and normal convergence proved above, not by a choice of a complex logarithm after integration.

We choose $c_{z,J}$ so that the disc $|z| \leq r_z$ lies strictly inside the margins of Lemma 20.7, of the free product, and of the logarithm. On this disc, (20.32) and the bounds with one and two changes give

$$\|F(z)\|_{\mathcal{X}^\phi} \leq C_J |z| Hp.$$

At $z = 0$ every fluctuating monomial vanishes. The coefficient of z is cubic in the fluctuation variables for the classical terms and linear for the quantum, Haar density, determinant, and incoming terms. Each of these is odd under the simultaneous reversal $w \mapsto -w$, so its expectation under the symmetric reference measures on balls vanishes. At first order the logarithm contains a single monomial occurrence, hence $F(0) = F'(0) = 0$ coefficientwise, at every real frozen value.

The normally convergent series $F(z)/z$ is holomorphic, vanishes at zero, and has norm at most $C_J H p$. Cauchy's coefficient bound on $|z| = r < r_z$, followed by $r \uparrow r_z$, gives for $t \le r_z/2$

$$\|F(t)\|_{\mathcal{X}^\phi} \le 2C_J t^2 H p / r_z \le C'_J t^2 H(p^4 + Hp^2),$$

where in the last step we used $p \ge 1$. The integral proof of the coefficient bound applies to the supremum over the fixed index at every background degree, and then to their sum, by the triangle inequality.

Finally, Lemma 18.9 restores the incoming radii when the whole zone with reduced radius is frozen with the stated bounds on the frozen values. All conversions of coefficients were made on the fixed outer and intermediate profiles, and none is iterated at later steps. This proves the return of the same profile and the stated independence of the constants. □

20.5 Effective interactions and normalization constants

Theorem 20.10. *Consider a full renormalization group step, $s = J$, on admissible data as in Theorem 20.9. Set*

$$\mathsf{P}^\Omega R(v) = R\big(\operatorname{Log} C^\Omega(v, 0; b_{\mathrm{rec}})\big), \qquad \mathsf{Q}^\Omega = B^\Omega_{\mathrm{ref}} - \sum_i f_i \log z_{p_i} - \log \Xi^\Omega_0,$$

$$B_{\mathrm{ref}} = \sum_i B_i(\widehat{c}_{i+1}),$$

where f_i is the number of free blocks at scale i and $z_p = \int_{|w|\le p} e^{-|w|^2/2}\, d^3w$, in the convention of Theorem 12.13. The field-independent factors of the block averaging constraint and of the Haar measure extracted from L_i are kept in Λ. Up to the exact constant kept in Λ, the new effective interaction $\mathsf{M}^\Omega R$ produced by the step satisfies

$$\mathsf{M}^\Omega R = \mathsf{Q}^\Omega + \mathsf{P}^\Omega R + \mathsf{D}^\Omega R.$$

Here Q^Ω is the newly generated term, $\mathsf{P}^\Omega R$ is the pullback of the incoming interaction by the zero-fluctuation reconstruction, and $\mathsf{D}^\Omega R$ is the fluctuation correction of Theorem 20.9. For the

matched torus reference with zero extension of the fixed slots, there are constants A_J, K_J, and C_J, independent of the later widths, such that

$$\mathcal{X}^{\phi}\big(\mathsf{Q}^{\Omega} - \mathsf{Q}^{\mathbb{T}}|_{\Omega'} + \mathsf{P}^{\Omega}(r_{d_0}|_{\Omega}) - (\mathsf{P}^{\mathbb{T}} r_{d_0})|_{\Omega'}\big) \le A_J(1+E),$$
$$\mathcal{X}^{\phi}(\mathsf{P}^{\Omega} f) \le K_J \mathcal{X}^{\rho}(f).$$

Here Ω' is the set of unfixed scalar output labels. Assume that the column bounds of Theorem 19.6 and their perturbed versions hold on the product with doubled output analytic radii, and that the image under the reconstruction majorant on this product is at most half the incoming radius, as in Lemma 19.7. Then one may take $K_J = 4(\log 2)K_{\mathrm{col},J}$. Here $K_{\mathrm{col},J}$ bounds, for one fixed output, the sum over all old input labels, weighted by their boundary decay, of the distinguished derivative series of the perturbed zero-fluctuation reconstruction; it is chosen uniformly on the preliminary perturbation ball by Theorem 19.9. The degree-one terms and every nonconstant dependence of an omitted torus density on the unfixed labels are included.

At every admissible complex value of the coarse background and every fixed real admissible frozen value, let I_i and H_i be the sets of unfixed and of missing scalar free labels at scale i. With matched torus arguments extended by zero,

$$\log\det K_i^{\Omega} = \sum_{x\in I_i} (\log K_i^{\mathbb{T}})_{xx} + \mathcal{B}_i, \qquad |(\log K_i^{\mathbb{T}})_{xx}| \le C_J, \qquad |\mathcal{B}_i| \le C_J |\partial_{\mathrm{blk}}\Omega|.$$

These determinant statements also hold in the coefficient norm before evaluation. Scalar determinant labels and fluctuation blocks are counted separately. All constants have the dependence described in item (3) of Definition 4.14 and are independent of the later widths.

Proof. Every step here is a full step, $s = J$; a final composition of fewer than J averaging steps that is evaluated deterministically adds no fluctuation integral.

Step 1: the exact factorization. The triangular calculation in the proof of Lemma 20.3 gives, at a fixed coarse background and fixed frozen values, the value of the integral

$$\Big(\prod_i \mathcal{J}_{i,\mathrm{ref}} g_i^{3f_i}\Big) e^{-F_{\mathrm{out}}/g_s^2 - B_{\mathrm{ref}} - R(\mathrm{Log}\, C(v,0;b_{\mathrm{rec}}))} \prod_i z_{p_i}^{f_i}\, \Xi_R(v), \tag{20.37}$$

where F_{out}/g_s^2 is the classical value of the step with the output coupling, and the $\mathcal{J}_{i,\mathrm{ref}}$ are the extracted constant Haar disintegration factors. Inserting the definitions of Q, P, and D into the exponent of (20.37), and writing $\log \Xi_R = \log \Xi_0 - \mathsf{D}R$, we obtain $\mathsf{M}R = \mathsf{Q} + \mathsf{P}R + \mathsf{D}R$. This proves the recursion, including its signs and its Gaussian convention. Centering moves the value at zero into Λ and changes no factor of this identity.

Step 2: the generated term and the torus pullback. The deterministic part of $\mathsf{Q}^{\Omega} - \mathsf{Q}^{\mathbb{T}}|$ is the difference of the Haar densities at the minimizers and of the diagonal matrix-logarithm densities along the two zero-fluctuation chains. Their rooted comparisons with

boundary decay are part (3) of Theorem 20.2. A density based at a missing torus label is not discarded: a nonconstant coefficient with an unfixed index has a network to that missing label, and its sum over the missing label is bounded from the unfixed index by (20.1). Its constant is left in Λ. The terms $\log z_{p_i}$ and the constant Haar factors have no nonconstant background coefficient. The difference of the logarithms without insertion has the same fixed rates by Theorem 20.9, with a bounded norm in the cluster expansion. We obtain a finite bound C_J for the comparison of the nonconstant generated terms.

For the torus pullback, denote by a_Ω the zero extension of $\operatorname{Log} C^\Omega(v, 0; b_{\mathrm{rec}})$ and by $a_{\mathbb{T}}$ the matched torus argument; in this paragraph $a_{\mathbb{T}}$ is an argument, not the torus rate. We have

$$r_{d_0}(a_\Omega) - r_{d_0}(a_{\mathbb{T}}) = \int_0^1 Dr_{d_0}\big(a_{\mathbb{T}} + \tau(a_\Omega - a_{\mathbb{T}})\big)\,[a_\Omega - a_{\mathbb{T}}]\,d\tau. \tag{20.38}$$

Both absolute images are below half the incoming radius, so the whole segment admits the coefficient expansion of the integrand. On an unfixed old input, the difference of the arguments is the unperturbed defect of the reconstruction followed by the gauge transformation (Theorem 19.6) plus the defect of the perturbation (Theorem 19.9). On a fixed old input, the difference is a visit to Ω^c. The action and interaction tensors join every output index to that visit, even if the source does not decay inside its own component of Ω^c. The jet bound (20.28) with $\sigma_0 = 0$ bounds the integrand by $C_J E$, with its visit. The conversion of networks and degrees in the proof of Theorem 20.9 therefore bounds its $\mathcal{X}^\phi$ norm by $C_J E$. Together these bounds prove the first inequality, with A_J fixed on the larger products. No first derivative of the output was canceled.

Step 3: the pullback of the boundary function. For the zero-fluctuation reconstruction $\Phi_e(v) = \operatorname{Log} C_e(v, 0; b_{\mathrm{rec}})$, we define

$$C_{e,x}(2\phi) = \sum_\nu \nu_x |\Phi_{e,\nu}|(2\phi)^\nu e^{a_1 \mathfrak{t}(\{e\}\cup \operatorname{supp}\nu)}.$$

All constants in this step refer to the perturbed map. Let D_J^0 bound the unperturbed distinguished series on the larger product with doubled output analytic radius. The difference of the reconstructions in Theorem 19.9, rooted at every index, with the uniform incoming norm and the inequalities on the conditional forces checked above, bounds the additional distinguished series by $\sigma_* D_J^1$ there. We fix a spatial decay rate $b > \alpha$ and define

$$D_J^{\mathrm{act}} = D_J^0 + \sigma_0 D_J^1, \qquad C_{e,x}(2\phi) \le D_J^{\mathrm{act}}(2\phi_x) e^{-b\,\mathrm{dist}(e,x)}. \tag{20.39}$$

The factor $2\phi_x$ appears because the input index is distinguished before the sum of absolute coefficients is taken. The rates are below the common exponent available in the coefficient bounds of the potential, and both D_J^0 and D_J^1 are computed at the preliminary bound on fixed larger products, before the later widths. Here and below, for an old input label e of R (a label of the incoming set D_{in}, on the input lattice of the step), we write

$d_{\mathrm{old}}(e) = d_{D_{\mathrm{in}}}(e)$ for its distance to the incoming fixed complement, measured in units of the input lattice as in the incoming norm. For a current unfixed background input x, we write $d_{\mathrm{out}}(x) = d_{\Omega}(x)$ for its distance to Ω^c, in units of the output lattice. Finally, $\mathrm{dist}(e, x)$ is the distance between x and the position e/B_s of e, in units of the output lattice. Applying (20.7) on the old input set of R, which is the same set of unfixed labels, with quantum radius ρ, and dividing by B_s, we obtain

$$d_{\mathrm{out}}(x) \le d_{\mathrm{old}}(e)/B_s + \mathrm{dist}(e, x) + C_{\mathrm{buf},J}/B_s.$$

In Theorem 19.6 the distance d_{old} is measured in units of the output lattice, and the inequality $d_{\mathrm{out}}(x) \le d_{\mathrm{old}}(e) + \mathrm{dist}(e, x) + C_J$ is an explicit hypothesis of that theorem. With d_{old} there equal to our $d_{\mathrm{old}}(e)/B_s$, the inequality just displayed verifies this hypothesis, with buffer $C_{\mathrm{buf},J}/B_s$; it holds because the incoming fixed complement lies on the current fixed side. Since $B_s \ge 1$, this also gives the weaker comparison with $d_{\mathrm{old}}(e)$ in place of $d_{\mathrm{old}}(e)/B_s$. The density of the old labels then implies

$$\sum_{e \text{ old unfixed}} e^{-\alpha d_{\mathrm{old}}(e)} C_{e,x}(2\phi) \le K_{\mathrm{col},J}\, \rho\, e^{-\alpha d_{\mathrm{out}}(x)}. \tag{20.40}$$

We define $K_{\mathrm{col},J}$ as a common bound for this inequality, uniformly on the preliminary perturbation ball. One admissible choice is any number at least $2D_J^{\mathrm{act}} e^{\alpha C_{\mathrm{buf},J}/B_s} S_J(b - \alpha)$, with the fixed volume factors included in S_J, and at least the unperturbed column bound; we take the finite maximum over the label types and the stages. The absolute image on the product with doubled output analytic radius is at most $\rho/2$. The construction used a ratio larger than two between the profiles, so no repeated reduction of radii is involved. This is the column calculation of Theorem 19.6, with its constant enlarged by (20.39). The hypotheses on the doubled product and on the incoming image at half the radius are used here.

Let $x_f = \mathcal{X}^{\rho}(f)$. At an old input root e, the distinguished derivative sum evaluated at $\rho/2$ satisfies

$$\sum_{\eta : \eta_e > 0} \eta_e |f_\eta| (\rho/2)^{|\eta|-1} e^{a\mathrm{t}(\mathrm{supp}\,\eta)} \le 4\rho x_f e^{-\alpha d_{\mathrm{old}}(e)}. \tag{20.41}$$

For degree l this follows by multiplying the normalized coefficient with this input fixed by $l 2^{1-l}\rho$, which is at most 4ρ; the case $l = 1$ is included. The chain rule for coefficientwise majorants, the union of networks, and (20.40) bound the distinguished coefficient sum of the output at 2ϕ by $4K_{\mathrm{col},J}\rho^2 x_f e^{-\alpha d_{\mathrm{out}}(x)}$. At degree k the fixed-index weight of the coefficient norm with boundary decay inserts the factor $1/k$, and evaluation at ϕ instead of 2ϕ inserts 2^{-k}. We take the supremum over the fixed index at each degree and then sum. Since integrating $\sum_{j \ge 0} u^j = (1-u)^{-1}$ over $[0, 1/2]$ gives $\sum_{k \ge 1} 2^{-k}/k = \log 2$, we obtain

$$\mathcal{X}^{\phi}(\mathsf{P}^{\Omega} f) \le 4(\log 2) K_{\mathrm{col},J} x_f.$$

This also shows that a finite K_J exists when no particular column constant is specified.

Step 4: the logarithmic determinants. The diagonal coefficient series of $\log K_i^{\mathbb{T}}$ is bounded uniformly for each scalar label. To bound the constant as well as the derivatives, we write

$$\log K = \int_0^\infty \left[(1+t)^{-1} I - (K+t)^{-1}\right] dt.$$

Near $t = 0$ the gap bounds the integrand. For large t, the resolvent identity with I bounds it by $C_J(1+t)^{-2}$, since $K - I$ has a bounded coefficient row on the larger product. This integrable bound and the derivative bounds with every index rooted allow us to integrate coefficient by coefficient. The exact normalization of the scales adds only the same term $i \log M$ for each scalar label, with $i < J$. Thus $|(\log K_i^{\mathbb{T}})_{xx}| \le C_J$ on the stated complex profile, not only at zero background.

The comparison of a regional logarithm with the restriction of the torus logarithm is the sum of (20.19) and (20.20). Its diagonal density at an unfixed root u is bounded in coefficient norm by $C_J e^{-c_J d_\Omega(u)}$. Summing these diagonal defects and using (20.3), we obtain the bound on $\mathcal{B}_i$. If Ω^c is empty, the defect is zero. □

To state the recursion for Λ we fix the counts that enter it.

Definition 20.11. Consider a full step on the block region Ω and the matched torus step. Every scalar label is counted on the lattice on which it is introduced.

1. For each scale i, $|H_i|$ is the number of missing scalar free labels at scale i, that is, free labels of the torus step that are not labels of the regional step.
2. N_{missing} is the number of scalar labels of the torus step (background labels on the output lattice and free labels at the intermediate scales) that are not labels of the regional step. We write $\mathcal{M}_{\text{block}}$ for the set of missing torus fluctuation blocks; since each such block consists of three missing scalar labels, $|\mathcal{M}_{\text{block}}| \le N_{\text{missing}}$.
3. N_{bd} is the number of scalar labels of the regional step whose positions lie within the fixed distance $w_{\text{band}} \ge 1$ of W, where w_{band} is the width of the interface band determined by the construction stencils; it does not depend on the later widths. This is N_{band} of (20.4), so $|\partial_{\text{blk}}\Omega| \le N_{\text{bd}} \le C_J|\partial_{\text{blk}}\Omega|$, including for isolated final blocks. Both counts are zero when W is empty.
4. N_{freeze} is the number of analytic scalar labels that are newly frozen at the end of the step, including, at the first step, the labels frozen at initialization.

When the steps are indexed by t, these counts are written $|H_i|$ for the scales i of step t, and $N_{\text{missing},t}$, $N_{\text{bd},t}$, $N_{\text{freeze},t}$.

Lemma 20.12. *Assume the hypotheses on the products and the small-interaction hypothesis of Theorem 20.9, in a full step, and fix a real admissible coarse background, a real admissible frozen value, and a real coupling $t = t_{\max}$. Use the potential without or with the insertion, from Lemma 20.3, and remove its entire zero-fluctuation part before forming the interaction $U_\bullet$,*

$\bullet \in \{0, R\}$. Let π be the product of the identical normalized three-dimensional Gaussian reference measures on balls, including the reference measures of all missing torus blocks, and write

$$\Xi_\bullet^{\mathbb{T}} = \int e^{-U_\bullet^{\mathbb{T}}}\, d\pi, \qquad \Xi_\bullet^{\Omega} = \int e^{-U_\bullet^{\Omega}}\, d\pi, \qquad \bullet \in \{0, R\}.$$

The regional interaction does not depend on the adjoined variables. With N_{missing} and N_{bd} as in Definition 20.11, there is a restricted interaction $U_\bullet^c$ on the same product such that

$$\|U_\bullet^{\mathbb{T}} - U_\bullet^c\|_\infty \le C_J \mathfrak{s}(t)(N_{\mathrm{missing}} + N_{\mathrm{bd}}),$$
$$\|U_\bullet^{\Omega} - U_\bullet^c\|_\infty \le C_J \mathfrak{s}(t) N_{\mathrm{bd}}.$$

Consequently, for the positive real logarithms,

$$|\log \Xi_\bullet^{\mathbb{T}} - \log \Xi_\bullet^{\Omega}| \le C_J \mathfrak{s}(t)(N_{\mathrm{missing}} + N_{\mathrm{bd}}). \tag{20.42}$$

This includes evaluation at coarse background zero, with the frozen values unchanged. Empty products have integral one.

Proof. The reference measure on a block (i, e) is $z_{p_i}^{-1} \mathbf{1}_{|w| \le p_i} e^{-|w|^2/2}\, d^3 w$. We take the product of these measures over the union of the two sets of blocks. Adjoining blocks multiplies the regional integral by one, even for blocks at different scales with different radii.

For this comparison of constants only, we resolve the torus monomials as in Definition 20.6, and let $\mathcal{D}_{\mathrm{mon}} = \{\lambda : S_\lambda \cap \mathcal{M}_{\mathrm{block}} \ne \varnothing\}$ be the set of deleted monomials. We call the remaining interaction U^c. The bound on W_{16} gives

$$\|U^{\mathbb{T}} - U^c\|_\infty \le \sum_{x \in \mathcal{M}_{\mathrm{block}}} \sum_{\lambda : x \in S_\lambda} b_\lambda \le C_J \mathfrak{s}\, |\mathcal{M}_{\mathrm{block}}|.$$

The set of monomials may be infinite; no bound on its cardinality is used. By Definition 20.11, $|\mathcal{M}_{\mathrm{block}}| \le N_{\mathrm{missing}} \le N_{\mathrm{missing}} + N_{\mathrm{bd}}$. This proves the first inequality.

For the regional and the restricted monomials, we compare coefficients on the common set of unfixed fluctuation labels, at the same background argument extended by zero. We use the comparison before the logarithm in Theorem 20.2 and Lemma 20.3: a reconstruction formula, a minimizer, an inverse square root, or a Haar density is replaced one factor at a time. A change of the coarser arguments is the integral of their derivative against the difference of the reconstructions, which carries a visit to Ω^c. For an incoming torus term we integrate Dr_{d_0} on the segment between the two absolute images, which lie below half the radius; fixed old input slots are visits to Ω^c, and unfixed slots use the defect of the reconstruction in Theorem 19.9. The boundary function f enters with its own incoming boundary weight. By the versions with every index rooted, these comparisons keep a visit to Ω^c and every specified unfixed fluctuation index, including all degree-one

terms. They are estimates on monomials before either logarithm is expanded, so the present restriction need not coincide with the one used in the earlier expansions.

Every remaining fluctuation monomial has an unfixed fluctuation index. We assign each compared monomial to its first such index y. The comparison of coefficientwise majorants with every index rooted bounds its absolute sum there by $C_J \mathfrak{s}(t) e^{-\alpha d_\Omega(y)}$. Summing over these indices, we obtain

$$\|U^\Omega - U^c\|_\infty \le C_J \mathfrak{s}(t) \sum_{y \text{ unfixed}} e^{-\alpha d_\Omega(y)} \le C'_J \mathfrak{s}(t) |\partial_{\mathrm{blk}} \Omega| \le C'_J \mathfrak{s}(t) N_{\mathrm{bd}},$$

by (20.3) and Definition 20.11. This proves the second inequality, at every fixed real frozen value.

The zero-fluctuation values of F_i, L_i, B_i, and R in Lemma 20.3 were subtracted before this sum and stay in the prefactor. In particular, a constant depending on the frozen values does not enter the boundary estimate. The convergent coefficientwise majorants justify all assignments and sums, by finite truncation and monotone convergence of absolute sums.

Finally, if real bounded U, V satisfy $|U - V| \le D$ pointwise, then $e^{-D} e^{-V} \le e^{-U} \le e^{D} e^{-V}$. Integrating against a probability measure and taking logarithms gives

$$\left| \log \int e^{-U} \, d\pi - \log \int e^{-V} \, d\pi \right| \le D.$$

All integrals here are finite and strictly positive because the potentials have bounded majorants. We apply this twice, through U^c, which proves (20.42). For a real interaction, the integral with the interaction multiplied by $0 \le \theta \le 1$ is positive and equals one at $\theta = 0$. The logarithm given by the cluster expansion vanishes at $\theta = 0$ and therefore agrees with the positive real logarithm along this path. The comparison therefore also bounds the constant used in the analytic recursion. □

Theorem 20.13. *Use full steps on admissible data, the exact extraction of field-independent factors, and the centered torus recursion of Theorem 20.10. Restrict the coarse backgrounds, the couplings, and the frozen values to real data on the chosen products of fluctuation balls. Index the full steps by $t = 0, 1, \ldots$, keep the exact incoming value of Λ, and write $\Delta\Lambda_t = \Lambda_t - \Lambda_t^{\mathbb{T}}$ for the difference between the regional and the torus normalization constants before step t. At the end of step t, the newly frozen analytic scalar labels form a set F, frozen simultaneously at the values $c^\sharp$. Assume the following.*

(a) The outgoing centered effective interaction of step t has the form $R^{\mathrm{out}} = r_{\mathbb{T}} + f$ with $R^{\mathrm{out}}(0) = 0$, $D r_{\mathbb{T}}(0) = 0$, $\mathcal{B}_{\rho,a}(r_{\mathbb{T}}) \le E$, and $\mathcal{X}^{\phi}_{\Omega}(f) \le Y$, where Y is a fixed bound.

(b) Every newly frozen value satisfies $|c^\sharp_j| \le \phi(j)/4$ for $j \in F$.

Then at each step, including the simultaneous restriction to fixed values at its end,

$$\Delta\Lambda_{t+1} \le \Delta\Lambda_t + \sum_{i \text{ in step } t} |H_i| \log(1/g_i) + C_J (N_{\mathrm{missing},t} + N_{\mathrm{bd},t} + N_{\mathrm{freeze},t}), \tag{20.43}$$

with the counts of Definition 20.11, where C_J may also depend on E and Y. Each Gaussian dimension occurs once, and the normalized auxiliary variables and the Haar measure of the block axial gauge trees have mass one. The restriction to fixed values is exactly

$$R_{\mathrm{new}}(v) = R^{\mathrm{out}}(v, c^\sharp) - R^{\mathrm{out}}(0, c^\sharp), \qquad \Lambda_{\mathrm{new}} = \Lambda^{\mathrm{out}} - R^{\mathrm{out}}(0, c^\sharp),$$

and the frozen constant satisfies

$$|R^{\mathrm{out}}(0, c^\sharp)| \le \rho^2 |F| (E/16 + Y/4). \tag{20.44}$$

The classical constants remain in the full classical action. A constant of the incoming interaction is first moved into Λ exactly, using $e^{\Lambda - R} = e^{\Lambda - R(0)} e^{-(R - R(0))}$; no nonconstant norm bounds this constant. No additional term proportional to $|\Omega| \log(1/g)$ appears. The restriction at initialization is included, with R^{out} the torus reference and $f = 0$. The constant C_J has the dependence described in item (3) of Definition 4.14 and is independent of the later widths, of the preceding depth, and of the number of steps. No inequality for complex values and no recursion for compositions of fewer than J averaging steps is asserted.

Proof. We compare the logarithms of the regional and the torus factorizations term by term: first the deterministic factors (Step 1), then the fluctuation integrals (Step 2), then the pullback at zero fluctuation (Step 3), and finally the constant produced by fixing coordinates (Step 4).

Step 1: coupling powers, determinants, and Haar factors. At fixed real frozen values, the factorization (20.37) contains exactly one factor g_i for each scalar free coordinate and one triangular determinant. Subtracting the logarithms of the regional and the torus factorizations, we find for the coupling powers

$$\sum_i \Big[\sum_{x \in I_i} \log g_i - \sum_{x \in I_i \cup H_i} \log g_i \Big] = \sum_i |H_i| \log(1/g_i).$$

The determinant statement of Theorem 20.10 bounds the difference of the logarithmic determinants by C_J for each missing scalar label plus $C_J |\partial_{\mathrm{blk}} \Omega| \le C_J N_{\mathrm{bd}}$, by (20.4). The same argument applies to the Haar densities at zero fluctuation, by the comparison in part (3) of Theorem 20.2. Their constant normalizations depend only on M and J and contribute C_J for each omitted or interface coordinate. Since $p_i \ge 1$ we have $0 < z_1 \le z_{p_i} \le (2\pi)^{3/2}$, so the terms $\log z_{p_i}$ contribute a bounded amount for each missing block. The Haar measure of the block axial gauge trees and the adjoined reference measures contribute no dimension.

Step 2: the fluctuation integrals. At coarse background zero, Lemma 20.12 bounds the difference of the fluctuation logarithms without insertion, and of those with insertion whenever the factorization uses them, by $C_J \mathfrak{s}(N_{\mathrm{missing}} + N_{\mathrm{bd}})$. In that proof, each missing

fluctuation block is counted among the missing labels and each comparison at unfixed roots in the interface count; no geometric crossing argument is needed. Using $\mathfrak{s} \le \epsilon_J$, we find that this step contributes $C_J(N_{\mathrm{missing}} + N_{\mathrm{bd}})$.

Step 3: the pullback at zero fluctuation. The zero-fluctuation value of the pullback has not entered Step 2. For its centered torus and boundary parts we assign each monomial of degree $l \ge 1$ to its input roots with the shares η_e/l, whose sum is one. The input norms of Definition 4.6 give $C_J E$ or $C_J \sigma_*$ for each input root, after the common image at half the radius has summed the degree series. Missing roots are counted as missing labels. Differences rooted at unfixed labels carry the visit in (20.38) and are summed by (20.3). The incoming constant was moved into Λ exactly before this calculation.

Step 4: fixing coordinates. Finally we apply Lemma 18.9. To prove (20.44), note that when the unfixed variables are set to zero, only monomials supported in F survive. On such a monomial of degree l we have $\sum_{j\in F} \nu_j/l = 1$, and by hypothesis (b) its frozen value has modulus at most $4^{-l}|f_\nu|\phi^\nu$. Summing over $j \in F$ and using the definition of $\mathcal{X}_\Omega^\phi$ with the weights larger than one dropped, we find that the boundary part contributes at most $|F|\rho^2 Y/4$, since $l \ge 1$. The torus part has $l \ge 2$ and $|c_j^\sharp| \le \rho/4$, so the seminorm bounds its contribution by $|F|\rho^2 E/16$. This proves (20.44); the bound contributes C_J for each newly frozen analytic label, degree one included. The value is subtracted from Λ with the sign in the statement, and its absolute value gives the upper bound. The same identity applies at initialization. Data deep inside the fixed complement stay in the external factors, and the classical constants stay in the classical action. Adding the finitely many contributions proves (20.43). Every estimate used a coefficient bound for each label or the boundary sum (20.3), which does not depend on the shape of the region; none of them estimates the incoming constant or introduces a factor depending on the number of components or of steps. □

20.6 Preservation of the analytic bounds under iteration

The following theorem is the main result of this section.

Theorem 20.14. *Fix the torus analytic radii and rates, the torus support weights and spatial margins, and M, and fix $A_{\mathrm{w}} \ge 1$. Choose J once so that the conditions on J of the torus construction used in Lemma 19.7 hold and $B \ge B_{\mathrm{geom}}$, as in Theorem 20.9. There exist positive fixed radii ρ, ρ_{cl}, R_{raw}, R_W, and R_{en}, rates a, α as in Theorem 20.9, a perturbation bound σ_*, the classical and quantum radius profiles defined in Section 20.1, a width s_{er} of the frozen layer, a bound β_{rec} on the frozen values, a support radius r, and a coupling bound $g_* < e^{-1}$, with the following property. One may take $\rho = \rho_{\mathrm{cl}}$; other fixed ratios are allowed if both image conditions are imposed. The bound g_* may depend on A_{w}.*

Consider a full step on an admissible block region satisfying the protected-neighborhood conditions of Lemma 19.5, at any preceding depth and after any number of earlier steps, with a real admissible frozen value and an input satisfying

$$\mathcal{X}^{\mathrm{cl}}(\bar{P}) \le 2\sigma_*, \qquad \mathcal{B}_{\rho,a_{\mathbb{T}}}(r_{d_0}) \le E, \qquad \mathcal{X}^{\rho}(f) \le \sigma_*, \qquad \max_i g_i \le g_*.$$

Assume the uniform incoming classical norm on D_{in}, the boundary comparison (20.7)*, and the inequality on the conditional forces of Theorem 19.9 and Lemma 19.3. Set $p(t) = A_{\mathrm{w}} \log(1/t)$ and require at the t-th step, with $t_t = \max_i g_{t,i}$,*

$$p(t_t) \le p_{t,i} \le p(t_t) + \tfrac{1}{2} A_{\mathrm{w}} (J-1) \log M.$$

Assume the inclusion of the products, the positivity of the rational image denominators, the small-interaction condition, and the conditions on the auxiliary half-disc of Lemma 20.3 and Theorem 20.9, with the bound chosen for this whole family of radii. The small-field event uses $p_{t,i} = p(t_t)$. Under these hypotheses the perturbed objective has all of the following properties: the coefficient bounds of the potential with each index fixed in turn, the gap of the constrained Hessians at every stage, and the strict bounds on the image under the reconstruction majorant, on the outer profile times the whole enclosing product; the comparisons with boundary decay of Theorem 20.2; the potential of Lemma 20.3; the expansions without and with insertion of Theorem 20.9, with input support weight $e^{16|S|}$ and output support weight $e^{4|S|}$ as in Lemma 20.8, and with the same returned rates and radii; the bounds on the generated term, the pullback, and the determinants of Theorem 20.10; and the recursion for Λ of Theorem 20.13. These properties are conclusions of the earlier results.

More explicitly, let $x_t = \mathcal{X}(f_t)$ and $x_t^{\mathrm{cl}} = \mathcal{X}^{\mathrm{cl}}(P_t)$ be the incoming boundary norms of the quantum and the classical parts at step t, the boundary-completion adjustment of the classical part being understood. Before coordinates are fixed, the outgoing boundary norms y_t and y_t^{cl} satisfy

$$\begin{aligned} y_t &\le A_J(1+E) + K_J x_t + C_J t_t^2 (E + x_t)\big[p_t^4 + (E+x_t)p_t^2\big], \\ y_t^{\mathrm{cl}} &\le A_J^{\mathrm{cl}} + K_J^{\mathrm{cl}} x_t^{\mathrm{cl}}, \qquad t_t = \max_i g_{t,i}, \quad p_t = \max_i p_{t,i}. \end{aligned}$$

Under the hypotheses on the doubled output analytic radius and on the incoming image at half the radius, $K_J = 4(\log 2) K_{\mathrm{col},J}$, where $K_{\mathrm{col},J}$ is the column bound of Theorem 20.10 for the perturbed zero-fluctuation reconstruction, uniform on the preliminary perturbation ball. The recursion for Λ is Theorem 20.13.

Whenever coordinates are fixed, fix every label with reduced radius and keep the remaining unfixed labels at distance at least s_{er} from the previous boundary. For $\bullet \in \{\mathrm{cl}, \mathrm{q}\}$, with $(\rho_{\mathrm{q}}, E_{\mathrm{q}}) = (\rho, E)$ and $(\rho_{\mathrm{cl}}, E_{\mathrm{cl}})$ the classical radius and the classical torus bound, require

$$C_{\mathrm{bc},\bullet} E_\bullet \beta_{\mathrm{rec}} / \rho_\bullet \le \sigma_*/4, \qquad |c_j^\sharp| \le \min\{\beta_{\mathrm{rec}}, \phi_\bullet(j)/4\}.$$

Here $C_{\mathrm{bc},\bullet} \geq 8$ is fixed before β_{rec} and the later widths, and includes any finite sum over types of boundary-completion differences and over conversions between coordinates; a single simultaneous restriction of the union of all newly frozen labels to their fixed values uses $C_{\mathrm{bc},\bullet} = 8$ in the coordinates in which the labels were introduced. Every frozen label, whether in the boundary layer, in a protected neighborhood, or among the boundary-crossing coordinates, and including the labels frozen at initialization, is covered by this bound. Here $c^\sharp$ is the value in the analytic coordinates in which the label was introduced; any conversion from group values or transported coordinates is included in the bound by β_{rec} beforehand. Assume $x_0, x_0^{\mathrm{cl}} \leq \sigma_*$. Then, including the new boundary-completion differences of the torus parts,

$$x_{t+1} \leq z_t + 2e^{-\alpha(s_{\mathrm{er}}-1)} y_t, \qquad x_{t+1}^{\mathrm{cl}} \leq z_t^{\mathrm{cl}} + 2e^{-\alpha(s_{\mathrm{er}}-1)} y_t^{\mathrm{cl}},$$

where z_t and z_t^{cl} are the norms of the boundary-completion differences of the torus parts created when coordinates are fixed at the end of step t. The choices can be made with

$$x_0, x_0^{\mathrm{cl}} \leq \sigma_*, \qquad z_t, z_t^{\mathrm{cl}} \leq \sigma_*/4,$$

and with the last terms of both recursions at most $\sigma_*/2$, uniformly on the input ball. In particular

$$x_t, x_t^{\mathrm{cl}} \leq 3\sigma_*/4 \qquad (t \geq 1)$$

after any finite number of steps, with no further loss of radius or rate. For $|v_i| \leq \phi(i)$ the oscillation of the centered effective interaction satisfies

$$|R_t(v; b_{\mathrm{rec}}) - R_t(0; b_{\mathrm{rec}})| \leq \rho^2 \Big[E|\Omega_t| + \sigma_* \sum_{j \in \Omega_t} e^{-\alpha d_{\Omega_t}(j)} \Big],$$

where, for this count and this sum, Ω_t denotes the set of unfixed scalar labels, directions and colors included. At the output of a step that is not followed by fixing coordinates, σ_* in this formula is replaced by the fixed output bound for y_t.

All constants have the dependence described in item (3) of Definition 4.14 and exclude the later widths. The output bounds are computed first and s_{er} afterwards; J is not enlarged by means of these constants for fixed J. The theorem concerns admissible data; that the configurations of the large-field decomposition are covered by them is proved separately in Section 21. For a composition of $s < J$ averaging steps the estimates at each stage hold on their admissible products, but a conclusion about the two images or about the enclosing product also requires the separate image condition for that shorter composition; the preservation of the profile is asserted only for full steps. An empty set of unfixed labels has nonconstant norm zero, determinant one, logarithmic determinant zero, and fluctuation integral one.

Proof. The proof has three parts. Steps 1 to 3 prove the bounds on y_t and y_t^{cl} before coordinates are fixed. Steps 4 to 10 make the parameter choices in the order summarized in Table 20.1 and check that each choice uses only quantities fixed before it. Steps 11 and 12 prove the iteration and the bound on the oscillation.

Quantity	Chosen after
K_*, torus support weights, and margins	fixed data
J	K_* and the torus data
$\rho, \rho_{\mathrm{cl}}, R_{\mathrm{raw}}$	J
a, α	J and the exponents of the coefficients of the potential
σ_0, r_q	radii and rates
$A, C_0, C_1, C_{\mathrm{en},J}, \mathcal{L}_V$, and all output, tensor, and image constants	σ_0
R_W, then σ_*	these constants
$\rho_{\partial,\bullet}$, w_{bd}	these constants
Y, Y^{cl}, then s_{er}	σ_*
$C_{\mathrm{bc},\bullet}$, $C_{\mathrm{word},J}$, $C_{\mathrm{conv},J}$	the larger charts
β_{rec}, then r, then R_{en}	σ_* and the conversion constants
g_*	all of the above, and A_{w}

Table 20.1. The order of the parameter choices in the proof of Theorem 20.14. The requirements are stated in Steps 4 to 10.

Step 1: the hypotheses at each step. We fix $A_{\mathrm{w}} \geq 1$ before the coupling bound. The coefficient constants of the potential and the torus and geometric conditions used to choose J do not depend on A_{w}; only the final coupling bound may depend on it. At each step, the incoming classical norm is the uniform norm on D_{in}, the boundary comparison (20.7) holds by assumption, with all label positions and volume factors on the lattices where the labels were introduced, and the conditional forces satisfy (20.11) and (20.12). The strict bounds on the two images place all segments of evaluation inside the uniform incoming products. Thus, at the fixed frozen value $b = (\xi, b_{\mathrm{rec}})$, both the perturbation and its comparison with zero satisfy the hypotheses of Theorem 19.9.

Step 2: the classical comparison before coordinates are fixed. Let a_R and a_T be the two admissible zero-fluctuation chains before the gauge transformation, the regional one with its missing slots set to zero. The comparison of values, before the common factor M^J, is

$$F_R(v, a_R) - F_T(v, a_T) = F_R(v, a_R) - F_T(v, a_R) + \int_0^1 D_z F_T\big(v, a_T + \tau(a_R - a_T)\big)\big[a_R - a_T\big]\, d\tau.$$

The fixed larger charts contain this segment, since the smaller solution neighborhoods have strict room in them. The first difference has the representation (20.15) through changed formulas. On unfixed free slots, the difference of the chains in the integral is the comparison of minimizers in Theorem 20.2, here with perturbation zero; on missing

free slots it is a bounded source in Ω^c. Every nonconstant coefficient with an unfixed output index therefore has a network to Ω^c, by the action tensors rooted at every index and Lemma 18.15. This includes derivatives falling on the action tensor while the source stays undifferentiated. We sum over the indices in Ω^c from the unfixed index using (20.1). Pure constants supported in Ω^c stay in the classical value. The conversion of coefficients and profiles in the proof of Theorem 20.9, without its expansions, now yields a finite bound A_J^{cl} for the centered comparison. The factor M^J depends only on J and is included in this constant. No interpolation between different fibers is used in this calculation of values.

Step 3: the perturbation and the quantum comparison. Next we interpolate in the adjusted input perturbation. By the envelope formula, the derivative of the minimum value is the evaluation of the perturbation at the minimizer. The strict bound on the image under the reconstruction majorant bounds its input jets, and joining its input boundary network to the reconstruction networks proves the output bound $K_J^{\mathrm{cl}} x^{\mathrm{cl}}$. Equivalently, this is the conclusion of Theorem 19.9 on the minimum values for two perturbations, with its exact boundary-completion adjustment. The fixed small boundary-completion difference is included with the unperturbed term in A_J^{cl}. This proves $y^{\mathrm{cl}} \le A_J^{\mathrm{cl}} + K_J^{\mathrm{cl}} x^{\mathrm{cl}}$. The coefficient networks in this argument are the classical ones, with the common rates chosen in Theorem 20.9.

We subtract the matched torus recursion from the recursion of Theorem 20.10. The difference is the sum of the comparison of the generated terms and torus pullbacks, the term $\mathsf{P}^{\Omega} f$, and the compared fluctuation correction. The first two are bounded in Theorem 20.10 by $A_J(1+E)$ and $K_J x$, and the third by Theorem 20.9. By the triangle inequality, we obtain the stated bound on y.

Step 4: radii, rates, and the perturbation bound. We fix K_* before J and choose J for the torus conditions and the geometric condition. We choose the base radii inside the fixed larger construction domains; one may choose $\rho = \rho_{\mathrm{cl}}$, and different fixed ratios simply keep both image conditions. We choose the common rates below the intrinsic coefficient and unperturbed image exponents at fixed J, and impose the separate output-rate conditions against Ba and $B\alpha$ for the inherited perturbation. Its controlled coefficient difference preserves the half-radius image at these working rates after the final perturbation bound is decreased. We decrease R_{raw} and the base radii if necessary, for the fixed margin of the larger construction domain and for $C_{T,\bullet} K_* \rho_\bullet \le 1/4$. The torus conditions are used with their stronger torus rate, not through an estimate involving an uncontrolled regional constant.

We choose a preliminary bound σ_0 below the admissible inverse, conditional force, and real gap margins, and a free radius r_q with

$$C_{\mathrm{seq},J}(2I_0 C_P \sigma_0 \rho_{\mathrm{cl}} + r_q) < \varepsilon_{\mathrm{tube}}/2.$$

The constants are those of the larger construction neighborhoods in (20.11), whose uniformity in all higher parameters was checked there. We compute all output, tensor, image, sequential, and enclosure constants uniformly for this bound on the fixed larger products. In particular we fix A, C_0, C_1, $C_{\mathrm{en},J}$, and $\mathcal{L}_V$, and the difference-row constants $C_{P,\bullet}$ at the allocated working rates, and choose R_W from the positive minimum in Lemma 20.3. Then we fix $\sigma_* \le \sigma_0$ so that, for both radii,

$$\sigma_* \rho_{\mathrm{cl}} \le \lambda_* R_W / (6 C_{\mathrm{en},J}), \qquad C_{P,\bullet} \sigma_* \rho_{\mathrm{cl}} \le \rho_\bullet / 64.$$

This order is necessary because this summand of the enclosure remains when r and β_{rec} are decreased.

Step 5: the boundary radii. We choose the two reduced boundary radii so that the bounds on the image at zero fluctuation near the boundary in Lemma 19.7 are at most $\rho_\bullet/16$. Then we choose a fixed width w_{bd} of the boundary layer so that the bounds on the tails far from the boundary are at most $\rho_\bullet/16$. The remaining bounds at zero fluctuation are the torus bulk bound and the bound for the frozen values. The first is a torus condition, and the second will be imposed on β_{rec}. All constants in these choices were computed independently of these widths and reduced radii.

Step 6: output bounds and the width of the frozen layer. We set

$$c_J^{\log} = \tfrac{1}{2} A_{\mathrm{w}} (J-1) \log M, \qquad p^+(t) = A_{\mathrm{w}} \log(1/t) + c_J^{\log}, \qquad H_* = E + \sigma_*. \tag{20.45}$$

By the hypothesis on the radii, we have $1 < p(t) \le p_{t,i} \le p^+(t)$ when $t < e^{-1}$. On the input ball we impose provisionally the requirement

$$C_J t^2 H_* \big[(p^+(t))^4 + H_* (p^+(t))^2 \big] \le 1,$$

which holds for small couplings. We then take the fixed output bounds

$$Y = A_J (1 + E) + K_J \sigma_* + 1, \qquad Y^{\mathrm{cl}} = A_J^{\mathrm{cl}} + K_J^{\mathrm{cl}} \sigma_*.$$

We choose the integer width of the frozen layer with

$$s_{\mathrm{er}} \ge \max\Big\{ 2,\ w_{\mathrm{bd}},\ 1 + \alpha^{-1} \log\big(4 \max\{Y, Y^{\mathrm{cl}}, 1\} / \sigma_* \big) \Big\}.$$

The bound may be enlarged to account for the fixed buffer between label positions in Lemma 18.9. Each output restricted to the interior of the frozen layer is then at most $\sigma_*/2$, since $2 e^{-\alpha(s_{\mathrm{er}}-1)} \max\{Y, Y^{\mathrm{cl}}\} \le \sigma_*/2$.

Step 7: the frozen values and the new boundary-completion differences. Whenever coordinates are fixed, let F be the union of all newly frozen analytic labels: the whole zone with reduced radius, the protected neighborhoods, and the boundary-crossing coordinates. The same convention covers the restriction at initialization. In the coordinates in which the labels were introduced, a single application of Lemma 18.9 to this union bounds the torus boundary-completion difference by $8E_\bullet\beta_{\mathrm{rec}}/\rho_\bullet$. The rate hypothesis of part (2) of that lemma holds with the torus rate $a_{\mathbb{T}}$ and the regional rates a, α, since $\sqrt{3}\,(a+\alpha) < a_{\mathbb{T}}$ by Theorem 20.9. No separate factor arises for each component of Ω^c. If a fixed finite list of types of boundary-completion differences is kept separately, with conversion factors $L_{k,\bullet}$, the triangle inequality yields instead the bound with $C_{\mathrm{bc},\bullet} = 8\sum_k L_{k,\bullet}$. We include the classical boundary-completion adjustment among these types whenever it is recorded separately. These constants are fixed on the larger charts, before β_{rec} and all later widths.

The bound concerns the analytic values $c_j^\sharp$ in the coordinates in which the labels were introduced. For a frozen group element in the identity chart, $|\operatorname{Log} U| = \rho_G(U)$ in the Euclidean norm of the Lie algebra, so this conversion has constant one. A longer fixed chart formula, in the coordinates before the gauge transformation or in transported coordinates, has a finite bound $C_{\mathrm{word},J}$ on its derivative rows on the larger construction domain. Integrating along the input segment, we bound its logarithm in the identity chart by $C_{\mathrm{word},J}$ times the maximal input norm. These conversion constants are fixed before the bounds on the frozen values are chosen. If a separate estimate for the initial frozen values is provided with a constant $C_{\mathrm{ad},J}$, we choose $C_{\mathrm{conv},J} \geq \max\{1, C_{\mathrm{ad},J}, C_{\mathrm{word},J}\}$ before using a condition relating the support radius to the frozen values. The theorem assumes the bound on every $c_j^\sharp$. It does not deduce this bound from a small support radius in an arbitrary gauge representative, and it transports a norm bound between gauge frames for the frozen coordinates only when the change of frame is the norm-preserving adjoint action of a block.

We choose $\beta_{\mathrm{rec}} > 0$ below the bound for the frozen values in the image, below the enclosure bound $\lambda_* R_W/(6C_{\mathrm{en},J})$, and, for both $\bullet \in \{\mathrm{cl}, \mathrm{q}\}$, below

$$\min\Big\{\rho_{\partial,\bullet}/4,\ \rho_\bullet/4,\ \frac{\sigma_*\rho_\bullet}{4C_{\mathrm{bc},\bullet}(E_\bullet+1)}\Big\}. \tag{20.46}$$

These are upper bounds on a quantity chosen after their constants, and they remain positive when a bound $E_\bullet$ is zero. They imply the two inequalities $C_{\mathrm{bc},\bullet}E_\bullet\beta_{\mathrm{rec}}/\rho_\bullet \leq \sigma_*/4$ in the statement. The hypothesis $|c_j^\sharp| \leq \min\{\beta_{\mathrm{rec}}, \phi_\bullet(j)/4\}$ is imposed on all of F, not only on the old boundary zone.

Step 8: initialization. The assumption $x_0, x_0^{\mathrm{cl}} \leq \sigma_*$ of the iteration can be met: starting from the torus reference, both boundary parts are zero before initialization, and the same restriction of the union to fixed values, together with (20.46), gives initial boundary parts

of norm at most $\sigma_*/4$. For other prescribed inputs the bounds on the initial norms are kept as hypotheses. The coverage of the configurations and the estimate for the initial frozen values are separate inputs of the later applications.

Step 9: the support radius. We choose $r > 0$ inside all margins of the small-link domain and of the larger construction domain, below $\lambda_* R_W/(6C_{\mathrm{en},J})$, and, when an estimate for the frozen values in terms of the support radius is provided, with $C_{\mathrm{conv},J} r \le \beta_{\mathrm{rec}}$, imposed after the conversion constant has been fixed. Then $R_{\mathrm{en}} = 2C_{\mathrm{en},J}(r + \beta_{\mathrm{rec}} + \sigma_* \rho_{\mathrm{cl}})/\lambda_*$ is positive and at most R_W. Both image denominators and the curvature bound on the whole product now hold by Lemma 20.3.

Step 10: the coupling bound. Finally, we choose $g_* < e^{-1}$ so that the following inequalities hold for every $0 < t \le g_*$, with the largest constant C_J of Lemma 20.7 and the fixed $\epsilon_J, c_{z,J}$ of Theorem 20.9:

$$\begin{gathered} tp^+(t) < R_{\mathrm{en}}, \qquad C_J t p^+(t) \le \tfrac{1}{2}, \\ 2C_J t D^+(t) \le \epsilon_J, \qquad tD^+(t) \le c_{z,J}/2, \qquad D^+(t) = (p^+(t))^3 + (1 + H_*)p^+(t), \\ C_0 t^2 \mathcal{L}_V \le 1/16, \qquad C_1 t(\mathcal{L}_V + 2) < 1/(4\sqrt{3}), \\ C_J t^2 H_* \big[(p^+(t))^4 + H_*(p^+(t))^2\big] \le 1. \end{gathered} \tag{20.47}$$

The image denominators are at least $1/2$ on the whole enclosing product by the earlier image bounds, which do not involve the coupling. For any radii in the stated logarithmic range we have $p_t \le p^+(t)$ and $E + x_t \le H_*$. The first line implies the inclusion of the products. The next line implies $\mathfrak{s}(t) \le \epsilon_J$ and $t \le c_{z,J}/(2[p_t^3 + p_t + (E + x_t)p_t]) = r_z/2$. The third line implies (20.25); since $p(t) > 1$, it also implies the condition $C_1 t(\mathcal{L}_V + 2) \le p(t)/(2\sqrt{3})$ on the means in Lemma 20.5. The last line is the provisional requirement of Step 6. The choice is simultaneous, because every left side that has to be small is a fixed combination of $t \log^q(1/t)$ and $t^2 \log^q(1/t)$ for finitely many integers q. Writing $t = e^{-u}$, we have $e^{-u} u^q \to 0$; for example the power series of $e^{u/2}$ bounds $u^q e^{-u}$ by a constant times $e^{-u/2}$. These upper bounds hold for all sufficiently small positive t, so a single bound works for all scales of every full step in the prescribed family of radii. The common cutoff has $p_{t,i} = p(t)$, and the cutoffs at the individual scales, $p(g_i) = p(t) + A_{\mathrm{w}} \log(1/\lambda_i)$, lie in the same range. The expansions are used on these chosen products, not on the enclosing product $\mathcal{K}_{\mathrm{en}}$. This final choice does not change the output bounds or the width s_{er}, which were computed before.

Step 11: the iteration. By Lemma 18.9 with $\eta = 1/4$, fixing the coordinates of the union F bounds the old boundary part by $2e^{-\alpha(s_{\mathrm{er}}-1)} y_t$, since $|c_j^\sharp| \le \phi_\bullet(j)/4$ and all labels with reduced radius are frozen. Independently, the boundary-completion differences of the torus parts satisfy, by the hypothesis on the frozen values,

$$z_t^\bullet \le C_{\mathrm{bc},\bullet} E_\bullet \beta_{\mathrm{rec}}/\rho_\bullet \le \sigma_*/4, \tag{20.48}$$

where $z_t^{\mathrm{q}} = z_t$. Fixing coordinates at an additional interior component of Ω^c satisfies the same estimate, because its values are also bounded by β_{rec}. Combining the two bounds, we obtain

$$x_{t+1} \le z_t + 2e^{-\alpha(s_{\mathrm{er}}-1)} y_t, \qquad x_{t+1}^{\mathrm{cl}} \le z_t^{\mathrm{cl}} + 2e^{-\alpha(s_{\mathrm{er}}-1)} y_t^{\mathrm{cl}}.$$

These estimates hold for arbitrary additional components of Ω^c, by Lemma 18.9. If both input norms are at most σ_*, then $y_t \le Y$ and $y_t^{\mathrm{cl}} \le Y^{\mathrm{cl}}$, and by Step 6 the right sides are at most $3\sigma_*/4$. Starting from the initial bounds, finite induction proves the bounds on x_t, x_t^{cl} after every number of steps. The older frozen values are simply fixed in the next application. The remaining labels keep their input radii because the whole zone with reduced radius was frozen: the conclusion of Lemma 18.9 is the norm with the uniform radius on the remaining labels. This verifies the hypothesis of a uniform incoming profile at the next step. The classical boundary-completion adjustment satisfies

$$\mathcal{X}^{\mathrm{cl}}(\bar{P}) \le \mathcal{X}^{\mathrm{cl}}(P) + \mathcal{X}^{\mathrm{cl}}(S_{\bar{\xi}}^{\mathrm{cl}}) \le \sigma_* + \sigma_*/4 < 2\sigma_*,$$

by the included bound on the boundary-completion differences. The inclusion of the old fixed complement and the positions of the labels in the next geometry are hypotheses of that step, not conclusions of this norm inequality. The inequality on the conditional forces then holds at every coarser parameter of the next step, by (20.11). Every operation preserves the Borel dependence on the frozen values, as proved in Theorem 20.2. No analytic loss is summed over earlier steps.

Step 12: the oscillation. We write the centered effective interaction as its torus part plus its boundary part. At each degree we assign each monomial to its roots with the shares $\nu_i/|\nu|$, whose sum is one. Evaluating at $|v_i| \le \phi(i)$ and dropping the network weight, we obtain for the boundary part

$$|f_t(v) - f_t(0)| \le \rho^2 \mathcal{X}(f_t) \sum_{i \in \Omega_t} e^{-\alpha d_{\Omega_t}(i)}.$$

The degree-one term is included in this assignment. For the torus part the same assignment and its seminorm give $\rho^2 E|\Omega_t|$. These are the stated bounds on the oscillation; before coordinates are fixed we use Y instead of σ_*.

The preceding results, with the choices just made, imply every assertion of the theorem. All local constants were evaluated before the later widths, and none of them was used to choose J. A composition of fewer than J averaging steps keeps its estimates at each stage on its admissible products, but its conclusions about the full radius require the separate image condition. The iteration for Λ and for the norms uses only full steps. A final composition of fewer than J averaging steps may remain as a deterministic function; no recursion for Λ is asserted for it here. The assertions for an empty set of unfixed labels are the usual conventions for empty sums, products, and determinants. This completes the proof. □

20.7 Summation of truncation errors

Lemma 20.15. *Fix $0 < \Gamma < \infty$, $M > 1$, a finite set $\mathcal{R}$ of ratios $R > 1$, a finite set of positive numbers η, and finitely many positive constants a, c, C, and ε.*

1. *For every finite list of nonnegative integers k, there is a minimum side m_0, independent of $0 < \gamma \le \Gamma$, such that*

$$C[1 + \log(m/\gamma)]^k \le \varepsilon m/\gamma \qquad (m \ge m_0).$$

2. *With $z = (1/2)\log(Mm/\gamma)$, the functions*

$$X_c(m,\gamma) = m^3 e^{-cm/\gamma}, \qquad W_a(m,\gamma) = m^3 e^{-az^2}$$

are decreasing in m and increasing in γ for $m \ge m_0$ and $0 < \gamma \le \Gamma$, after increasing m_0, and they satisfy $X_c(Rm,\gamma) \le X_c(m,\gamma)/2$ and $W_a(Rm,\gamma) \le W_a(m,\gamma)/2$ for $R \in \mathcal{R}$. Their sums over the sides mR^k, $k \ge 0$, are at most twice their first terms, and tend to zero as $m \to \infty$, uniformly on $(0,\Gamma]$.

3. *Let $m_k = mR^k$, $k \ge 0$, for some $R \in \mathcal{R}$, together with at most one additional side $\eta m R^j$, and let nonnegative errors δ and z_{ext} at these sides satisfy $\delta \le CW_a$ and $z_{\mathrm{ext}} \le CX_c$. After increasing m_0, depending only on Γ, M, $\mathcal{R}$, the set of η, and the constants, the following holds uniformly for $m \ge m_0$, $0 < \gamma \le \Gamma$, and the number of sides, finite or infinite. Every δ is at most $1/2$, every z_{ext} is at most $1/4$, and $\epsilon = \delta/(1 - z_{\mathrm{ext}})$ satisfies $\epsilon \le (4/3)\delta \le 1/2$. The sums of the δ, of the z_{ext}, and of the ϵ are finite, and*

$$\log \prod (1-\delta)^{-1} \le 2\sum \delta, \qquad \log \prod (1-\epsilon)^{-1} \le 2 \sum \epsilon,$$

also for every finite subproduct. These sums are bounded by any prescribed positive number after increasing m_0, and they tend to zero as $m \to \infty$, uniformly on $(0,\Gamma]$.

In particular, part (3) of Lemma 20.5 holds. All constants in this lemma have the dependence described in item (4) of Definition 4.14; the local constants of Lemma 20.5 keep their own dependence.

Proof. Let $x = m/\gamma \ge m_0/\Gamma$. For every fixed k we have $(1+\log x)^k/x \to 0$ as $x \to \infty$: with $y = \log x$, the exponential series bounds $y^k e^{-y/2}$ on a half-line $y \ge y_0$. This proves part (1), for finitely many k simultaneously, and allows us to assume $x \ge e$ throughout.

For part (2), let $\Delta_R = (1/2)\log R > 0$. Since $z(Rm) = z(m) + \Delta_R$, the ratios are

$$\frac{W_a(Rm,\gamma)}{W_a(m,\gamma)} = R^3 e^{-a(2\Delta_R z + \Delta_R^2)}, \tag{20.49}$$

$$\frac{X_c(Rm,\gamma)}{X_c(m,\gamma)} = R^3 e^{-c(R-1)m/\gamma}. \tag{20.50}$$

Their maxima over $m \geq m_0$ and $0 < \gamma \leq \Gamma$ occur at the smallest m and the largest γ, and they tend to zero as m_0 increases, since $z \geq (1/2)\log(Mm_0/\Gamma) \to \infty$ and $m/\gamma \geq m_0/\Gamma \to \infty$. We choose m_0 so that both ratios are at most $1/2$ for every $R \in \mathcal{R}$. The logarithmic derivatives in $\log m$ are $3 - cm/\gamma$ for X_c and $3 - az$ for W_a, and those in $\log \gamma$ are cm/γ and az. Hence X_c and W_a are increasing in γ, and they are decreasing in m once $cm_0/\Gamma > 3$ and $(a/2)\log(Mm_0/\Gamma) > 3$. The logarithms of the first terms at $\gamma = \Gamma$ are $3\log m - cm/\Gamma$ and $3\log m - a\log^2(Mm/\Gamma)/4$, and both tend to $-\infty$. By monotonicity in γ, the first terms tend to zero uniformly on $(0, \Gamma]$. Summing the series with ratio at most $1/2$ shows that the sums over mR^k are at most twice their first terms, which proves part (2).

For part (3), the additional side $\eta m R^j$ is handled in the same way. Let $m_{\mathrm{low}} = \min\{1, \min \eta\} m$. For sufficiently large m, monotonicity in m bounds the term at the additional side by the corresponding function at m_{low}, whether or not $\eta < 1$. Since m_{low} is a fixed positive multiple of m, the sums over all sides are at most three times the first terms evaluated at m_{low}, and these tend to zero uniformly on $(0, \Gamma]$ as $m \to \infty$, for finitely or infinitely many sides. We take the maximum of the finitely many minimum sides so obtained. Increasing m_0 once more, we make every δ at most $1/2$, every z_{ext} at most $1/4$, and the sums smaller than any prescribed positive number. Then $\epsilon = \delta/(1 - z_{\mathrm{ext}}) \leq (4/3)\delta$, so the sum and the maximum of the ϵ can be made as small as desired as well, in particular every ϵ at most $1/2$. For $0 \leq u \leq 1/2$,

$$-\log(1-u) = \int_0^u (1-v)^{-1}\, dv \leq 2u.$$

Summing this inequality bounds the logarithms of all reciprocal products, including every finite subproduct; the infinite products are defined by the increasing finite sums of logarithms. This proves part (3).

Part (3) of Lemma 20.5 is the case $R = B$, with $C = C_J$, $a = a_{\mathrm{w}}$, $c = b$, and the finite set of additional ratios, since $\log^2 \sqrt{Mm/\gamma} = z^2$; its bound $\epsilon_t \leq 2\delta_t$ follows from $\epsilon_t \leq (4/3)\delta_t$. The local concentration statements of Lemma 20.5 use only its hypotheses on the products and on the coupling at the given step; the restriction to a coupling bound enters only in the summation just proved, so those local statements and their prefactors are unchanged. □

SECTION 21

Large-field decompositions and conditional densities

This section connects the renormalization group on unions of blocks, constructed in Sections 18 to 20, with the two measures to which it is applied in Sections 22 and 23: the Wilson measure and the stopped measure. All statements concern a fixed lattice and are finite-dimensional.

The analytic theorems of Section 20 integrate the normalized fluctuation variables of one RG step over a fixed product of balls. They work in local coordinates near the identity, on a block region from which a fixed complement has been removed, with the link variables of that complement held fixed as frozen coordinates. To apply them to the Wilson measure, we must solve three problems. The first is coverage. A fiber of the block averaging map consists of all fine configurations with a given average. It is a Borel subset of the compact configuration space, can contain many gauge-equivalent representatives, and need not lie in a coordinate chart. We show that every point of every fiber carrying mass becomes, after a gauge transformation that fixes all prescribed vertices, a point of the domain of the local inverse coordinates, and that its normalized fluctuation coordinates lie in an enclosing product domain on which the conditional fluctuation potential is uniformly convex. The second problem is the choice of a density. The later estimates evaluate densities at particular gauge representatives. These form sets of Haar measure zero, so a Radon–Nikodym derivative defined only almost everywhere does not suffice. We construct an explicit Borel density from the Haar disintegration formulas and prove that it is invariant at every point under the relevant gauge transformations. The third problem is the preservation of frozen coordinates. When the integration stops near a region of large curvature, the link variables there are kept on the lattice where they were frozen. The gauge transformations used afterward must not change them, and the analytic estimates require their logarithms to be small.

Section 21.1 proves locality of the iterated block averaging map (Lemma 21.1) and a gauge-fixing theorem on arbitrary unions of large closed cells (Theorem 21.3). The last part of that theorem is a rule that protects the endpoints of all frozen coordinates. Section 21.2 defines a deterministic sequence of curvature tests, partitions the configuration space according to their outcomes into large-field decompositions (Theorem 21.5), and verifies the hypotheses of the analytic theorems of Sections 19 and 20 on each decomposition (Lemma 21.7). Section 21.3 proves the coverage of every supported fiber point and constructs, at all stages, the representatives satisfying the reconstruction identities

(Theorem 21.8): they are obtained from the coarsest scale downward by the reconstruction maps, so that each reproduces the output field above it and contains the frozen values. At the first RG step under the Wilson measure, this section uses the lower bound for the constrained Hessian of Lemma 18.14, which is uniform in the region and in the frozen variables. Section 21.4 constructs the invariant densities (Theorem 21.9), and Section 21.5 proves the identity relating the densities before and after freezing (Lemma 21.10). Section 21.6 first compares an integral over a fiber with an integral over the fluctuation cutoff domain (Lemma 21.11), and then combines these results in the induction of Theorem 21.12.

The inputs are the quantitative extension of maps into $\mathrm{SU}(2)$ in Lemma 7.5; the stopped measure and its coordinates on the torus (Theorems 14.3 and 14.6); the Haar disintegration on block regions (Lemma 18.7); the gauge transformation fixed at prescribed endpoints and the perturbation theorem of Lemma 19.5 and Theorem 19.9; and the analytic integration, the comparison of normalization constants, and the concentration estimate of Theorems 20.13 and 20.14 and Lemma 20.5. Theorems 21.5, 21.9, and 21.12 are used in Section 22 for the bounds on Wilson densities and the exponential moment bounds, and Theorems 21.3, 21.5, and 21.8 are used in the choice of parameters in Section 23.

The organization by nested regions, fields frozen on their complements, and effective densities on the remaining regions follows Bałaban's large-field renormalization [18, 20, 21]. Dimock's account of Bałaban's method for the scalar ϕ_3^4 model describes the partition into small-field and large-field regions, the unintegrated complement, and localized block averaging [67, §§1–2]; the summation of the resulting expansion is in [69]. These works concern a different model and different coordinates. The deterministic tests for the block averaging map T_M, the gauge construction on arbitrary unions of cells, the protection of frozen endpoints, the coverage of every fiber point, and the invariant density versions below are proved here.
