Conventions. Throughout, $M \geq 3$ is odd, $J \geq 1$, and $B = M^J$. One application of T_M (Definition 4.3), including its Borel extension, is an averaging step, and an RG step consists of J consecutive averaging steps. A group of $1 \leq s \leq J$ consecutive averaging steps with output side m has intermediate scales $0 \leq i < s$ and couplings

$$g_i = t_{\max} M^{(i-s+1)/2}, \qquad t_{\max} = \sqrt{\gamma/(Mm)}, \qquad \lambda_* = M^{-(J-1)/2} \leq g_i/t_{\max} \leq 1.$$

The angle of $U \in \mathrm{SU}(2)$ is $\rho_G(U)$, its distance from I in the bi-invariant metric of Section 4; we have $\rho_G(U_1 \cdots U_l) \leq \sum_j \rho_G(U_j)$ and $|\operatorname{Log} U| = \rho_G(U)$ when $\rho_G(U) < \pi$. We write c for the output field. In analytic functions and in the coordinates of Definition 18.6, the coarse argument is its identity-chart logarithm $\operatorname{Log} c$, which we also denote by c when no confusion can arise; since $|\operatorname{Log} c_e| = \rho_G(c_e)$ for every output link e, bounds on the two agree. A block region Ω is a union of blocks of the output lattice of the current group

of averaging steps; its complement is the fixed complement. The frozen coordinates are written b_{rec}. They consist of frozen links and of based transports of frozen links across the boundary of the block region (defined in Section 21.2), each kept on the lattice on which it was frozen. A link is across the boundary of the block region if exactly one of its endpoints lies in it.

Fix the cutoff amplitude $A_{\mathrm{w}} \geq 1$ at the outset. Every application of Theorem 20.14 below uses the coupling ceiling g_* chosen after this amplitude, and g_* may depend on A_{w}. The analytic constants and the conditions used to choose J do not depend on A_{w}.

Unless stated otherwise, constants written C_J, c_J, u_J, ϵ_J, and similar depend only on M, J, the fixed larger construction and analytic domains and their radius ratios, the spatial and boundary decay rates and their margins, the bounded density of labels, and the fixed ceilings on actions and perturbations. They are independent of L, γ, all lattice sides, the total and the preceding depth, the number of RG steps since a coordinate was frozen, the shape, topology, and number of components of the regions, and the values of the frozen coordinates. This is the dependence described in item (3) of Definition 4.14. Where stated, these constants are also independent of the widths of boundary bands, removed bands, protected neighborhoods, and cells chosen later; such widths enter only through explicit geometric counts. No uniformity as $J \to \infty$ is asserted. The constant C_δ in Theorem 21.12 has instead the dependence described in item (4) of Definition 4.14.

21.1 Local path products and closed cell complexes

The full dependence set of a link of an averaged configuration is the set of links read by the block averaging map, including its Borel extension at exceptional values, by its reference path, and by every path product used to check that the logarithms involved lie in the correct branch. For an iterate we replace every link recursively by its full dependence set, and for a plaquette we take the union of the sets of its four links. These lists are treated as sets when we define excluded label sets; repetitions are kept only to estimate the lengths of path products. Geometric neighborhoods use the periodic maximum coordinate distance. Replacing it by the lattice distance used in the analytic norms changes only dimensional comparison constants.

Lemma 21.1. *Fix M and J. There exist finite constants D_J, L_J, v_J, depending only on M and J, and constants $u_J > 0$ and $C_J < \infty$, with the following properties for every group of $s \leq J$ averaging steps.*

1. *The full dependence set of a link, of a plaquette, or of a prescribed based transport of an averaged configuration is contained in the neighborhood of radius D_J of its output label, in output lattice units, and contains at most v_J input labels per output unit cube. The expanded hierarchical tree paths have length at most L_J.*

2. *Suppose that every input link of such a full dependence set has angle at most $u \le u_J$. Then the links of the i-th iterate have angle at most $(10M)^i u$ for $i \le s$, and the relative logarithmic coordinates of the block averaging constraint, including the eliminated coordinates, have size at most $C_J u$. After one fixed reduction of u_J, they belong to the domain of the local inverse of the block averaging constraint, with a fixed positive margin.*

These conclusions do not depend on the region or on its components.

Proof. An ordered path from the center of an M-block to a vertex of the block has length at most $3(M-1)/2$. The path $F_{c,x}$ of Definition 4.3 has length at most $4M-3$, and $F_{c,x}C_c^{-1}$ has length at most $5M-3$. If $(5M-3)u < 2\pi$, every relative transport $U(F_{c,x})U(C_c)^{-1}$ is in the identity chart, and the exponential of the average of their logarithms has angle at most $(5M-3)u$. Multiplying by $U(C_c)$, we obtain the bound $(6M-3)u \le 10Mu$. Iteration is permitted when $(10M)^J u$ is smaller than the fixed positive margin of one averaging step. The Borel extension reads the same finite list of links, so the locality of the list does not require this smallness.

The based tree gauge on a block is obtained by multiplying transports along its ordered tree paths. It sets each tree link to I, equals I at the root, and is unique with these properties, since the equation on an oriented tree edge determines the gauge at the child from the gauge at the parent. At the next intermediate scale we make the same construction and lift the new gauge as a constant on each of the previous blocks. Such a lift conjugates each previously fixed tree link and hence preserves the value I. The conditions at coarser scales are fixed before the finer variables are expressed. The resulting hierarchical transports are products of these tree factors at the various scales; no eliminated constraint edge is inserted into a tree. Each factor equals I on the hierarchical tree gauge section. There are at most J scales, each with finitely many paths in a fixed block, and by substitution we obtain a finite maximal path length L_J and a finite maximal radius D_J of the dependence neighborhoods. Equivalently, we may take these constants to be the maxima over the finitely many oriented dependence neighborhoods for $1 \le s \le J$ on the infinite cubic lattice: restriction to a region only deletes path products, and passage to a periodic quotient only identifies labels. The maximal number of input labels in the same dependence neighborhoods gives v_J.

After the tree gauge transformation, every link outside the trees is a product of a number, bounded in terms of M and J, of the small links just bounded, and the coarse-field lift of the target is another such product. The relative vector is therefore bounded by $C_J u$. The constraints have the eliminated-edge inverse and the uniqueness neighborhood, with its positive margin, used in Lemma 18.7 and Theorem 20.14. We choose u_J so that the preceding bound is less than half the radius of that neighborhood, taking the minimum over $s \le J$. Then the relative solution, including its eliminated entries, is the unique solution given by that inverse. This identifies the branch of a given solution; it

does not solve the constraints anew. Every path used above stays in a block of at most J scales, and none follows a tree spanning a whole component. □

The next corollary gives the initial bounds for a stopped measure; it is used in the proofs of Theorems 21.5 and 21.8.

Corollary 21.2. *Before the bound β_{rec} for frozen coordinates and the support radius r are fixed, one can fix $C_{\mathrm{ad},J} < \infty$, depending only on M, J, and the fixed tree conventions, with the following property. Let $U \in D_r$ be an initial configuration of a stopped measure on a lattice of side $M^s m$, with $s \le J$, $m \ge 4$, and no previously frozen coordinates, and assume that r is below the fixed margin of the finite path-product charts. Then, for every union of blocks, there exists a gauge representative in which the output field and all frozen links and based transports at the input level are bounded by $C_{\mathrm{ad},J} r$. This is a geometric existence statement, uniform in the preceding depth, the side, and the region.*

Proof. A gauge transformation taking U into B_r gives the bound r, not $r/2$, at the input. By Lemma 21.1, all intermediate internal links have angle at most $(10M)^J r$. The expanded hierarchical tree paths have at most L_J factors of these links. A link after the tree gauge transformation is a product of a path, a link, and an inverse path, and has angle at most $(2L_J + 1)(10M)^J r$. A based transport is a path times its link across the boundary of the block region and has the smaller bound $(L_J + 1)(10M)^J r$. Links lying entirely in the fixed complement remain below r, since the regional tree gauge is the identity there. The output roots are fixed by the tree gauge, and the output bound is $(10M)^J r$. We conclude that $C_{\mathrm{ad},J} = 2(2L_J + 3)(10M)^J$ exceeds twice each of these bounds. We fix it now, and only afterward require $C_{\mathrm{ad},J} r$ to be below the fixed identity and inverse chart radii. □

We now turn to gauge fixing on large closed cells. Small curvature does not force small links: a flat configuration with nontrivial holonomy around a noncontractible cycle cannot be gauge transformed to the identity. The following theorem shows that on a union of closed cells of side about R, plaquette angles of order R^{-2} allow a gauge in which all links have angle of order R^{-1}. The term R^{-1} comes from distributing compact gauge values over the edges of the cell grid, which have length at least $R/2$; the curvature contributes $O(\delta R)$ through an axial gauge in each cell. Transitions between the frames of neighboring cells are compared only on common edges and are never multiplied along chains of cells, so the constants do not depend on the topology of the union. We combine standard axial frames and the extension of maps into $\mathrm{SU}(2) \simeq S^3$ with the quantitative patching estimate of Lemma 7.5, preserving all prescribed vertices. The gauge fixing of lattice configurations with small plaquettes goes back to Bałaban [14]; the version below, on arbitrary unions of cells and with prescribed vertex values, is proved here.

Theorem 21.3. *There exist universal constants $C, C', R_0 < \infty$ and $c > 0$ with the following properties. Work in lattice units, let $R \ge R_0$ be an integer and $n \ge 8R$, and partition each*

coordinate circle of the periodic lattice of side n into intervals of lengths in $[R/2, 2R]$. Let P be any union of the resulting closed three-dimensional cells, and let U be a configuration on the links of P such that

$$\rho_G(U_p) \le \delta \quad \text{for every plaquette of every cell of } P, \qquad \delta R^2 \le 1,$$

including the plaquettes in the boundaries of the cells. These hypotheses are in force in all parts below.

1. *There exists a gauge transformation k on the vertices of P with*

$$\max_{e \subset P} \rho_G(U_e^k) \le C(\delta R + R^{-1}) \le C'/R.$$

This holds for disconnected P, for cells meeting only at vertices or edges, and for arbitrary holes, handles, periodic wrapping, and holonomy; the constants depend on none of these features, nor on n, L, the coupling, the depth, or J. If $q(U_p) < d_*$ for every such plaquette, one may take $\delta = \pi\sqrt{2d_*}$. For a fixed sufficiently large A_8, the choice $R = \lceil A_8/r \rceil$ together with $\pi\sqrt{2d_*}R^2 \le 1$ gives the bound $\rho_G(U_e^k) < r/2$ for every link.

2. *Let $\Gamma \subset P$ be a union of closed cells of the grid, and let k_Γ be a gauge transformation on the vertices of Γ with*

$$\max_{e \subset \Gamma} \rho_G(U_e^{k_\Gamma}) \le \eta, \qquad K_R = 1 + \eta R + \delta R^2, \qquad K_R^2/R \le c.$$

Then there exists an extension k equal to k_Γ at every vertex of Γ with

$$\max_{e \subset P} \rho_G(U_e^k) \le C K_R^{10}/R.$$

Every link contained in a cell with no vertex in Γ satisfies the stronger bound C'/R. In particular, this bound holds after removing two layers of cells around Γ.

3. *For fixed M and J, let $C_B \ge (10M)^J$ also bound the lengths of the finite tree path products. Assume $\eta \le C_B r$, $r \le 1$, and $R = \lceil A_8/r \rceil$, and set*

$$K_B = 2 + C_B(A_8 + 1), \qquad C_{\mathrm{col}} = C K_B^{10}/A_8.$$

If $K_B^2 r/A_8 \le c$ and $C_{\mathrm{col}} r < \beta_{\mathrm{rec}}/2$, then all links of P are smaller than $\beta_{\mathrm{rec}}/2$, and, after one fixed increase of A_8, the links in cells with no vertex in Γ are smaller than $r/2$. The constants in this part have the dependence described in item (3) of Definition 4.14. These statements assert the existence of gauge transformations; no configuration-dependent gauge transformation is used as a change of variables in an integral.

4. *At later scales, use the following endpoint protection rule. On the lattice on which each frozen coordinate was frozen, mark both endpoints of every frozen link, both endpoints of every based transport, and every prescribed basepoint or root. A block of the current output*

lattice is excluded whenever its full centered preimage on the lattice of some mark contains that mark. Then every gauge transformation supported on the remaining blocks has a lift, constant on blocks, which equals I at every mark, and this lift preserves every frozen link and every based transport exactly. This holds at every finite depth, for coordinates frozen at any earlier step and at periodic seams, with no sum over the steps at which the coordinates were frozen. A newly chosen root of the Haar disintegration is fixed separately by the current based gauge. For the gauge transformation of Lemma 19.5, the current endpoints of the links across the boundary of the block region are included among the fixed vertices as well.

Proof. We give the absolute and the relative constructions on the same skeleton.

Step 1: axial frames. In each cell Q of P, we fix a corner o_Q, let τ_x be the coordinate-ordered path in Q from o_Q to x, and define $q_Q(x) = U(\tau_x)$. Then $U_{xy}^{q_Q}$ is the transport around the loop $\tau_x(x,y)\tau_y^{-1}$. To bound it, we compare the ordered paths to the adjacent vertices x and y. Moving the last elementary step through the ordered path inserts at most two rectangular strips, each of width one and length at most $2R$. After canceling consecutive inverse edges, the resulting loop is a product of conjugated elementary plaquettes. There are at most CR of them, all in Q, including its boundary. By the product inequality for ρ_G, we have

$$\rho_G(U_{xy}^{q_Q}) \le C_0 \delta R. \tag{21.1}$$

Here C_0 is absolute, since the aspect ratio of a cell is at most four. This local estimate is the closed-cell clause of Lemma 7.5; the strip argument shows that it applies to a cell cut out of a torus. A cell has an injective periodic lift because $2R \le n/4$.

Step 2: transitions. For two cells Q, Q' containing a common lattice edge (x,y), we define $t_{QQ'}(x) = q_Q(x) q_{Q'}(x)^{-1}$. Direct multiplication gives

$$t_{QQ'}(y) = (U_{xy}^{q_Q})^{-1} t_{QQ'}(x) U_{xy}^{q_{Q'}}, \qquad d(t_{QQ'}(x), t_{QQ'}(y)) \le 2C_0 \delta R, \tag{21.2}$$

where we used (21.1) and bi-invariance. This estimate holds whether the cells share a face or only an edge. When two cells share only a vertex, only the equality of the assigned value at that vertex is required.

Step 3: the edges of the grid. We write the desired gauge in the frame of Q as $s_Q(x) = k(x) q_Q(x)^{-1}$ and set $k = I$ at every vertex of the cell grid. On each edge of the grid, we fix one incident cell frame, interpolate the two endpoint values of s_Q by a shortest geodesic in $\mathrm{SU}(2)$, and sample it at the lattice vertices. Since the group has diameter 2π and the edge has length at least $R/2$, the speed is at most $4\pi/R$. Each edge of the grid is assigned once, regardless of the number of incident cells. By (21.2), changing to another incident frame adds at most $C\delta R$ per lattice edge. Since $\delta R^2 \le 1$, the assigned frame values on every edge of the grid have lattice Lipschitz constant at most C_1/R.

Step 4: the faces of the grid. On a face of the grid, we convert the assigned boundary values into the frame of one incident cell, and we use a single consistent fine triangulation on all faces of the grid. Since the vertices of each fine simplex can be joined by a bounded number of lattice edges in the boundary, their distances are at most C_2/R. We take R_0 so large that the normalized affine interpolation clause of Lemma 7.5 applies, with denominator at least $1/2$. The continuous boundary map then has Lipschitz constant C_3/R. The disk extension clause, rescaled to this rectangle, bounds the Lipschitz constant of its extension by $CR^{-1}(1+C_3)^2$. Sampling the extension at all lattice vertices of the face, we recover $k = s_Q q_Q$. This is done once for each face, and previously assigned vertices are preserved exactly.

Step 5: the cells. For a cell Q of P, we convert the assigned boundary values into the frame of Q. On every lattice edge in the boundary their difference is at most C_4/R, by the face bound and (21.2). The same consistent triangulation and normalized interpolation give a boundary map from the sphere with Lipschitz constant C_5/R; we increase R_0 once to satisfy its simplex margin. By the ball extension clause, we obtain a map with Lipschitz constant $CR^{-1}(1+C_5)^5$, and sampling it gives k at the remaining vertices. For an edge of Q, the final comparison is the sum

$$\begin{aligned} \rho_G(k_x U_{xy} k_y^{-1}) &= \rho_G\big(s_Q(x) U_{xy}^{q_Q} s_Q(y)^{-1}\big) \\ &\le \rho_G(U_{xy}^{q_Q}) + d(s_Q(x), s_Q(y)) \le C(\delta R + R^{-1}). \end{aligned} \tag{21.3}$$

In the last inequality, we used (21.1) and the Lipschitz bound of the extension. Since $\delta R \le R^{-1}$, this proves the absolute estimate with $C' = 2C$, after enlarging C to include the finitely many aspect and simplex constants. Since the assignments on the skeleton agree at every common vertex, they can be made directly on the periodic quotient and on any union of cells. Handles, the number of components, and the holonomy have not entered any constant.

Step 6: the relative construction. We keep every lattice vertex of Γ at its prescribed value. In the frame of a cell Q, the prescribed values satisfy, on each prescribed lattice edge,

$$d(k_\Gamma(x) q_Q(x)^{-1}, k_\Gamma(y) q_Q(y)^{-1}) \le \eta + C_0 \delta R \le C K_R / R. \tag{21.4}$$

This follows by applying the first inequality in (21.3) in reverse to the two transformed link matrices, whose angles are both known; it imposes no bound on the increments of k_Γ in the original frame. At the vertices of the grid not in Γ, we set $k = I$. An edge of the grid in Γ is kept, and every other edge of the grid is a geodesic in one incident frame between its assigned endpoint values. Since Γ is a union of closed cells of the grid, its intersection with an edge of the grid is either the whole edge or a subset of its endpoints, so this rule respects all prescribed values. Its lattice increments in any cell frame are bounded by CK_R/R.

We keep each face of the grid lying in Γ. On every other face, the boundary interpolation and the disk filling give the bound CK_R^2/R; the interpolation is legitimate when CK_R/R is below its fixed simplex margin. On the boundary of a cell not in Γ, all assigned frame increments, including those on a face kept from Γ, are now at most CK_R^2/R. The universal c in the hypothesis is taken smaller than both required interpolation margins divided by these fixed constants. Since $K_R \geq 1$, the condition $K_R^2/R \leq c$ implies the first margin as well. The boundary interpolation on the sphere and the ball filling then give

$$\operatorname{Lip}(s_Q) \leq CR^{-1}(1 + CK_R^2)^5 \leq CK_R^{10}/R.$$

All cells of Γ are kept unchanged. Using (21.3) and $\delta R \leq R^{-1} \leq K_R^{10}/R$, we obtain the relative bound.

Step 7: cells away from Γ. If Q has no vertex in Γ, no face or edge of Q is prescribed. Each edge of the grid in the boundary of Q is then a shortest geodesic of speed at most C/R, even if its endpoint values were assigned in the frame of another incident cell, and frame changes add at most C/R. The disk extensions on the faces of Q then have Lipschitz constant C/R, and so does the ball extension in Q. By (21.3), we obtain the stronger conclusion for every edge of Q. Removing two layers of cells around Γ removes every cell with a vertex in Γ.

Step 8: the choice of δ and of A_8. If $U = e^X$ and $x = |X| \leq 2\pi$, then $q(U) = 2\sin^2(x/4)$ and $\sin(x/4) \geq x/(2\pi)$. Hence $x^2 \leq 2\pi^2 q(U)$, and the stated value of δ is valid. Let A_8 be larger than $4C'$ and R_0, increased by the fixed geometric factors used later in the excluded sets. Then $R \geq A_8/r \geq R_0$ and $C'/R \leq (C'/A_8)r < r/2$. For part (3) we have $A_8/r \leq R \leq (A_8+1)/r$, so

$$K_R \leq 2 + C_B(A_8+1) = K_B, \qquad CK_R^{10}/R \leq C_{\mathrm{col}} r, \qquad K_R^2/R \leq K_B^2 r/A_8.$$

The two smallness conditions in part (3) then imply the stated bounds. Since the constant C_B is fixed before r, these conditions are upper bounds on r and a lower bound on the ratio β_{rec}/r, and they are not circular.

Step 9: endpoint protection. In one coordinate, the balanced-digit identity

$$\Big\{ \sum_{j=0}^{s-1} M^j a_j : a_j \in \{-(M-1)/2, \dots, (M-1)/2\} \Big\} = \{-(M^s-1)/2, \dots, (M^s-1)/2\}$$

holds: existence follows by successively taking the balanced residue modulo M, and uniqueness by reducing two such expressions modulo M and dividing their difference by M. Taking the product over the three coordinates and then the periodic quotient, we find that each vertex of the lattice of a mark has exactly one ancestor in any current centered partition, also at a seam. A mark in the preimage of a block would exclude that block. A

gauge transformation supported on the remaining blocks is I at every such ancestor, and its lift, constant on blocks, is I at the mark. For any path, the gauge factors at the interior vertices cancel in order, and only the two endpoint factors remain. This proves that every marked frozen link and every based transport is preserved exactly, for all marks at once and with no sum over earlier steps. Finally, the cutoff in Lemma 19.5 vanishes at the prescribed endpoints of the links across the boundary of the block region as well, which proves the last statement. □

21.2 Deterministic large-field decompositions

In this section, we partition the support of the initial measure according to the outcomes of a deterministic sequence of curvature tests, and we show that on each piece every block region admits a representative with small links and small newly frozen coordinates.

Based transports and frozen coordinates. Let $e = (u_e, v_e)$ be a link across the boundary of the block region, oriented from its endpoint u_e in the block region to its endpoint v_e in the fixed complement, and let σ_e be the hierarchical tree path of Lemma 21.1 from the root α_e of the block containing u_e to u_e. The based transport of e is $\widehat{b}_e = U(\sigma_e)U_e$, the transport from α_e to v_e; its endpoints are α_e and v_e, while the endpoints of the link itself are u_e and v_e. When integration stops at a boundary, such links are frozen through their based transports, and the other links leaving the integration are frozen as links. We write $c^\sharp$ for the analytic coordinates of newly frozen coordinates: in the coordinates we use, the logarithm $\operatorname{Log} b$ of the frozen group value b, or a fixed analytic function of finitely many such logarithms (see (21.5)). Group values of frozen coordinates are never compared with analytic radii directly.

Parameters. We fix M, J, the construction domains of Theorem 20.14, and A_8 sufficiently large as in Theorem 21.3. Then we fix the frozen-coordinate conversion constant $C_{\mathrm{conv},J}$ of (21.7) below. It is computed from the relative extension of Theorem 21.3, the finite path products of the constraints and trees, the constant $C_{\mathrm{ad},J}$ of Corollary 21.2, the constant converting the near values at the first step under the Wilson measure, and the constants converting frozen group values into analytic coordinates. It is fixed before the two radii below. Then $r > 0$ and the bound $\beta_{\mathrm{rec}} > C_{\mathrm{conv},J} r$ for frozen coordinates are taken so small that every newly frozen analytic coordinate satisfies

$$|c_j^\sharp| \le \min\{\beta_{\mathrm{rec}}, \phi_\bullet(j)/4\}, \qquad C_{\mathrm{bc},\bullet} E_\bullet \beta_{\mathrm{rec}}/\rho_\bullet \le \sigma_*/4, \qquad \bullet \in \{\mathrm{cl}, \mathrm{q}\},$$

for the classical and the quantum spatially varying analytic radii $\phi_{\mathrm{cl}}, \phi_{\mathrm{q}}$, with the radii $\rho_\bullet$, ceilings $E_\bullet$, and boundary-completion constants $C_{\mathrm{bc},\bullet}$ of Theorem 20.14. These are conditions on deterministic parameters, imposed before the coupling. The deep frozen group variables at the first step under the Wilson measure are arbitrary elements of

SU(2), not small analytic logarithms; they are kept as fixed parameters and are never inserted into this analytic freezing. We set

$$R_{\mathrm{cell}} = \lceil A_8/r \rceil, \qquad W = 8BR_{\mathrm{cell}}, \qquad \pi\sqrt{2d_*}R_{\mathrm{cell}}^2 \le 1.$$

The width W is measured in output units of the current RG step; in output units of the next RG step it is $W/B = 8R_{\mathrm{cell}}$. The excluded sets below also contain the band of width s_{er} removed at each boundary (Theorem 20.14) and the protected neighborhoods of the finite path products. We may decrease r initially so that $W \ge s_{\mathrm{er}}$.

At each boundary between RG steps, the previous fixed complement and the earlier frozen basepoints lie outside the next block region, up to the fixed buffer of the dependence neighborhoods of the path products. Equivalently, their incoming and current boundary distances satisfy the comparison required in Theorem 19.9; this is proved as (21.10). The endpoint protection rule of Theorem 21.3 contains these basepoints and the newly frozen labels, and additional excluded regions preserve the inclusion. At the first step, there is no previous fixed complement, and the condition is vacuous.

Cell grids. At each lattice side $n \ge 8R_{\mathrm{cell}}$, we fix the cell grid deterministically. For example, we divide each coordinate circle into $\lceil n/R_{\mathrm{cell}} \rceil$ intervals, distributing the remainder among intervals of the two nearest integer lengths. For $R_{\mathrm{cell}} \ge 2$ these lengths lie in $[R_{\mathrm{cell}}/2, 2R_{\mathrm{cell}}]$. When an input grid must be aligned with the blocks, we perform the same construction in units of the blocking grid and round its scale up to a multiple of the block side. Since B is fixed and R_{cell} may be taken larger than B initially, this changes the scale by at most a fixed factor.

Definition 21.4. Fix a finite range of scales consisting of complete RG steps and an initial configuration U. The ordered tests are the following finite procedure.

1. Before any gauge transformation, compute the iterates $V^\ell = T_M^\ell U$ at all levels of the current RG step, with the Borel extension of T_M. Go through these levels in increasing order and, at each level, through the plaquettes in a fixed order.
2. A plaquette f fails if $q_f = q(V_f^\ell) \ge d_*$ and its full dependence set does not meet the current excluded label set. When f fails, all variables of its full dependence set that are not yet frozen are frozen at the input of its RG step, together with those of a fixed neighborhood of the dependence set. This neighborhood is aligned with the blocks of the output lattice and has output radius $2W$. It includes the fixed margins of the dependence neighborhoods and the protected neighborhood of the endpoint protection rule. Previously frozen variables stay where they are. The neighborhood is added to the excluded label set. A plaquette whose dependence set meets the excluded label set is not tested; it is excluded, not declared good.
3. After the tests of an RG step, retain only the closed cells of the output cell grid whose full dependence sets and protected neighborhoods avoid the excluded label set, and

add every touching excluded cell to the fixed complement. Freeze the full output boundary band: the layer of retained cells next to the excluded set, its incident cells, all labels of reduced analytic radius, the removed band of width s_{er}, and the margins of the dependence neighborhoods. Enlarge the previous fixed complement by an output neighborhood of width W, and then by the protected neighborhood of the endpoint protection rule of Theorem 21.3, using every endpoint and basepoint of every frozen coordinate on the lattice where it was frozen. A cell is retained only if its closure avoids all these exclusions, so a plaquette in the boundary of a cell is tested on the same terms as an interior plaquette.

4. For the next RG step, keep only the blocks that lie, together with their full dependence neighborhoods, in the retained interior. The discarded band is frozen. Excluded regions are combined by taking unions. If the block region becomes empty, its frozen coordinates are kept and the procedure stops.

When the initial measure is the Wilson measure, the first RG step is modified as in Theorem 21.5(4). The outcome of the procedure, consisting of the failing plaquettes, the excluded regions, and the label lists of the coordinates frozen at all steps, is a large-field decomposition, denoted $\mathcal{X}$. The values of these coordinates are variables of the stage measures and are not part of the finite index $\mathcal{X}$. We write $\mathcal{A}_{\mathcal{X}}$ for the set of initial configurations for which the procedure produces $\mathcal{X}$.

Theorem 21.5. *Make the parameter choices above.*

1. *For every finite range of scales, every initial side, every preceding depth $d_0 = aJ$ with $a \geq 0$, and every normalized stopped measure*

$$d\widehat{\nu} = \widehat{Z}^{-1}\mathbf{1}_{D_r} e^{-E_{d_0,\mathrm{sat}}/g^2_{m_{\mathrm{base}}} - [R_{d_0,\mathrm{sat}} - R_{d_0}(I)]}\, dH_{m_{\mathrm{base}}},$$

   the sets $\mathcal{A}_{\mathcal{X}}$ form a finite deterministic Borel partition of the support of $\widehat{\nu}$, provided that the output side of every complete RG step is at least $8R_{\mathrm{cell}}$. The same holds when the initial measure is the Wilson measure, with the first step described in part (4). Every tested plaquette that is not excluded satisfies $q_f < d_*$. The gauge transformations used below to exhibit small representatives do not enter the tests.
2. *At every boundary between RG steps there exists a gauge representative in which the links in the interior of the block region are smaller than $r/2$, and the newly frozen links and based transports are smaller than β_{rec} on the lattice where they are frozen. All previously frozen coordinates are preserved together with their endpoints; no smallness of their later averaged images is asserted. A block region that becomes empty keeps its frozen coordinates, and the procedure stops there.*
3. *Every added cell and every frozen label can be assigned to a failing plaquette by a local rule. For a failing plaquette f, the radius $R_t(f)$ of the neighborhood assigned to f, measured at*

the outputs of successive RG steps, satisfies

$$R_{t+1}(f) \le B^{-1} R_t(f) + C_J(W + R_{\mathrm{cell}} + 1), \qquad R_{\mathrm{first}}(f) \le C_J(W + R_{\mathrm{cell}} + 1),$$

where $R_{\mathrm{first}}(f)$ refers to the RG step in which f fails. The number of scalar labels assigned to f is at most $C_J(BW + R_{\mathrm{cell}} + 1)^3$ in that RG step and at most $C_J(W + R_{\mathrm{cell}} + 1)^3$ in each later RG step. The final plaquettes whose full dependence sets meet a neighborhood assigned to f are at most

$$F_J = C_J(W + R_{\mathrm{cell}} + 1)^3$$

in number, with a fixed enlargement for each of the finitely many remaining numbers of averaging steps after the last RG step (Theorem 21.12). These estimates are subadditive under unions. A set of failing plaquettes that can be produced by the ordered tests determines at most one large-field decomposition. The constants C_J have the dependence stated at the beginning of this section and are independent of the later widths; the displayed polynomials exhibit the dependence of the counts on the widths.

4. *For the first RG step under the Wilson measure, the ordered tests also test the plaquettes of the input configuration, before any representative is chosen. On a fixed input cell grid of scale S, aligned with the blocks, with $C_J^{-1} R_{\mathrm{cell}} \le S \le C_J R_{\mathrm{cell}}$, retain only the closed cells whose full dependence sets avoid the final excluded set. Move the block region inward by one full layer of cells and by the full dependence neighborhood of the constraint, tree, and basing path products, and require*

$$n_{\mathrm{input}} \ge 8S, \qquad \pi\sqrt{2d_*}\,S^2 \le 1.$$

Then every plaquette of the resulting closed cell complex, including its boundary plaquettes, is a tested plaquette with $q < d_*$. The complex contains every plaquette whose Wilson term depends on an integration variable and every constraint and tree path product of the block region. There are no earlier frozen vertices at this step. The gauge transformation of Theorem 21.3(1) on this complex makes the integration variables and the near values small; it extends to the remaining vertices, whose links are kept as arbitrary elements of $\mathrm{SU}(2)$ (the deep frozen group variables). The relative extension at the output gives the bounds of part (2) for the newly frozen coordinates. All additional excluded sets are assigned to the same failing plaquettes and satisfy the bounds of part (3) after one enlargement of C_J.

5. *For either initial measure ν define the stage measures*

$$\eta_t^{\mathcal{X}} = (\mathcal{O}_t^{\mathcal{X}})_{\#}(\mathbf{1}_{\mathcal{A}_{\mathcal{X}}}\nu),$$

where $\mathcal{O}_t^{\mathcal{X}}$ maps a configuration to the field on the current block region together with all frozen links and based transports, each on the lattice where it was frozen. All the tests remain in these measures. For every Borel set S (an event, not the grid scale of part (4)), in particular for every small-field event of the form (4.6) *on the same finite hierarchy,*

$$\mathbf{1}_S = \sum_{\mathcal{X}} \mathbf{1}_S \mathbf{1}_{\mathcal{A}_{\mathcal{X}}} \quad \nu\text{-almost surely.}$$

The partition does not change S and imposes no additional restriction on the Wilson measure. All statements are uniform in the holonomy, the number of RG steps since coordinates were frozen, the topology of the regions, and the deep frozen group variables. A remaining group of fewer than J averaging steps at the end of the range stops before the geometric conditions on the minimal side fail.

The following lemma records which changes of representative preserve the bounds on frozen coordinates; it is used in the proof of Theorem 21.5 and afterward.

Lemma 21.6. *Consider a representative as in Theorem 21.5(2) whose analytic frozen coordinates satisfy* (21.8).

1. *Every gauge transformation supported on the current block region and lifted under the endpoint protection rule equals I at the endpoints of all earlier frozen links and based transports. It fixes their group values and their logarithms exactly.*
2. *A gauge transformation equal to I at the roots of the block region and at the outer endpoints v_e of the links across the boundary of the block region fixes every based transport $\widehat{b}_e$, although it may move the inner endpoint u_e. The gauge transformation of Lemma 19.5 fixes u_e as well.*
3. *A simultaneous conjugation $b \mapsto kbk^{-1}$ of the frozen coordinates preserves* (21.8).
4. *A change $b_{xy} \mapsto k_x b_{xy} k_y^{-1}$ with independent k_x, k_y need not preserve* (21.8).

In the following, analytic estimates are transported between representatives only by the changes in parts (1)–(3). Changes as in part (4) are used only for the invariance of densities in Theorem 21.9. None of these conventions changes the tests or restricts the initial measure.

Proof. Part (1) is Theorem 21.3(4). For part (2), the gauge factors at the interior vertices of the path σ_e and of the link e cancel, so $\widehat{b}_e$ changes only by the factors at α_e and v_e, which are I; the factor at u_e cancels. The gauge transformation of Lemma 19.5 is I at the protected endpoints of the links across the boundary of the block region, including u_e. For part (3), we have $\operatorname{Log}(kbk^{-1}) = \operatorname{Ad}_k \operatorname{Log} b$ on the identity chart, and Ad_k is an isometry of $\mathfrak{su}(2)$. For part (4), take $b = I$ and $k_y = I$; then $\rho_G(k_x b k_y^{-1}) = \rho_G(k_x)$ is arbitrary. □

Proof of Theorem 21.5. We first fix all margins and constants that do not depend on a configuration (Steps 1 and 2). We then show that the tested plaquettes that are not excluded are good (Step 3), construct the small representatives by induction over the RG steps (Step 4), and compare boundary distances (Step 5). Steps 6 and 7 prove the counts and the measurability, Step 8 treats the first step under the Wilson measure, and Step 9 identifies the stage measures.

Step 1: fixed margins. All excluded sets in this proof are sets of labels, chosen by their locations and dependence sets; their construction uses no link representative. We fix

D_J, L_J, v_J from Lemma 21.1 and $C_{\mathrm{ad},J}$ from Corollary 21.2. The protected neighborhoods include one full copy of each dependence neighborhood, its incident cells, and the removed band of width s_{er}, and A_8 includes the factors required in Theorem 21.3. The support radius will be required to give $R_{\mathrm{cell}} \geq R_0$ and W larger than s_{er} and than the radii of these finitely many dependence neighborhoods. The number of copies and their enlargement factors depend only on M, J, and the fixed construction domains; in particular, they are fixed before W or R_{cell} is evaluated.

Step 2: constants for frozen coordinates. We specify the margins for frozen coordinates before using any representative. On the lattice where it is frozen, the analytic coordinate of a frozen link b_e or based transport $\widehat{b}_e$ is its identity-chart logarithm. If its angle is below π, then

$$|\mathrm{Log}\, b_e| = \rho_G(b_e), \qquad |\mathrm{Log}\, \widehat{b}_e| = \rho_G(\widehat{b}_e). \tag{21.5}$$

Here $|\cdot|$ is the adjoint-invariant Euclidean norm on $\mathfrak{su}(2)$, and the conversion constant is one. If the fixed coordinate convention also uses a longer path product or a relative eliminated coordinate, let $C_{\mathrm{cr},J} \geq 1$ bound its path length and the row sums of the first derivative of its fixed inverse chart on the larger construction domain. Such maps vanish at the configuration with all links equal to I. By the product inequality for angles, or by integration of the first derivative along the straight segment, their size is at most $C_{\mathrm{cr},J}$ times the bound on their inputs. This constant depends only on the fixed charts and on M, J, not on any width or number of steps.

We fix $C_{\mathrm{conv},J}$ by (21.7) below, after A_8 and before either radius; it includes $C_{\mathrm{ad},J}$ and $C_{\mathrm{cr},J}$. Let $\rho_{\partial,\mathrm{cl}}$ and $\rho_{\partial,\mathrm{q}}$ be the boundary values of the two spatially varying radii, and define

$$b_{\min} = \tfrac{1}{4} \min\{\rho_{\mathrm{cl}}, \rho, \rho_{\partial,\mathrm{cl}}, \rho_{\partial,\mathrm{q}}\}.$$

We take $\beta_{\mathrm{rec}} < \min\{\pi, \rho/4, \rho_{\mathrm{cl}}/4\}$ satisfying the two conditions $C_{\mathrm{bc},\bullet} E_\bullet \beta_{\mathrm{rec}}/\rho_\bullet \leq \sigma_*/4$, and then require

$$C_{\mathrm{conv},J} r < \min\{\beta_{\mathrm{rec}}, b_{\min}\}. \tag{21.6}$$

These are the conditions on frozen coordinates in the choice of parameters. All quantities on the right side are fixed positive parameters, so this upper bound on r is compatible with its other upper bounds.

Step 3: the tests and the goodness of retained plaquettes. We first consider a stopped measure. At the input of the first RG step, a gauge transformation into B_r gives all links smaller than r. By Corollary 21.2, which precedes this construction, the initial frozen coordinates at the input are bounded by $C_{\mathrm{ad},J} r$ in a common representative. Since $C_{\mathrm{conv},J} \geq C_{\mathrm{ad},J}$, their analytic coordinates satisfy (21.6) as well. At later inputs, by the induction in Step 4, the links in the interior of the block region are small, with all earlier frozen coordinates fixed. Before any gauge transformation, we compute the iterates at

every level of the current RG step and perform the ordered tests of Definition 21.4. The tests always use the values of the iterates themselves, also when a path product that is not used has an exceptional value of the Borel extension.

After the tests, the retained cells are those of Definition 21.4(3). A dependence set avoiding the final excluded set also avoided the smaller excluded set at the time of its test. If that plaquette had value at least d_*, its failure would have put the dependence set into the excluded set. This contradiction shows that every tested plaquette that is not excluded is good, that is, $q_f < d_*$. Adding excluded sets after the tests can only reduce this set of plaquettes.

Step 4: small representatives. We prove part (2) by induction over the boundaries. Let P be the retained closed cell complex. Every link read for an output link of P comes from links of the current interior, before the new freezing at the input. By Lemma 21.1, its angle in the incoming representative is at most $C_B r$, where C_B includes the finite tree path lengths. By Step 3 and Step 8 of the proof of Theorem 21.3, all plaquettes of P have angle at most $\delta = \pi\sqrt{2d_*}$. Let Γ consist of one layer of retained cells next to the excluded set, enlarged to contain all prescribed boundary vertices. We prescribe the identity gauge on Γ in this representative; its link bound is $\eta \le C_B r$. After the initial reduction $K_B^2 r/A_8 \le c$, parts (2) and (3) of Theorem 21.3 apply. The resulting gauge transformation is exactly I at every prescribed lattice vertex, has link bound $C_{\mathrm{col}} r$ on P, and has the bound $< r/2$ in cells without prescribed vertices. It extends by I outside P, because every boundary vertex of P is prescribed. We lift it as a constant through the current RG step. By the endpoint protection rule, the lift is I at all earlier marks and at the variables already frozen at the input in this RG step. Hence every earlier frozen coordinate, its endpoints, and every newly frozen input variable keep their values.

We freeze the full output boundary band, including Γ, its incident cells, all labels of reduced analytic radius, the removed band, and the margins of the dependence neighborhoods. Since the remaining interior is separated from Γ by two layers of cells, its links are smaller than $r/2$. The newly frozen links have angle at most $\max(C_B, C_{\mathrm{col}})r$. A based transport multiplies such a link by a hierarchical transport with at most L_J factors, and its angle is at most the sum of their angles. As announced before the radii were chosen, we may therefore fix

$$C_{\mathrm{conv},J} > 2C_{\mathrm{cr},J}(1+L_J)\max\{C_B, C_{\mathrm{col}}, C'/A_8, C_{\mathrm{ad},J}\}, \tag{21.7}$$

with any additional fixed factors of dependence neighborhoods absorbed once. Every analytic coordinate of the union of the newly frozen boundary band, boundary layer, and based transports then has size at most $C_{\mathrm{conv},J} r$. By (21.5) and (21.6), we have simultaneously

$$|c_j^\sharp| < \beta_{\mathrm{rec}}, \qquad |c_j^\sharp| \le \phi_\bullet(j)/4 \quad (\bullet \in \{\mathrm{cl}, \mathrm{q}\}). \tag{21.8}$$

This includes every label of reduced radius, not only the boundary links of a layer. The constant is computed from A_8, C_B, and the universal relative extension before r and β_{rec} are chosen.

For the next RG step, we retain only the blocks that lie, together with their full dependence neighborhoods, in the remaining interior. The discarded band has thickness at most C_J in that input lattice and consists of links that were small before discarding. The fixed factor coming from its dependence neighborhood was included in $C_{\mathrm{conv},J}$ before the radii were fixed, so the band may be frozen with the same bound. The previous excluded region was enlarged by W in the current output lattice. After the next RG step, this is $W/B = 8R_{\mathrm{cell}}$ units, which suffices for the required layer of cells and the fixed incidences; the full dependence neighborhood is included in addition. None of these operations requires a later averaged image of a frozen coordinate to be small, since the coordinate stays on its own lattice. This completes the induction.

Step 5: incoming and current boundary distances. For the next RG step, let D_{in} be its list of remaining analytic input labels after the whole freezing, and let Ω' be the set of its current retained blocks. Each incoming label is kept at its location on the lattice where it was created, with its original volume factor. A current block is retained only when its full input dependence neighborhood is contained in D_{in}. An omitted incoming label lies outside the block region, apart from the fixed displacement between the location of a chart label and its path product. A newly frozen boundary label, or a label of a link across the boundary of the block region, is omitted from D_{in} and satisfies the same statement. By the endpoint protection rule, an earlier frozen endpoint or basepoint has its current centered ancestor in an excluded block. By the balanced-digit identity, the difference between its rescaled position and that ancestor is less than one current unit, uniformly in the number of steps. Including the finite dependence neighborhoods of the charts, we may take $L_{\mathrm{buf},J} = 3D_J + 6$, so that every omitted input label x satisfies

$$\operatorname{dist}(x/B_s, (\Omega')^c) \le L_{\mathrm{buf},J}, \qquad B_s = M^s. \tag{21.9}$$

In the induction $s = J$. The same inclusion holds for a single group of $s \le J$ averaging steps when its own domain conditions are imposed. Enlarging the excluded regions can only decrease the distance to $(\Omega')^c$, so it preserves the inclusion.

If the incoming fixed complement is nonempty, let i be an incoming retained label and x a nearest omitted input label. For a current retained label e we use the same distance as in the two boundary-weighted norms; the factor 3 in $L_{\mathrm{buf},J}$ covers the comparison with the maximum-distance convention for dependence neighborhoods. By the triangle inequality and (21.9), we have

$$d_{\mathrm{current}}(e) \le \operatorname{dist}(e, i/B_s) + B_s^{-1} d_{D_{\mathrm{in}}}(i) + L_{\mathrm{buf},J} + 1,$$

where the last term 1 accounts for the choice of a cell rather than a vertex as location. Rearranging, we obtain

$$d_{D_{\mathrm{in}}}(i) \geq B_s d_{\mathrm{current}}(e) - B_s \operatorname{dist}(e, i/B_s) - C_{\mathrm{buf},J}, \qquad C_{\mathrm{buf},J} = B_s(L_{\mathrm{buf},J} + 1). \tag{21.10}$$

Rescaling coordinates in this calculation does not rescale the counting measures of the labels or discard their volume factors in a column norm; these are the same as in the incoming analytic norm. If there is no incoming fixed complement, the boundary-weighted part of the input is zero, and no nearest omitted label is needed. A new excluded region satisfies the inclusion just proved once the initial split has been made. The buffer in (21.10) depends only on M, J, and the fixed charts, not on W, s_{er}, the number of steps, or the number of excluded components.

Step 6: locality and counts. We verify locality and the counts without counting connected components. We label each initially added neighborhood by its failing plaquette; when neighborhoods overlap, a label in their intersection is assigned to the first incident failing plaquette in the fixed order. The enlargement of a union by a fixed neighborhood is contained in the union of the corresponding enlargements of its members. A cell meeting such an enlargement lies within a further $4R_{\mathrm{cell}}$ of it, and a full dependence neighborhood costs at most $D_J + 1$ more. Projection of a mark to its current ancestor contracts distances by the blocking factor, with a rounding error of at most one current unit for the whole projection, not one for each earlier step. This follows from the balanced-digit identity in the proof of Theorem 21.3, since the whole preimage has radius less than half a block side.

If $R_t(f)$ bounds all current neighborhoods and projected marks assigned to f, the next RG step gives, with a fixed $a_J < \infty$,

$$R_{t+1}(f) \leq B^{-1} R_t(f) + a_J(W + R_{\mathrm{cell}} + 1). \tag{21.11}$$

The neighborhood created when f fails satisfies the same bound in the output units of its RG step. We take $C_J \geq a_J/(1 - B^{-1})$ and at least the corresponding constant for the step in which f fails. Iterating (21.11), we obtain $R_t(f) \leq C_J(W + R_{\mathrm{cell}} + 1)$ at every later boundary between RG steps. A remaining group of fewer than J averaging steps at the end is read as a fixed finite dependence neighborhood at the last boundary; it creates no additional integrated step and no update of the normalization constant. All endpoint marks added when boundary layers are frozen lie in the same neighborhoods, so the protected neighborhoods of the endpoint protection rule obey (21.11) too, even if the frozen coordinates contain marks on many lattices.

A ball of radius a in the maximum distance contains at most $(2a+3)^3$ vertices. The link direction, the color component, the intermediate scale, and the type of frozen coordinate multiply this by a fixed C_J. In the RG step in which f fails we convert the radius into

input units, which costs a factor B; at later RG steps we use the bound in current units just proved. We obtain the counts

$$C_J(BW + R_{\mathrm{cell}} + 1)^3, \qquad C_J(W + R_{\mathrm{cell}} + 1)^3$$

of scalar labels. The lists of missing labels, boundary-band labels, and frozen labels used in Theorem 20.13 are subsets of these lists of bounded density; deterministic images of earlier frozen coordinates are not new independent labels. A final plaquette whose full dependence set meets an excluded region lies in a further fixed dependence neighborhood of one of the assigned sets. Counting the three plaquette directions there, we obtain the bound F_J. The finitely many remaining numbers of averaging steps after the last RG step only enlarge the dependence neighborhood. On a periodic quotient these counts can only decrease. Since we use unions rather than hulls of components, all the bounds are subadditive, including for excluded regions that touch or wrap around the torus.

Step 7: Borel measurability. The outcome of the ordered tests is determined by its set of failing plaquettes: replaying the ordered list and adding the prescribed excluded sets at exactly those failures reproduces it. Hence there is at most one decomposition for each set of failing plaquettes that the procedure can produce. Each event $\mathcal{A}_{\mathcal{X}}$ is Borel, since it is a finite Boolean combination of tests of Borel iterates and of membership in deterministic dependence lists. These events are disjoint and exhaust the support. The small representatives were used only after these events had been specified.

Step 8: the first step under the Wilson measure. For the Wilson measure, we perform the same tests, including the plaquettes of the input configuration, without assuming a small input representative. Let F be the final excluded dependence set. On the fixed input cell grid of scale S, aligned with the blocks, we form the initial good-cell complex P_{in}, consisting of all closed cells whose full dependence sets avoid F. The blocks of the block region are chosen only after moving inward by one full layer of cells and by the full dependence neighborhood of the constraint, tree, basing, and plaquette path products. This choice implies that every input plaquette whose Wilson term depends on an integration variable, and every path product of the block region, is contained in P_{in}. For example, a point of a retained block together with its dependence neighborhood still lies in a retained cell or in its incident layer, and that layer was retained before moving inward. The near links are the links outside the block region read by these path products and plaquettes, as in (18.32), and their values are the near values. All remaining input links are deep links; their values are the deep frozen group variables, that is, the frozen group variables in the fixed complement that are not near values.

An input plaquette of P_{in}, including a boundary plaquette, avoids the final set F; by the argument of Step 3, it is good. The absolute part of Theorem 21.3 applies with $n_{\mathrm{input}} \geq 8S$ and $\delta S^2 \leq 1$, and we obtain the bound $C(\delta S + S^{-1}) \leq C'/S$. Fixing the

mesh factors when A_8 is chosen makes this smaller than the required fixed multiple of r. At this first input there are no earlier fixed vertices, and we extend the resulting gauge transformation arbitrarily to the other vertices. All transformed deep links are kept as arbitrary elements of $\mathrm{SU}(2)$ in the frozen data. The finite path-product estimate and the relative construction at the output of Step 4 give the claimed bounds for the new boundary layers and based transports. The near values are small in this representative, not in the original configuration. Every additional excluded set lies within a neighborhood of radius $C_J S$ of an excluded neighborhood, and we assign it to the same failing plaquette. Since $S \le C_J R_{\mathrm{cell}}$, the radius and label counts keep their displayed forms after one fixed enlargement. After this first step, the induction of Step 4 applies.

All analytically frozen adjacent variables of this first step lie in the complex P_{in}, and hence obey the same conversion and (21.8). A dependence set frozen because its averaged plaquette fails can contain arbitrary elements of $\mathrm{SU}(2)$. Such deep frozen group variables are fixed parameters, not variables of the analytic freezing, and their plaquettes involving only frozen variables remain in the external Wilson factor. For a stopped measure, the corresponding initial variables lie in its gauge-invariant small-field domain, by Corollary 21.2.

Step 9: stage measures. By Lemma 21.6, every gauge transformation used in this construction fixes the earlier frozen coordinates and their logarithms; this is the form in which the representatives of part (2) are used later. All stage maps are Borel, since they are compositions of restrictions, the block averaging map, and finite transport products; their pushforwards are the measures in part (5). Each frozen coordinate is recorded once, as an independent link or based transport, and carries all its dependence through the density; no statement about independence under the probability measure is needed. Since the events $\mathcal{A}_{\mathcal{X}}$ partition the support of ν, multiplying their pointwise sum by $\mathbf{1}_S$ gives the identity in part (5), and no restriction is added to the Wilson measure. All geometric arguments were finite local constructions; no step involves L, γ, d_0, the depth, the number of steps since freezing, or the number of components. A final group of fewer than J averaging steps is stopped before its minimal-side condition fails, as stated. □

The next lemma verifies, on every large-field decomposition, the hypotheses of Theorems 19.9 and 20.14 that concern the incoming radius, the boundary distances, the conditional forces, and the cutoff domains. We use the notation of Lemma 19.3. For each initial segment I of the integrated intermediate scales, $y = z_{I^c}$ denotes the remaining free coordinates, $\mathcal{T}_I$ their domain, $a_I(c, y; \xi)$ the unperturbed conditional minimizer, and A_I the unperturbed conditional Hessian at a_I. Further, r_I is the radius of the conditional coordinate neighborhood, r_q the bound on the scaled fluctuations $g_i w_i$, $\varepsilon_{\mathrm{tube}}$ the fixed margin, and $C_{\mathrm{seq},J}$ the constant of the sequential construction. As in Theorem 19.9, Φ_0 is the reconstruction in the target-dependent gauge and $\overline{P}$ is the classical perturbation ad-

justed by the boundary-completion difference. Here $\Phi_0(c,u;\xi)$ has the joint normalized argument u used in that theorem: if z_0 is the unperturbed joint stationary point, K_0 the unperturbed Hessian there, and $S_0 = K_0^{-1/2}$, then $z = z_0 + S_0 u$. In the lemma below, the perturbing function in the original free coordinates is

$$V(c,z;b) = \overline{P}\big(\Phi_0(c, S_0^{-1}(z-z_0);\xi);b\big). \tag{21.12}$$

Thus V_I and V_{II} below are derivatives in the original free coordinates z, at fixed c and real b, and the constants C_P and C_P' include the fixed coefficient bounds of this affine change of coordinates. For a function f of the labels D and frozen values $c^\sharp$ on $F \subset D$, we write $T_{c^\sharp} f$ for the function of the labels $D \setminus F$ obtained by inserting these values, and $\mathcal{X}_D^\phi$ for the coefficient norm with boundary decay of Definition 18.1 with spatially varying radius ϕ.

Lemma 21.7. *Assume the conditions on frozen coordinates and the construction conditions of Theorem 21.5.*

1. *Freezing at the boundary of a complete RG step removes every label of reduced analytic radius and leaves the incoming perturbation on the remaining labels with a uniform analytic input radius, separately for the classical and the quantum radius. Its incoming and current boundary distances satisfy* (21.10).
2. *Fix real $b = (\xi, b_{\mathrm{rec}})$, and suppose that the adjusted classical perturbation $\overline{P}$ has uniform norm at most $2\sigma_*$. Then the preconditioned conditional force δ_V, taken over every initial segment I and every $y \in \mathcal{T}_I$ and defined by the first expression below with V as in* (21.12)*, satisfies*
$$\delta_V = \max_I \sup_{y\in\mathcal{T}_I} \|A_I^{-1} V_I(c, a_I(c,y;\xi), y; b)\|_{\mathrm{coeff}} \le I_0 C_P \sigma_* \rho_{\mathrm{cl}}, \tag{21.13}$$
where I_0 and C_P are fixed bounds on the larger domains, independent of the later widths.
3. *The enclosing product domain and every conditional coordinate neighborhood lie in the domains of Lemma 19.3 when the construction conditions include*
$$\delta_V < \tfrac{1}{4}\min_I r_I, \qquad R_{\mathrm{en}} < r_q, \qquad C_{\mathrm{seq},J}(2I_0 C_P \sigma_* \rho_{\mathrm{cl}} + r_q) < \tfrac{1}{2}\varepsilon_{\mathrm{tube}}, \tag{21.14}$$
together with the fixed Hessian conditions and the two reconstruction-image conditions (21.17).
4. *The fluctuation cutoff domain with common radius $p(t) = A_{\mathrm{w}} \log(1/t)$ is one of the cutoff domains allowed in Theorem 20.14. Its containment and expansion conditions hold below a single coupling ceiling, chosen after these fixed positive radii.*

None of these statements requires a derivative in ξ or in b_{rec}.

Proof. Steps 1 and 2 prove part (1) and the bound on the new boundary-completion differences, Step 3 proves part (2), Steps 4 and 5 verify the image and convexity conditions behind part (3), and Step 6 proves part (4).

Step 1: uniform radius on the remaining labels. The uniform radii are used in the freezing part of Theorem 20.14. We write D for the old output list, I for the remaining labels, and $F = D \setminus I$. All labels of reduced radius belong to F, and $d_D(i) \geq s_{\mathrm{er}}$ for $i \in I$. If there is no old boundary, the boundary-weighted part of the incoming norm is zero, and the estimate below is immediate. Otherwise, since the full neighborhood of width $s_{\mathrm{er}} - 1$ of the old boundary was removed, a shortest route from i to the old boundary meets F at least $s_{\mathrm{er}} - 1$ steps earlier, and additional excluded regions can only shorten the distance to F. Hence

$$d_D(i) \geq d_I(i) + s_{\mathrm{er}} - 1.$$

For a monomial of degree $k \geq 1$ in the remaining labels and degree $j \geq 0$ in the frozen labels, inserting the frozen values multiplies its absolute coefficient contribution by at most η^j with $\eta \leq 1/4$, by (21.8). The new fraction ν_i/k contributes at most a factor $(k+j)/k \leq 1 + j$, and the remaining connecting network is no longer than the original one. Since every remaining label had the full radius $\rho_\bullet$, the resulting series is estimated at the uniform radius $\rho_\bullet$ on I, not at a reduced boundary radius. Summing $\sum_{j\geq 0}(1+j)\eta^j = (1-\eta)^{-2} < 2$ and using the distance inequality, we obtain, including degree one,

$$\mathcal{X}_I^{\rho_\bullet}(T_{c^\sharp} f) \leq 2e^{-\alpha_\bullet(s_{\mathrm{er}}-1)} \mathcal{X}_D^{\phi_\bullet}(f). \tag{21.15}$$

Replacing the radius and rates by the classical radius and rates in this monomial calculation, we obtain the classical statement, with the same factor $(1-\eta)^{-2}$.

Step 2: new boundary-completion differences. The bound $|c_j^\sharp| \leq \phi_\bullet(j)/4$ controls the inherited boundary term. Freezing also inserts the frozen values into the torus functions, and this produces a new boundary-completion difference. For it we use the bound $|c_j^\sharp| \leq \beta_{\mathrm{rec}}$ from (21.8). Every contributing monomial has frozen degree $j \geq 1$ and degree $k \geq 1$ in the remaining labels. For a fixed remaining index i, the graph connecting network joins i to a frozen label, so $d_I(i) \leq \mathtt{t}(\nu)$ and $\mathtt{t}(\nu_I) \leq \mathtt{t}(\nu)$. Let $\mathtt{t}_2$ denote the Euclidean network length in the torus coefficient norm, and let $\bar{a}_\bullet$ be its Euclidean rate. The rate choices of Theorem 20.9 give $\bar{a}_\bullet \geq \sqrt{3}(a_\bullet + \alpha_\bullet)$. Therefore

$$a_\bullet \mathtt{t}(\nu_I) + \alpha_\bullet d_I(i) \leq (a_\bullet + \alpha_\bullet)\mathtt{t}(\nu) \leq \sqrt{3}(a_\bullet + \alpha_\bullet)\mathtt{t}_2(\nu) \leq \bar{a}_\bullet \mathtt{t}_2(\nu).$$

With $\eta_\bullet = \beta_{\mathrm{rec}}/\rho_\bullet \leq 1/4$, the ratio of the new and old fractions ν_i/k is at most $1 + j$. For each fixed original degree we split its absolute coefficient sum according to the frozen degree j, which is uniquely determined. Taking the supremum over the remaining index before the sum over degrees, we lose at most the factor

$$\sum_{j\geq 1}(1+j)\eta_\bullet^j = \frac{\eta_\bullet(2-\eta_\bullet)}{(1-\eta_\bullet)^2} \leq 4\eta_\bullet.$$

The normalization is $\rho_\bullet^{-2}$ in both norms, and the powers of $\rho_\bullet$ cancel against the factors of the frozen labels. This includes the new degree-one terms, and gives the bound $8E_\bullet\beta_{\mathrm{rec}}/\rho_\bullet$ for one simultaneous freezing of the union of the frozen labels. The fixed constant $C_{\mathrm{bc},\bullet}$ includes every required conversion and any finite sum of such terms. The total contribution therefore satisfies

$$z_t^\bullet \le C_{\mathrm{bc},\bullet}E_\bullet\beta_{\mathrm{rec}}/\rho_\bullet \le \sigma_*/4. \tag{21.16}$$

The boundary band, the new boundary layers, the based transports, and the initialization are all included in this single bound. For a new excluded region in the interior, we do not claim that the removed band alone makes this difference small. Equations (21.15) and (21.16) imply the uniform incoming norms in the recursion of Theorem 20.14. The frozen coordinates ξ are parameters of those norms and need not have the full incoming analytic radius.

Step 3: conditional forces. We use the absolute coefficient bounds for the derivatives of $\overline{P}$ in Theorem 19.9, on its uniform input image, which lies strictly inside the input ball. By the fixed construction hypotheses, every conditional coordinate neighborhood has the same image, together with its connecting segments. Composing with the row-sum bounds of the first derivative of Φ_0 and of the affine change of coordinates in (21.12), we find $\|V_I\|_{\mathrm{coeff}} \le C_P\sigma_*\rho_{\mathrm{cl}}$, uniformly in $y \in \mathcal{T}_I$. Multiplying by the conditional inverse bound I_0, we obtain (21.13). The second derivative also contains the term $\overline{P}'\Phi_{0,II}$, where $\Phi_{0,II}$ is the second z_I-derivative of $z \mapsto \Phi_0(c, S_0^{-1}(z - z_0); \xi)$; keeping it, we obtain $\|V_{II}\|_{\mathrm{coeff}} \le C_P'\sigma_*$. The unperturbed neighborhoods are fixed first, so that their own Hessian variation uses at most half of the preconditioned margin. Reducing the fixed ceiling for σ_* makes $I_0C_P'\sigma_*$ fit the remaining margin and preserves the real half-gap and the complex inverse margin. At an unperturbed conditional minimizer, we have $F_{0,I} = 0$, so the condition on inverse times force is precisely $\lambda\|A_I^{-1}V_I\| \le \delta_V < r_I/4$ for $0 \le \lambda \le 1$. This verifies the hypothesis of the fixed-parameter contraction at every y, and its solution moves by at most $2\lambda\delta_V$. The uniform mixed coefficient bounds of the same theorem control its dependence on the higher parameters. The sequential conclusion of Lemma 19.3 then applies under (21.14) to all intermediate scales. In particular, a product with $|g_iw_{i,e}| \le R_{\mathrm{en}} < r_q$ stays inside every parameter and solution neighborhood with margin. This is a check of the conditional force at moving parameters, not only at the joint minimizer.

Step 4: the image conditions. Both inherited image conditions are checked with the bound $s_q = R_{\mathrm{en}}$ for the scaled fluctuations. For each radius, the four zero-fluctuation terms of Lemma 19.7 satisfy

$$B^{-1}Z_\bullet(K_*\rho_\bullet) \le \rho_\bullet/16, \qquad C_{\Delta,\bullet}C_{a,\bullet}R_{\partial,\bullet} \le \rho_\bullet/16,$$
$$C_{\Delta,\bullet}C_{a,\bullet}e^{-a_Ww_{\mathrm{bd}}/2}K_*\rho_\bullet \le \rho_\bullet/16, \qquad C_{F,\bullet}\beta_{\mathrm{rec}} \le \rho_\bullet/16.$$

Their sum is $A_{0,\bullet}$. The initial good-cell complex at the first step under the Wilson measure and the endpoint protection rule change neither these analytic constants nor the bound on the current data. In the notation of the fixed construction constants of Lemma 19.7, the image conditions are

$$A_{0,\bullet} \le \rho_\bullet/4, \quad 1 - C_{T,\bullet}(K_*\rho_\bullet + R_{\mathrm{en}}) \ge \tfrac{1}{2}, \quad \frac{C_{T,\bullet}R_{\mathrm{en}}}{1 - C_{T,\bullet}(K_*\rho_\bullet + R_{\mathrm{en}})} + C_{\Delta,\bullet}R_{\mathrm{en}} \le \rho_\bullet/8. \tag{21.17}$$

Here $R_{\partial,\bullet} = K_*\rho_{\partial,\bullet}$. The margin in the larger construction domain of radius R_{raw} is, explicitly,

$$C_{\mathrm{lift},J}[K_* \max(\rho, \rho_{\mathrm{cl}}) + r + \beta_{\mathrm{rec}} + q_{\mathrm{raw}}] < R_{\mathrm{raw}}/8,$$

where q_{raw} is the fixed upper bound given by the row sums of the first derivative for the sequential product of scaled fluctuations and for all its initial segments; this bound is fixed before the eventual enclosing radius. Together with this margin, the image conditions give the image $3\rho_\bullet/8$ without spatial weights. The fixed interpolation of spatial rates in Theorem 20.14 then gives an absolute weighted image strictly below $\rho_\bullet/2$, so all evaluations and segments used for the force estimates above lie strictly in the uniform input ball, for both the classical and the quantum radius. These conditions on the parameters are already required by Theorem 21.5 and the analytic theorem, and they involve no test on the support of the measure.

Step 5: convexity on the enclosing product domain. The radius R_W of the scaled fluctuations is fixed independently of the logarithmic cutoff. We first compute its constants on the fixed larger perturbation domain. Then R_W is taken below the joint and sequential bounds, the bound of the larger construction domain, and the two inherited image bounds of the analytic theorem, as well as below $1/(4A)$ and $1/(16C_0)$, where A and C_0 are the constants of Lemma 20.3. The remaining deterministic choices satisfy

$$r,\ \beta_{\mathrm{rec}},\ \sigma_*\rho_{\mathrm{cl}} \le \frac{\lambda_* R_W}{6C_{\mathrm{en},J}}, \qquad R_{\mathrm{en}} = \frac{2C_{\mathrm{en},J}(r + \beta_{\mathrm{rec}} + \sigma_*\rho_{\mathrm{cl}})}{\lambda_*} \le R_W. \tag{21.18}$$

Here $C_{\mathrm{en},J}$ is evaluated on the fixed larger products, as in the proof of Theorem 21.8, before these radii are reduced. Then $AR_{\mathrm{en}} \le 1/4$ and $C_0R_{\mathrm{en}} \le 1/16$. When $C_0t^2\mathcal{L}_V \le 1/16$, the potential estimate of Theorem 20.14 yields

$$\|D_w^2(V - |w|^2/2)\|_{\mathrm{row,col},a'} \le \frac{C_0(R_{\mathrm{en}} + t^2\mathcal{L}_V)}{(1 - AR_{\mathrm{en}})^3} \le \frac{1/8}{(3/4)^3} = \frac{8}{27} < \frac{1}{2}.$$

This verifies the Hessian margin on the whole enclosing product domain, separately from any expansion on the smaller logarithmic cutoff domain.

Step 6: the logarithmic cutoff domain. Let $p(t) = A_{\mathrm{w}} \log(1/t)$, $c_J^{\log} = A_{\mathrm{w}}(J-1)(\log M)/2$, and $p^+(t) = p(t) + c_J^{\log}$. The common choice $p_i = p(t)$ lies in $[p(t), p^+(t)]$. Since $g_i/t = M^{(i-s+1)/2}$, the choice $p(g_i)$ at each intermediate scale lies in that interval as well; only the common choice is used here. With the fixed ceiling $H = 1 + E + \sigma_*$ and the construction constants of the analytic theorem, the relevant conditions on the coupling can be checked in the following sufficient form:

$$\begin{gathered} tp^+(t) < R_{\mathrm{en}}, \qquad C_J t p^+(t) < \tfrac{1}{2}, \\ \frac{C_J t[(p^+(t))^3 + p^+(t) + Hp^+(t)]}{1 - C_J t p^+(t)} \le \epsilon_J, \qquad 2t[(p^+(t))^3 + p^+(t) + Hp^+(t)] \le c_{z,J}, \\ C_0 t^2 \mathcal{L}_V \le \tfrac{1}{16}, \qquad C_1 t(\mathcal{L}_V + 2) < \min\{1/(4\sqrt{3}), p(t)/(2\sqrt{3})\}. \end{gathered} \tag{21.19}$$

The first line ensures that the chosen radii are enclosed, and the second checks the conditions on the interaction and on the auxiliary half-disc of Theorem 20.14. The last line checks the curvature and mean conditions of Lemma 20.5, in addition to the already fixed small radius R_W. Any needed provisional output remainder has the form $C_J t^2 (E + \sigma_*)[(p^+)^4 + (E + \sigma_*)(p^+)^2]$ and fits its fixed bound by the same reduction. Indeed, with $u = \log(1/t)$, each left side required to be small is bounded by a finite sum of terms $e^{-ku}(A_{\mathrm{w}} u + c_J^{\log})^l$ with $k > 0$, or by such a sum divided by a denominator at least $1/2$, and these tend to zero as $u \to \infty$. With the amplitude A_{w} fixed, we choose a finite U beyond all these thresholds and $g_* \le e^{-U} < e^{-1}$. Every condition then holds uniformly for $0 < t \le g_*$, and $p(t) \ge 1$. The ceiling may depend on A_{w}; it is independent of the side, the preceding depth, the number of steps, and the frozen coordinates. No expansion is applied on the larger radii R_{en}/t: that product is used only for the comparison of Lemma 21.11. □

21.3 Coordinate coverage and representatives satisfying the reconstruction identities

We show that every supported point of every relevant fiber has small relative coordinates in a suitable gauge, and that its normalized fluctuation coordinates lie in the enclosing product domain. We also construct, from the coarsest scale downward, the representatives satisfying the reconstruction identities, at which the densities will be evaluated. The comparison of the corresponding integrals with integrals over the fluctuation cutoff domain is Lemma 21.11 in Section 21.6. That comparison requires an incoming density bound, which is proved there by induction. The coverage statement proved here uses no density bound.

For a group of averaging steps, the conditional minimizers, Hessians K_i, and reconstruction maps C_t are those of Theorems 19.9 and 20.14, with the gauge transformation of

Lemma 19.5, which depends only on the target. For a supported fiber point, z^{act} denotes its free logarithmic coordinates and w^{act} its normalized fluctuation coordinates, obtained by inverting the reconstruction. The enclosing product domain is

$$\mathcal{K}_t = \prod_{i,e} \{|w_{i,e}| \le R_{\mathrm{en}}/t_{\max}\},$$

with R_{en} as in (21.18).

Theorem 21.8. *There exist $\epsilon_{\mathrm{en},J} > 0$ and $C_{\mathrm{en},J} < \infty$, with the dependence stated at the beginning of this section and independent of all later widths of boundary bands, removed bands, protected neighborhoods, and cells, such that the following holds for every large-field decomposition of Theorem 21.5. Assume its construction conditions, the two reconstruction-image conditions* (21.17)*, and $r + \beta_{\mathrm{rec}} < \epsilon_{\mathrm{en},J}$.*

1. *Let $1 \le s \le J$. Let (c, b_{rec}) be the output field and frozen coordinates of a configuration in the support of the stage measure, given either by a small representative of Theorem 21.5(2) (at the first step for a stopped measure, of Corollary 21.2), or by a representative obtained from such a representative by an output gauge change acting on the frozen coordinates as in Lemma 21.6(1)–(3). Assume that this representative and the associated fields before the target-dependent gauge transformation belong to the common larger construction domain of Theorem 20.14, and that its analytic frozen coordinates satisfy* (21.8)*. Let U be a configuration in the support of the fiber over (c, b_{rec}). Then there exists a correcting gauge transformation, equal to I at the roots of the block region, at the vertices of the frozen boundary layer on the side of the fixed complement (in particular at the endpoints v_e of the links across the boundary of the block region), and at all protected earlier endpoints and basepoints, with the following property. After the hierarchical tree gauge fixing, every relative constraint vector X_i of U, including its eliminated entries, and its free part z_i satisfy*

$$\max_{0 \le i < s} (\|X_i\|_\infty + \|z_i\|_\infty) \le C_J (r + \beta_{\mathrm{rec}}).$$

   They lie in the common domain of the local inverse of the block averaging constraint, with a fixed positive margin. The correcting gauge transformation is the composition of a smallness gauge and the lift, constant on blocks, of the inverse of its root values; its factors are not separately required to fix the roots. The inner endpoint u_e of a current link across the boundary of the block region may move before the tree gauge fixing, while the based transport is preserved, since its endpoints are fixed.
2. *Choose any small representative at the top of the decomposition, in the coordinate domains of part (1), whose frozen coordinates satisfy* (21.8)*. Define the reconstruction maps on their full spatially varying radii first, and descend through them, aligning the target at each step by the accumulated output gauge change. The unperturbed coordinates, conditional minimizers,*

and inverse square roots of the Hessians transform by blockwise adjoint orthogonal transformations, and the perturbing force is estimated separately. This constructs representatives satisfying the reconstruction identities at all stages, with

$$(T_M^s C_t(c, \zeta; b_{\mathrm{rec}}))|_{\Omega_t'} = c,$$

and for every point of every fiber over every resulting output datum, its normalized fluctuation coordinates satisfy

$$\max_{i,e} g_i |w_{i,e}^{\mathrm{act}}| \le \delta_{\mathrm{en}} = C_{\mathrm{en},J}(r + \beta_{\mathrm{rec}} + \sigma_* \rho_{\mathrm{cl}}).$$

With $R_{\mathrm{en}} = 2\delta_{\mathrm{en}}/\lambda_*$, each such point lies in the interior $|w_{i,e}^{\mathrm{act}}| \le R_{\mathrm{en}}/(2t_{\max})$ of the enclosing product domain $\mathcal{K}_t$. Each gauge transformation of Lemma 19.5 used here is I at all protected vertices, including the current endpoints of the links across the boundary of the block region. No estimate on the logarithm of the accumulated gauge transformation is used. The statement concerns every supported fiber point, including points near the boundary of the coordinate domains, not one selected point or almost every point under an auxiliary measure.

3. *At the first RG step for a stopped measure, every nonempty fiber over an output field and all input frozen coordinates that meets D_r has a representative in which all output links and input frozen coordinates are at most $C_{\mathrm{ad},J} r$. The scaled fluctuations of the unperturbed objective, $K_0^{1/2}(z^{\mathrm{act}} - z_0)$, are bounded by $C_J(r + C_{\mathrm{ad},J} r)$.*
4. *At the first RG step under the Wilson measure, let b^{near} be the near values, that is, the values on the near links of* (18.32)*, which are the links outside the block region read by a plaquette depending on an integration variable or by a path product of the block region in the initial good-cell complex. Let η_{deep} be the deep frozen group variables, the values on all remaining links. Then we have the exact identity*

$$S_W(U) = F_{\mathrm{bare}}(U_{\mathrm{int}}; b^{\mathrm{near}}) + E_{\mathrm{hole}}(b^{\mathrm{near}}, \eta_{\mathrm{deep}}),$$

where U_{int} denotes the integration variables and F_{bare} is the constrained Wilson-action objective of the first block integration, defined in Definition 18.13 and written in these variables; in the coordinates of Definition 18.6 this identity is (18.38)*. No smallness is imposed on η_{deep}; its factor $e^{-E_{\mathrm{hole}}/g_{\mathrm{base}}^2}$ remains with its original Haar integration and the original partition function. Every conditional minimizer, derivative, square root, and Haar disintegration factor of the integration variables is independent of η_{deep}. A plaquette containing only frozen links, near or deep, belongs to E_{hole}. At this step there is no inherited effective interaction, and the scaled fluctuations are bounded by $C_J(r + \beta_{\mathrm{rec}})$. The deep frozen group variables and exceptional values of the Borel extension in them are never logarithmized or inserted into a torus analytic action.*

The constants have the dependence stated at the beginning of this section, and they are uniform in the deep frozen group variables.

Proof. We first work at a small output representative and an arbitrary supported fiber point over it (Steps 1–3). Step 4 transports the estimate to the representatives produced from above, using only the unperturbed objective, and Step 5 estimates the perturbation. Step 6 constructs the representatives satisfying the reconstruction identities, Step 7 converts the bound to the enclosing product domain, and Steps 8 and 9 treat the first step for the two initial measures. For $s < J$, the image hypothesis includes the separately imposed interior image condition of that group of steps. Only its conditional local chart and force estimates are used here; for fewer than J steps there is no restoration of norms and no recursion of normalization constants.

Step 1: a smallness gauge for an arbitrary fiber point. We work at a small output representative (c, b_{rec}) supplied by Theorem 21.5, and keep this notation until Step 4. Its output links and the newly used near values and based data are bounded by $r/2$ and β_{rec}, respectively, and its analytic frozen coordinates obey (21.8). An arbitrary analytic background on a larger spatially varying radius need not satisfy the absolute bound on c used in this step. Fix any configuration U in the support of the fiber over this representative. By Theorem 21.5, there exists a smallness gauge S for the input links of the block region. We restrict S to the input vertices of the block region and set it equal to I elsewhere; internal links are unchanged by this restriction. By the endpoint protection rule, its lifts fix every earlier endpoint and basepoint. A current based transport, which is not a frozen coordinate, can move under this intermediate operation. We write $V = U^S$ on the block region and let u_{in} be its bound for interior links. At the initial input for a stopped measure we use $u_{\mathrm{in}} = r$; at later inputs $u_{\mathrm{in}} \le r/2$; at the first input under the Wilson measure $u_{\mathrm{in}} \le r$, after the fixed choice of A_8. By Lemma 21.1, for internal dependence neighborhoods reading only interior links, we have

$$\max_{e \text{ internal}} \rho_G((T_M^i V)_e) \le (10M)^i u_{\mathrm{in}}, \qquad 0 \le i \le s. \tag{21.20}$$

These dependence sets lie inside full blocks of the region. The display is not used for a path product reading a prescribed near value; such path products are bounded after the alignment below, using their frozen data as well as the interior bound.

Step 2: the root values. For each final root a of the region, let $h_a = S(a)^{-1}$. On an internal final link (a, a'), by the gauge covariance of the block averaging constraint, we have

$$c_{aa'} = h_a (T_M^s V)_{aa'} h_{a'}^{-1}.$$

Multiplying this identity by the appropriate inverse factor and using bi-invariance, we obtain

$$\rho_G(h_a h_{a'}^{-1}) \le \rho_G(c_{aa'}) + \rho_G((T_M^s V)_{aa'}) \le r + \beta_{\mathrm{rec}} + (10M)^s u_{\mathrm{in}}. \tag{21.21}$$

We lift h as a constant on each final block of the region, with value I off these blocks, and denote this lift by L (a gauge transformation, not the side of the torus). The total

correction is $H = LS$, since $(U^S)^L = U^{LS}$, and it equals I at every final root. At the vertices of the frozen boundary layer on the side of the fixed complement both factors are I, and the endpoint protection rule fixes the earlier frozen endpoints after lifting to their own lattices. An intermediate internal link either stays in one final block or crosses a single boundary between adjacent final blocks. In the first case L conjugates its value; in the second case its angle increases by at most the root increment in (21.21). Together with (21.20), this bounds all internal iterates by $C_J(r + \beta_{\mathrm{rec}})$. A component consisting of a single block has only the first case, and its root value causes no additional estimate.

The bound $\rho_G(c_{aa'}) \le r + \beta_{\mathrm{rec}}$ used in (21.21) belongs to this small representative. At the first step for a stopped measure, the representative of Corollary 21.2 has output bound $C_{\mathrm{ad},J} r < \beta_{\mathrm{rec}}$, by (21.6), so the displayed bound holds with $u_{\mathrm{in}} = r$.

Step 3: based transports and the branch. The endpoints of a current based transport are a root of the region and the endpoint of its link in the fixed complement, and the factors of H at both are I. The transport is therefore unchanged, although the endpoint u_e in the region can have moved. We now apply the hierarchical based tree gauge fixing of Lemma 21.1. Since its paths have length at most L_J, all internal links after the tree gauge fixing satisfy the same bound with a larger C_J. A link across the boundary of the block region that is read by a path product of the region is the inverse of such a bounded path times its prescribed based transport. It is therefore bounded by $C_J(r + \beta_{\mathrm{rec}})$ as well. Every path product of the region mixing integration variables and near values has at most L_J factors of these links and of its prescribed frozen data; its bound is $C_J(r + \beta_{\mathrm{rec}})$, including the contribution of the frozen data. We include the initial $C_{\mathrm{ad},J}$ and the constants for these mixed path products in this fixed C_J before choosing $\epsilon_{\mathrm{en},J}$ or the final radii. At the small representative, the relative vector X_i and its free part z_i then satisfy the estimate in part (1). We choose $\epsilon_{\mathrm{en},J}$ so that this bound is less than half the common uniqueness radius and all the fixed construction margins. Since the configuration solves the block averaging constraint, its eliminated entries equal the unique eliminated entries on this branch. This reasoning applies to the arbitrary point U itself, not to another point of its fiber, and neither S nor L has to fix the roots separately.

Step 4: transport to representatives produced from above. We carry the estimate to an output datum produced from above, using only the unperturbed objective with torus input. Let k be the accumulated output gauge change. Its lift, constant on blocks, preserves the tree identities, and the coarse-field lift of the target satisfies $U_0(c^k) = U_0(c)^{\widetilde{k}}$. Each relative factor therefore transforms as

$$e^{X_e} \longmapsto e^{\mathrm{Ad}_{k_a} X_e}, \qquad z_i \longmapsto A_{k,i} z_i, \tag{21.22}$$

where a is the root of its block and $A_{k,i}$ is block diagonal and orthogonal on the real color vectors. The equation for the eliminated edges transforms in the same way, as we see by

conjugating the constraint and using the uniqueness of its small inverse. We repeat this over the $s \le J$ intermediate scales. Since the changes at earlier marks are the identity, the prescribed frozen data are preserved. For a comparison of two representatives that are not related by a based change, the same formula uses their correspondingly transformed output data.

We apply this change separately to each fiber point and to the small representative of its gauge orbit. The given output datum and that small datum are outputs of the same configuration up to a gauge transformation, so the output change exists without choosing a different point of the fiber. Formula (21.22) transports the relative bound and the eliminated-edge inverse to every output datum as in part (1), even if its output links are bounded only by a larger analytic radius; no absolute bound $r/2$ on its iterates is asserted. All frozen coordinates used in this comparison satisfy (21.8), and only the changes of Lemma 21.6(1)–(3) are used.

All fields in this calculation, taken before the target-dependent gauge transformation, lie in the common larger construction domain of Theorem 20.14. In particular, the backgrounds at block boundaries, which need not be of order $M^{-s}\rho_{\mathrm{cl}}$, lie in that domain. The torus classical values used there are the gauge-invariant values on their common classical chart, as in Theorems 14.3 and 14.6, so their restrictions agree at such fields related by a compact gauge transformation in this chart. In a regional completion, the prescribed small frozen data transform at the endpoints of their paths. The earlier frozen coordinates that are completed by zero have both endpoints fixed by the endpoint protection rule, so appending them commutes with this change. For the unperturbed objective F_0 and the product color map A_k,

$$F_0(c^k, A_k z; b^k_{\mathrm{rec}}) = F_0(c, z; b_{\mathrm{rec}}). \tag{21.23}$$

This is the orthogonal transition of Theorem 14.3, restricted to the regional constraints and the fixed frozen data. Only the torus classical restriction is transported in this way.

By stationarity in z and the uniqueness of the unperturbed conditional minimizer, we have

$$z_0(c^k; b^k_{\mathrm{rec}}) = A_k z_0(c; b_{\mathrm{rec}}), \qquad K_0(c^k; b^k_{\mathrm{rec}}) = A_k K_0(c; b_{\mathrm{rec}}) A_k^{-1}. \tag{21.24}$$

The minimizer stays in the common uniqueness box; if boxes in scalar coordinates are used, the fixed comparison of color norms is included in the margin of the larger construction domain. An orthogonal conjugate of a positive square root is positive and squares to the conjugated matrix, so uniqueness of positive square roots gives the same identity for $K_0^{1/2}$ and $K_0^{-1/2}$. Applying this argument after each conditional minimization, we obtain it for every initial segment. At a small output representative, the unperturbed minimizers vanish when all current small parameters vanish, and the row sums of their

first derivatives are bounded by the constants of Theorem 20.14. Hence their size is $C_J(r + \beta_{\mathrm{rec}})$. Equations (21.22) and (21.24) carry the bound

$$\|K_0^{1/2}(z^{\mathrm{act}} - z_0)\|_\infty \le C_J(r + \beta_{\mathrm{rec}}) \tag{21.25}$$

to every output datum described in part (1). No bound on $\operatorname{Log} k$ is needed, since blockwise adjoint transformations have norm one for every compact value at the roots.

Step 5: the perturbation. We treat the perturbation separately, at fixed real $b = (\xi, b_{\mathrm{rec}})$. The uniform incoming radius, the boundary-distance comparison, and the conditional force estimates are Lemma 21.7; the analytic norm bounds are those of the recursion of Theorem 20.14, constructed without any density inequality. In the notation of Theorem 19.9, the preconditioned force is at most $C_J\sigma_*\rho_{\mathrm{cl}}$, the change of the constrained Hessian is at most $C_J\sigma_*$, and the rows of all square roots for initial segments are bounded by C_J. That theorem estimates the perturbation on the reconstructed field in the target-dependent gauge, including the full boundary-completion difference; it asserts no covariance of the perturbation, and none is needed. At each intermediate scale the inverse relation for the normalized fluctuations is

$$g_i w_i^{\mathrm{act}} = K_{P,i}(y_i; b_{\mathrm{rec}})^{1/2}\big(z_i^{\mathrm{act}} - z_{P,i}^*(y_i; b_{\mathrm{rec}})\big),$$

where y_i denotes the higher parameters of the fiber point, $z_{P,i}^*$ the perturbed conditional minimizer, and $K_{P,i}$ the perturbed conditional Hessian. On the smaller products for initial segments, the displacement of the minimizer from the unperturbed one is at most $2\delta_V \le C_J\sigma_*\rho_{\mathrm{cl}}$ at every y_i, by (21.13) and (21.14). The higher parameters of the fiber point belong to the required domains $\mathcal{T}_I$. Indeed, their unperturbed deviations satisfy the geometric bound just proved, and the conditional force condition leaves the factor-two margin of the neighborhoods for all scaled fluctuations up to R_{en}. We subtract and add the unperturbed minimizer, use (21.25), and apply the bounded rows of the square roots and inverse square roots. The substitutions of higher parameters have at most J stages. Their finite composition, including the derivatives of the higher minimizers in the integration and free higher parameters specified in Theorem 19.9, gives

$$\max_{i,e} g_i |w_{i,e}^{\mathrm{act}}| \le C_{\mathrm{en},J}(r + \beta_{\mathrm{rec}} + \sigma_*\rho_{\mathrm{cl}}). \tag{21.26}$$

The construction conditions ensure that these substitutions stay inside the conditional neighborhoods of the joint branch; we do not replace these neighborhoods by arbitrary slices of a joint box of free coordinates. The constants are evaluated on the fixed larger products and on a fixed perturbation ceiling, before the eventual small radii and widths. No perturbed derivative in a frozen coordinate ξ or in an earlier frozen coordinate is taken; these coordinates enter only as fixed real parameters of the uniform coefficient estimates.

Step 6: representatives satisfying the reconstruction identities. The construction downward is a finite induction. We start with any small top representative given by Theorem 21.5, including the bounds (21.8). At a boundary where coordinates are frozen, the hierarchical tree transports are I by Lemma 21.1, and the gauge transformation of Lemma 19.5 is I at their endpoints. Undoing the basing therefore inserts the already chosen new frozen values directly. At the next lower group of averaging steps, we lift the accumulated output change, take the free logarithmic coordinates of any configuration in its fiber, and invert the reconstruction defined beforehand. By the branch argument of Steps 1–4 and (21.26), these inverse coordinates lie in its domain. The reconstruction has the same target and the same free coordinates, and uniqueness of the eliminated-edge inverse identifies the reconstructed configuration, before the gauge transformation, with the configuration aligned by the accumulated output gauge change. We then apply the gauge transformation of Lemma 19.5, which depends only on the target; by that lemma, the target is unchanged and every protected vertex is fixed. This produces the present representative and permits the next step of the descent. By Lemma 21.6(1)–(2), the subsequent lifts and the based correcting and tree gauges fix every frozen coordinate chosen at this step, so (21.8) holds throughout the family, and all supported points over each fixed output datum are included. Other top representatives satisfying the same bounds on frozen coordinates are treated in the same way. Each step uses only the representative above and the analytic maps defined beforehand on their full radii, so the induction assumes no completed family of representatives. Keeping all choices gives all fibers over all resulting output data and the identity for the target in part (2).

Step 7: the enclosing product domain. At output side m, we have $g_i = t_{\max} M^{(i-s+1)/2} \geq \lambda_* t_{\max}$. Dividing (21.26) by g_i, we obtain

$$|w_{i,e}^{\mathrm{act}}| \leq \frac{\delta_{\mathrm{en}}}{\lambda_* t_{\max}} = \frac{R_{\mathrm{en}}}{2t_{\max}}.$$

Every point of $\mathcal{K}_t$ has $g_i |w_{i,e}| \leq R_{\mathrm{en}}$. Both the classical and the quantum image conditions are imposed on the whole product $\mathcal{K}_t$, not only on the supported subset or on the logarithmic cutoff domain.

Step 8: the first step for a stopped measure. We fix one point of a nonempty fiber over an output field and all input frozen coordinates, and apply Corollary 21.2 to it. In the resulting representative, all output links and all based input transports are at most $C_{\mathrm{ad},J} r$, and the remaining input frozen links are smaller than r. For any other point of the same fiber, we take its own gauge transformation into B_r, cancel its root values by the lift of the inverse root values, and cancel its gauge transformation at the vertices of the fixed complement. Equations (21.20) and (21.21) hold with $u_{\mathrm{in}} = r$ and the output increment $C_{\mathrm{ad},J} r + (10M)^s r$. All input variables used analytically, including all input frozen coordinates, are small after the tree gauge fixing. The unperturbed estimate is

$C_J(r + C_{\mathrm{ad},J} r)$. This is the regional form of the coordinates of Theorem 14.3 at the first step; it is uniform in the preceding depth and is not applied to frozen coordinates created at later steps.

Step 9: the first step under the Wilson measure. We use the initial good-cell complex of Theorem 21.5(4), together with the internal coordinates of Definition 18.6 and the completion of Definition 18.13: the links across the boundary of the block region are completed by (18.33), the other links by (18.34), and $\mathcal{P}_{\mathrm{var}}$ is a fixed list as in (18.35)–(18.36), namely the list of the split made in this step. The near links of (18.32) carry the near values b^{near}, and the deep links carry the deep frozen group variables η_{deep}. The hypothesis of Definition 18.13(3) that the near values lie in the identity chart is the conclusion of Theorem 21.5(4), since every near link lies in the initial good-cell complex. Indeed, the links of the path products in $\mathcal{E}_{\Omega}^{\mathrm{dep}}$ lie there because of the inset by the full dependence neighborhood. The plaquettes incident to $\mathcal{L}_0$ lie within one input step of a block of the region, while Theorem 21.5(4) moves inward by a full layer of cells and the full dependence neighborhood. The conversion between the value on a link across the boundary and its based value is included in $C_{\mathrm{conv},J}$.

In the hierarchical tree coordinates, we partition the plaquettes according to whether their Wilson term depends on an integration variable. By the definition of the near links, every term in the first class uses only integration variables and near values, and the sum of these terms is F_{bare}. Every remaining term is a function of frozen variables only and is assigned to E_{hole}, even if its plaquette contains both near and deep links. This partitions the sum $S_W = 4\sum_p q(U_p)$, and Lemma 18.14(1) implies the exact split (18.38), which is the identity in part (4). In particular, every objective of the integration variables and all its derivatives are independent of η_{deep}, without any estimate of a small remainder. The Haar disintegration path products also avoid the deep links, because of the inset by the full dependence neighborhood. By (18.39), the objective agrees with the objective of Theorem 18.12 at preceding depth zero, up to a function constant in the integration variables. The external factor $e^{-E_{\mathrm{hole}}/g_{\mathrm{base}}^2}$ remains the one in (18.38), with its original Haar variables and partition function.

We apply Lemma 18.14(2)–(3) to the block region of the first step, with the prescribed near completion. Its embedding of the free coordinates is A_Ω in (18.15), and its extraction matrix is (18.16). Equations (18.40)–(18.42) apply to the list $\mathcal{P}_{\mathrm{var}}$, including every case near the boundary. By (18.43), the flat joint Hessian in the free coordinates then satisfies

$$K_\Omega = \widehat{A}_\Omega^{\mathsf{T}} d_{\mathrm{var}}^{\mathsf{T}} d_{\mathrm{var}} \widehat{A}_\Omega \geq \lambda_{M,J} I,$$

It has uniformly bounded absolute rows and columns and the range (18.44), independently of the region and of the deep frozen group variables. By (18.39), this is also the case $d_0 = 0$, $\kappa_* = 1$ of Theorem 18.12. Every principal free matrix and every real Schur

complement of an initial segment keeps a fixed-J gap, by (18.47). No Hessian of a field outside the region is inverted.

All Wilson and constraint derivatives at this step are derivatives of finite local path products. Their absolute row sums are bounded on a fixed smaller identity chart, independently of the deep frozen group variables. We obtain the weighted inverses without a volume estimate. First let K be the flat joint matrix K_Ω, or one of its principal free submatrices, before the minimization over a lower scale. By Lemma 18.14(3), $\lambda_{M,J} I \le K \le Q_{M,J} I$, and K has range $D_{M,J}$. We set $a = 2Q_{M,J}$ and $T = I - K/a$. Then T has norm at most $q = 1 - \lambda_{M,J}/a < 1$, and the entries of T^k vanish beyond maximum distance $kD_{M,J}$, hence beyond graph distance $3kD_{M,J}$. By the bound on the density of labels in the proof of Lemma 18.14, each row of T^k has at most $C_J(k+1)^3$ nonzero entries, each of absolute value at most q^k. For $b > 0$ with $qe^{3bD_{M,J}} < 1$, the series (18.48) for K^{-1} and $K^{-1/2}$ have uniformly summable rows and columns, weighted in the graph distance; the second is the scalar binomial series applied to T, whose coefficients are at most one. Small complex perturbations are inverted by the Neumann series about these matrices. For the conditional matrices obtained after minimization over lower scales, we use (18.47) and the bounds for Schur complements in the proof of Lemma 18.14(3), which rest on the argument of Combes and Thomas [61]. These matrices and their inverse square roots have uniform exponential row and column bounds, although the Schur complements need not have finite range. The factors M^i are included in the corresponding matrices.

The equation for the conditional minimizers is a contraction on a fixed smaller box. We first prove this at the small representative used in Steps 1–3. There, its force at zero fluctuation is $C_J(r + \beta_{\mathrm{rec}})$, and by the third-derivative bound in the proof of Lemma 18.14(4) its derivative changes by at most C_J times the radius of the box. At this representative, the coarse argument of (18.45) is $\operatorname{Log} c$, and $\|\operatorname{Log} c\|_\infty$ and $\|\xi\|_\infty$ are at most $C_J(r + \beta_{\mathrm{rec}})$. In the choice of $\epsilon_{\mathrm{en},J}$, we require in addition $C_J(r + \beta_{\mathrm{rec}}) \le \epsilon_{M,J}$, and we require the radius of the box to be at most $\epsilon_{M,J}$, so that (18.45) applies on the whole box, including the coarse field. We reduce the radius of the box so that the inverse times the change of the derivative is at most $1/2$; the solution then has size $C_J(r + \beta_{\mathrm{rec}})$. The finitely many conditional products and their image margins are those required in Theorems 19.9 and 20.14, and their specialization at this step has no inherited effective interaction. Applying the inverse formula for the normalized fluctuations, we obtain the bound on the scaled fluctuations in part (4) at the small representative, without the perturbative term.

For an output representative transported from above, we use the output gauge change of Step 4, with the frozen values transformed consistently. The Wilson terms are traces of plaquette variables, so the exact split in part (4) gives for F_{bare} the same covariance identity as (21.23). Its conditional minimizers and Hessians therefore transform as in (21.24), and their square roots transform by the same orthogonal conjugations. Hence the minimizers at the transported representative are the images of those at the small

representative, and each normalized fluctuation $w_{i,e}$ is rotated by an orthogonal map, so the bound on the scaled fluctuations carries over. No bound of order $r + \beta_{\mathrm{rec}}$ on the transported coarse links is needed.

All constants arose from local path products, fixed construction products, and their row-sum bounds. □

21.4 Pointwise gauge-invariant densities

The densities of the stage measures will be evaluated at representatives satisfying the reconstruction identities, which form a set of Haar measure zero. We therefore construct an explicit Borel density and prove that it is gauge invariant at every point. The coverage hypothesis of Lemma 18.7 is supplied by Theorem 21.8(1), which uses no density bound.

Theorem 21.9. *Fix a finite lattice, a preceding depth that is a multiple of J, an initial measure (a stopped measure or the Wilson measure), and a large-field decomposition $\mathcal{X}$ of Theorem 21.5. At stage t, let X_t be the product of the link variables of the current block region and of all independent frozen links and based transports, each on the lattice where it was frozen. Let H_t be the product of the Haar probability measures on these factors, and let $\eta_t^{\mathcal{X}}$ be the stage measure, a subprobability measure. Let Γ_t be the group of consistent gauge assignments on the finite multiscale transport graph formed by these endpoints: repeated physical vertices are identified, and each recorded object transforms at the endpoints of its path. In particular, Γ_t contains arbitrary values at the output roots and their lifts, constant on the blocks of the region, together with the induced changes of earlier frozen coordinates used in Theorem 21.5. For a frozen link on the lattice of level ℓ and for a based transport, the action is*

$$b_{xy} \longmapsto k_x^{[\ell]} b_{xy} (k_y^{[\ell]})^{-1}, \qquad \widehat{b}_e \longmapsto k_{\alpha_e}^{[\ell]} \widehat{b}_e (k_{v_e}^{[\ell]})^{-1}, \qquad \widehat{b}_e = U(\sigma_e) b_e.$$

For each fixed assignment, this is a left and right multiplication in the independent group variables, and it preserves H_t.

There exists an explicitly defined nonnegative Borel density p_t such that

$$\eta_t^{\mathcal{X}} = p_t H_t, \qquad p_t(x^k) = p_t(x) \quad \text{for every } x \in X_t \text{ and } k \in \Gamma_t.$$

On the gauge-invariant chart domain containing the measure, p_t is given by the parameter integrals of the Haar disintegration formulas, with every indicator of the decomposition and every protected external factor retained, patched by their exact equalities on overlaps of fixed gauge translates. On the invariant complement of this domain, which has zero mass, its value is zero. In particular, the values of p_t at representatives satisfying the reconstruction identities are given by these formulas pointwise.

More explicitly, if $Z_{c,b_{\mathrm{rec}}}$ is the domain of the free coordinates of the fiber over an output datum (c, b_{rec}) satisfying the coordinate conditions of Theorem 21.8, then the outgoing density is

$$p_t^{\mathrm{out}}(c, b_{\mathrm{rec}}) = \int_{Z_{c,b_{\mathrm{rec}}}} \chi_t(c, z, b_{\mathrm{rec}})\, p_t(U_{c,b_{\mathrm{rec}}}(z), b_{\mathrm{rec}})\, J_{\mathrm{CO}}(c, z; b_{\mathrm{rec}})\, dz,$$

where χ_t is the product of the indicators of the decomposition and of the support, and the normalized integrals over the tree variables are kept until the covariance under based gauges has been applied. The factor at scale i of the Haar disintegration density J_{CO} is exactly

$$c_{\mathrm{Haar}}^{f_i} \frac{\prod_{e \text{ outside the trees}} j_H(\Gamma_{i,e})}{\prod_a \det D_{X_{e_a^*}} \mathsf{C}_a(\Gamma_i)}, \qquad j_H(X) = \mathrm{sinc}^2(|X|/2),$$

where the product in the denominator runs over the internal constraints, f_i is the number of free group variables at scale i, and the numerator includes the Haar factors of the eliminated edges. The reference measure already contains the Haar measure of the output field; no further coarse Haar density, Gram determinant, or orbit-volume factor occurs. For the stage densities and the tests of the decomposition, the covariance under based tree gauges makes each tree Haar integral equal to one; this elimination is not valid for arbitrary noncovariant Borel densities. Basing at a fixed field on the block region is the triangular Haar translation $b_e \mapsto U(\sigma_e) b_e$, with Jacobian one.

These statements concern the stage measures and the block averaging map with its Borel extension; they assert no gauge invariance or overlap identity for an auxiliary classical action or effective interaction. Deep frozen group variables, including exceptional values of the Borel extension, are allowed. All identities hold in each finite dimension and introduce no factor depending on the size, the number of steps, the shape, or the depth. The analytic chart bounds used in the construction have the dependence stated at the beginning of this section.

Proof. We construct the density and prove its pointwise invariance together. This avoids evaluating an unspecified Radon–Nikodym derivative on a set of representatives.

Step 1: the endpoint group. We identify repeated physical vertices in the finite list of endpoints. An endpoint assignment is an element of the resulting finite product of copies of $\mathrm{SU}(2)$, and any additional consistency identifications give the corresponding closed subgroup. Its action on an independent group variable is a left and a right multiplication by fixed matrices. Hence H_t is preserved by each fixed assignment, with no assumption of probabilistic independence of the frozen coordinates under $\eta_t^{\mathcal{X}}$.

Step 2: the initial density. At the initial scale we use the pointwise density of the Wilson measure, or the gauge-invariant density of the stopped measure, multiplied by the indicator of the decomposition. The initial density is invariant: the Wilson plaquette variables transform by conjugation, and the density of the stopped measure is the gauge-invariant density of Theorem 14.6. The indicator of the decomposition is invariant as well, since the decomposition is determined by traces of plaquette variables and by

deterministic dependence lists. The block averaging map is equivariant also on the exceptional set of its Borel extension: conjugation fixes $-I$, and the replacement reference transport transforms at the same two endpoints. These are pointwise statements. The first freezing is a splitting into independent variables followed by the triangular basing, treated in Step 5.

Step 3: the outgoing density on a chart. Assume that the incoming density has been constructed. At an output datum satisfying the coordinate conditions, we use Lemma 18.7 with all indicators; its coverage hypothesis is part (1) of Theorem 21.8. We keep the normalized tree variables $\mathfrak{f}$ at first. If J_i denotes the factor at scale i, we define the local outgoing value to be

$$\int dH(\mathfrak{f}) \int \mathbf{1}_{Z_{c,b_{\mathrm{rec}}}}(z,\mathfrak{f})\chi_t(c,z,\mathfrak{f},b_{\mathrm{rec}})p_t(U_{c,b_{\mathrm{rec}}}(z,\mathfrak{f}),b_{\mathrm{rec}})\prod_{i=0}^{s-1} J_i\,dz. \tag{21.27}$$

An indicator already contained in p_t is not counted again; it may equally be written again, since indicators are idempotent. This convention keeps all tests of the decomposition, including those whose information has already been integrated. By the disintegration identity, testing (21.27) against any nonnegative Borel function of the output gives the pushforward measure on this chart.

Step 4: pointwise covariance. We prove that these integrals are equal under the full group of consistent endpoint assignments. A fixed output assignment has a lift, constant on blocks, through the centered partitions of the block region; at earlier marks we use its prescribed values on the lattices of the marks. There is no conflict, since a mark in the preimage of a block of the region would have excluded that block, and repeated physical values are identified by consistency. Additional changes of the interior frames can be absorbed in the tree variables. The block averaging map and the map recording the frozen coordinates are equivariant, so the lift is a bijection of the fiber over (c, b_{rec}) onto the fiber over $(c^k, b_{\mathrm{rec}}^k)$. It preserves every test, including an equality in a threshold and every condition at earlier scales.

On the hierarchical tree section, the part of the lift that is constant on blocks acts as in (21.22). The adjoint action is orthogonal because it preserves $-2\,\mathrm{tr}(XY)$. Its determinant is 1, since it is a continuous function on the connected group $\mathrm{SU}(2) \simeq S^3$ with values in $\{-1,1\}$ and equals 1 at I. Hence the change of free coordinates preserves dz, and uniqueness of the eliminated-edge inverse transports every eliminated coordinate as well. The factors j_H are radial and unchanged. The derivative matrix of the eliminated edges is multiplied on its row and column frames by these adjoints of determinant one, so its determinant is unchanged, including its positive sign on the real branch. The constants $c_{\mathrm{Haar}}^{f_i}$ are the same. If the lift changes interior tree frames, the tree variables change by

left and right Haar translations, before any tree integral is removed. Using the inductive pointwise identity for p_t, we obtain

$$\begin{aligned} p_t^{\mathrm{out}}(c^k, b_{\mathrm{rec}}^k) &= \int_{Z_{c^k,b_{\mathrm{rec}}^k}} \chi_t(c^k, z', b_{\mathrm{rec}}^k)\, p_t(U_{c^k,b_{\mathrm{rec}}^k}(z'), b_{\mathrm{rec}}^k) J_{c^k,b_{\mathrm{rec}}^k}(z')\, dz' \\ &= \int_{Z_{c,b_{\mathrm{rec}}}} \chi_t(c, z, b_{\mathrm{rec}})\, p_t(U_{c,b_{\mathrm{rec}}}(z), b_{\mathrm{rec}}) J_{c,b_{\mathrm{rec}}}(z)\, dz = p_t^{\mathrm{out}}(c, b_{\mathrm{rec}}). \end{aligned} \tag{21.28}$$

The normalized tree integrals are understood in both lines when they have not yet been removed. This is an identity of explicit parameter integrals at each output datum; no uniqueness almost everywhere is used.

Step 5: freezing. Freezing has the required covariance too. We orient a link across the boundary of the block region from its endpoint u_e in the region to its frozen endpoint v_e, and let α_e be the root of its hierarchical transport. Cancellation at the interior vertices gives

$$\begin{aligned} U_{v^k}(\sigma_e) a_e^k &= k_{\alpha_e} U_v(\sigma_e) k_{u_e}^{-1} k_{u_e} a_e k_{v_e}^{-1} \\ &= k_{\alpha_e} \widehat{b}_e k_{v_e}^{-1}. \end{aligned} \tag{21.29}$$

At fixed v, the map from the independent variables a_e to their based transports is a product of left Haar translations. Together with the unchanged v, this is a triangular measure-preserving bijection; its inverse multiplies by $U_v(\sigma_e)^{-1}$. Recording any other link as a frozen link is Fubini's splitting of product Haar measure. The endpoint protection rule makes these endpoint changes consistent at every later stage. Equations (21.28) and (21.29) prove the inductive covariance for arbitrary values at the output roots and for all induced changes of earlier frozen coordinates.

Step 6: Borel patching. Before inserting the tests, we take the open chart domains of small block-region variables and small near values, with the positive margins of their inverses; the deep frozen group variables need no logarithm. Their gauge saturation $\mathcal{O}_t$ is open and invariant, and the proofs of Theorems 21.5 and 21.8 put all the mass in $\mathcal{O}_t$. A finite product of spheres is second countable and has a countable dense subset, for instance obtained by approximating quaternion coordinates by rational ones and normalizing; the finite endpoint subgroup has the same property after the consistency identifications. If a point is moved into an open chart by some fixed gauge assignment, the set of assignments doing so is open and meets this countable dense set. Hence countably many fixed gauge translates of the small charts cover $\mathcal{O}_t$, and their coordinate charts can be chosen countably as well.

On one such chart, the integrand of (21.27), extended by zero outside its domain in a fixed box of free and tree coordinates, is a nonnegative Borel function. Indeed, the Haar disintegration denominators and the reconstruction maps are continuous on their

branches, and the tests, including values of the Borel extension at the deep frozen group variables, are Borel. By Tonelli's theorem, its integral with respect to the finite product of Lebesgue and Haar measures on the box is a Borel function of (c, b_{rec}).

On an overlap, the fixed gauge assignments relating two charts give the change of variables in (21.28). Since both formulas include the same domain, they agree at every point of the overlap. We use the first chart in the countable cover containing a point to define p_t there, and set $p_t = 0$ on $X_t \setminus \mathcal{O}_t$. This function is Borel, it is a density by the disintegration identities, and it does not depend on the chart used. To check invariance under an arbitrary $k \in \Gamma_t$, we take charts containing x and x^k and perform the same change of variables; this proves equality of the two values also when k is not in the countable dense set. The complement of $\mathcal{O}_t$ is invariant and has zero mass, so the zero extension is invariant there as well. Countability was used only to define a Borel function, not to sum densities or to introduce a multiplicity of charts.

Step 7: removal of the tree integrals. Finally, at fixed target and frozen coordinates, we apply a based tree gauge fixing. The pointwise covariance just proved makes the density and its tests independent of the tree variables in (21.27), so each Haar probability integral over tree variables equals one. Removing them, we obtain the formula in the statement. Its factors at the scales i are exactly those of Lemma 18.7, in particular the numerator with the eliminated edges and the single inverse determinant of the eliminated-edge derivative. The Haar measure of the output is already the reference measure at the next scale, so this change of variables has no room for a further coarse Haar density, a Gram determinant, or an orbit-volume factor. For an arbitrary noncovariant Borel input density, the tree average would remain in (21.27), and its removal uses the covariance of the stage density. The argument uses the Haar disintegration before the change to normalized fluctuation variables. The deep frozen group variables, including exceptional values of the Borel extension, remain compact Borel data throughout. □

21.5 Freezing and substitution of frozen coordinates

When integration stops on part of the region, the corresponding variables become frozen coordinates. The next lemma shows that, at the representatives of the next stage satisfying the reconstruction identities, the inverse of the freezing map inserts the frozen values directly into the old variables. This identifies the density after freezing with the density before freezing at the same configuration, also on sets of Haar measure zero, and gives the exact substitution rules for the analytic functions.

Lemma 21.10. *At every boundary of a large-field decomposition where coordinates are frozen, use the hierarchical tree transports σ_e of Lemma 21.1, with the tree conditions at coarser scales fixed first. Split the old output into the remaining link variables v, the variables a_e on the links*

across the boundary of the block region, and the other links to be frozen. The freezing map $\mathcal{A}_t$ replaces each such variable by its based transport

$$\widehat{b}_e = U_v(\sigma_e)a_e$$

and records the other links as frozen links on that lattice. At fixed v this map preserves the product Haar measure and has Jacobian one.

Let $b^\sharp$ denote the new frozen group values and $\xi^\sharp = \operatorname{Log} b^\sharp$ their logarithms. For every reconstructed configuration of the next stage in the family of representatives satisfying the reconstruction identities,

$$v = C_{t+1}(c', \zeta'; b_{\mathrm{rec}}, b^\sharp),$$

the hierarchical tree transport has value I: each of its tree factors is I, and the gauge transformation of Lemma 19.5 is I at its two endpoints. All protected earlier endpoints are fixed as well. Hence

$$a_e = U_v(\sigma_e)^{-1}\widehat{b}_e = \widehat{b}_e, \qquad \mathcal{A}_t^{-1}(v, b_{\mathrm{rec}}, b^\sharp) = (v \oplus b^\sharp, b_{\mathrm{rec}}),$$

and the density versions of Theorem 21.9 satisfy the pointwise identity

$$p_{t+1}(v, b_{\mathrm{rec}}, b^\sharp) = p_t^{\mathrm{out}}(v \oplus b^\sharp, b_{\mathrm{rec}}).$$

At this configuration, all omitted old variables are exactly their new frozen values, based transports or links, with the same weights and indicators. In analytic functions, $\xi^\sharp$ is inserted in the corresponding analytic arguments. In particular, the freezing of the effective interaction subtracts only the value $R^{\mathrm{out}}(0 \oplus \xi^\sharp)$ and transfers it with a minus sign to Λ, and the freezing of the classical action is $E_{\mathrm{new}}(v) = E^{\mathrm{out}}(v \oplus \xi^\sharp)$. These are exact finite identities, uniform in the number of steps, the topology, the depth, and the coupling. They compare the same configuration and require no overlap identity between auxiliary functions at different gauges.

Proof. We fix the deterministic geometry of the freezing. The remaining variables and the independent variables on the links across the boundary are different coordinates of the old output product. At fixed v, left multiplication by each fixed matrix $U_v(\sigma_e)$ preserves the Haar probability measure of such a variable, and the inverse multiplication is defined for every value. Integrating first in these variables, we obtain the triangular statement with Jacobian one for every nonnegative Borel integrand; earlier frozen coordinates and the other frozen links do not change.

We verify the value of the transport at a reconstructed configuration. On the based section of one scale, the tree equations set each ordered tree factor to I, and the fixing gauges of the coarser scales, lifted as constants on the finer blocks, conjugate these factors and leave them equal to I. By induction over the scales, with the coarser conditions fixed first, every factor of the prescribed hierarchical transport is I on the hierarchical tree section. This is the finite algorithm of Lemma 21.1, and it uses no path through an

eliminated edge. Hence the product has value I for every target and every free coordinate in the domain, not only at zero fluctuation.

The reconstructed configuration is obtained from that section by the gauge transformation of Lemma 19.5. This gauge transformation multiplies a transport from α_e to u_e by its values at exactly these two vertices, and both values are I by that lemma, with the full set of protected vertices supplied by Theorem 21.5. The transport remains I. On the lattices of earlier frozen coordinates, the endpoint protection rule fixes all their endpoints. This proves, at this reconstructed configuration,

$$U_v(\sigma_e)^{-1}\widehat{b}_e = \widehat{b}_e.$$

Inverting the freezing map therefore inserts the new based transports directly into the old variables on the links across the boundary, and every other omitted variable is its new frozen link value. At this configuration, the inverse map is $(v, b_{\mathrm{rec}}, b^\sharp) \mapsto (v \oplus b^\sharp, b_{\mathrm{rec}})$.

The general formula for the density after freezing is the composition of the old outgoing density with the inverse triangular map, since its Haar Jacobian is one. We use the versions of Theorem 21.9 on both sides; that construction uses the same formulas and their pointwise overlap identities. Composing with the inverse, we obtain the pointwise identity, even when the reconstructed configuration lies in a set of representatives of Haar measure zero. All weights and indicators of the decomposition are values of the same functions at the same old configuration.

For a variable that was analytic before this freezing, its new group value lies in the small chart of frozen coordinates, and we insert $\xi^\sharp = \operatorname{Log} b^\sharp$ there. The deep frozen group variables at the first step under the Wilson measure are fixed parameters instead and are not part of this logarithmic substitution. For every old analytic function F we have the exact identity

$$F(v \oplus \xi^\sharp) = \big[F(v \oplus \xi^\sharp) - F(0 \oplus \xi^\sharp)\big] + F(0 \oplus \xi^\sharp). \tag{21.30}$$

Applying it to R^{out}, the factor $e^{\Lambda^{\mathrm{out}} - R^{\mathrm{out}}}$ becomes

$$e^{\Lambda^{\mathrm{out}} - R^{\mathrm{out}}(0\oplus\xi^\sharp)} e^{-[R^{\mathrm{out}}(v\oplus\xi^\sharp) - R^{\mathrm{out}}(0\oplus\xi^\sharp)]},$$

which proves the minus sign of the transfer to Λ. For the classical function we keep the whole value $E^{\mathrm{out}}(v \oplus \xi^\sharp)$, including its constant. Centering the effective interaction changes no first derivative: the new first derivative in the remaining variables is the old one evaluated at $(0, \xi^\sharp)$, and it is kept. □

21.6 Conditional integration and normalization on large-field decompositions

This section proves the density bounds used in Section 22. The induction has three stages. First, the analytic effective actions, effective interactions, normalization constants,

and reconstruction maps are defined from fine to coarse scales, by the recursion of Theorem 20.14, for every value of the frozen coordinates and without reference to any measure. Second, representatives satisfying the reconstruction identities are chosen from coarse to fine scales, using these maps. Third, the stage densities are bounded from fine to coarse scales at exactly these representatives. The construction is not circular, since each stage uses only objects defined in the preceding ones. One step of the third stage is the following comparison, which needs an incoming density bound; the bound is supplied by the induction itself.

Lemma 21.11. *Assume the hypotheses of Theorem 21.8, together with the conditions* (21.18) *and* (21.19)*, which give the hypotheses of Lemma 20.5 on the whole enclosing product domain. Fix a stage t and an output datum (c, b_{rec}) of the family of representatives satisfying the reconstruction identities in Theorem 21.8(2), with real frozen coordinates, and define the fluctuation cutoff domain*

$$\mathcal{W}_t = \prod_{i,e} \{|w_{i,e}| \le p(t_t)\}, \qquad t_t = \max_i g_{t,i}, \qquad p(t) = A_{\mathrm{w}} \log(1/t). \tag{21.31}$$

Let $V = V_{c,b_{\mathrm{rec}}}$ be the conditional fluctuation potential of Theorem 20.14 at this datum, and let $S_{c,b_{\mathrm{rec}}} \subset \mathcal{K}_t$ be the set of normalized fluctuation coordinates of the supported fiber points over (c, b_{rec}). For an invariant Borel function $0 \le \chi \le 1$, let $G_{t,\chi}(c, b_{\mathrm{rec}})$ be the outgoing density of Theorem 21.9 at (c, b_{rec}) with χ inserted in the integrand. Suppose that there exist a finite prefactor $P_t(c, b_{\mathrm{rec}}) \ge 0$ and a Borel function χ_t on $S_{c,b_{\mathrm{rec}}}$ with values in $[0,1]$ such that

$$G_{t,\chi}(c, b_{\mathrm{rec}}) \le P_t(c, b_{\mathrm{rec}}) \int_{S_{c,b_{\mathrm{rec}}}} \chi_t(w) e^{-V(w)}\, dw. \tag{21.32}$$

Then $S_{c,b_{\mathrm{rec}}}$ is a Borel set, $0 < \int_{\mathcal{K}_t} e^{-V}\, dw < \infty$, and

$$G_{t,\chi}(c, b_{\mathrm{rec}}) \le (1-\delta_t)^{-1} \widetilde{F}_t(c, b_{\mathrm{rec}}), \qquad \widetilde{F}_t = P_t(c, b_{\mathrm{rec}}) \int_{\mathcal{W}_t} e^{-V(w)}\, dw,$$

with $0 \le \delta_t < 1$, $\delta_t \le 6\mathsf{b}_t e^{-p(t_t)^2/48}$, and $\mathsf{b}_t \le C_J m^3$, where b_t is the number of three-dimensional free blocks of fluctuation variables of the step. Factors depending only on the output datum multiply both sides. The indicators are removed only in this upper bound. The constants have the dependence stated at the beginning of this section, and they are uniform in the deep frozen group variables.

At the first RG step, for either initial measure, (21.32) *holds with equality. In that case P_t consists of the inverse partition function of the initial measure, the external weights, the Haar disintegration constants, the powers of the couplings, the output classical factor, and the zero-fluctuation factors, and χ_t is the product of χ and the indicators composed with the inverse coordinates. At a later stage,* (21.32) *is obtained by inserting an incoming bound on the density at the representatives satisfying the reconstruction identities, with the incoming multiplicative loss included in the same prefactor P_t; this incoming bound is proved in Theorem 21.12.*

Proof. At an output datum, the set $S_{c,b_{\mathrm{rec}}}$ is defined with all indicators still inserted, and before any upper comparison the Haar disintegration is the exact formula of Lemma 18.7. The radii of $\mathcal{W}_t$ belong to the logarithmic family of Theorem 20.14 and satisfy $t_t p(t_t) < R_{\mathrm{en}}$ by (21.19); for a complete RG step $t_t = t_{\max}$. The product $\mathcal{K}_t$ is used only in this positive comparison, never as the product for the expansion defining the analytic output. At the first step, the Haar disintegration and the change to normalized fluctuation variables give the density integral in the form

$$G_{t,\chi}(c, b_{\mathrm{rec}}) = P_t(c, b_{\mathrm{rec}}) \int_{S_{c,b_{\mathrm{rec}}}} \chi_t(w) e^{-V_{c,b_{\mathrm{rec}}}(w)}\, dw, \qquad \widetilde{F}_t = P_t(c, b_{\mathrm{rec}}) \int_{\mathcal{W}_t} e^{-V_{c,b_{\mathrm{rec}}}(w)}\, dw, \tag{21.33}$$

with the prefactor described in the statement. At a later step the equality in the first formula is replaced by the inequality (21.32).

By Theorem 21.8(2), $S_{c,b_{\mathrm{rec}}} \subset \mathcal{K}_t$ for every such datum. We check the measure-theoretic hypotheses of Lemma 20.5 at this fixed real datum. The finite products $\mathcal{K}_t$ and $\mathcal{W}_t$ are compact Borel sets. The map from free logarithmic coordinates to normalized fluctuation coordinates is a homeomorphism onto its open image, with the continuous inverse already constructed, so the image of the Borel set of free coordinates of supported points is Borel. Composing the Borel tests with that inverse gives a Borel function χ_t, extended by zero outside $S_{c,b_{\mathrm{rec}}}$, with $0 \le \chi_t \le 1$. The conditional fluctuation potential is analytic on a neighborhood of $\mathcal{K}_t$ and real at its real points, by Theorem 20.14. Its finite minimum $\underline{V}$ and maximum $\overline{V}$ on this compact product give

$$0 < e^{-\overline{V}} \operatorname{vol}(\mathcal{K}_t) \le Z_{\mathcal{K}_t} = \int_{\mathcal{K}_t} e^{-V}\, dw \le e^{-\underline{V}} \operatorname{vol}(\mathcal{K}_t) < \infty. \tag{21.34}$$

The volume is finite and positive, since every ball has a finite positive radius. For an empty free product its zero-dimensional measure is one and $V = 0$, so $Z_{\mathcal{K}_t} = 1$. No uniform bound on $\underline{V}$ or $\overline{V}$ is needed here. The prefactor is finite at each real datum; if it vanishes, both sides vanish, and otherwise it is positive.

The hypotheses of Lemma 20.5 on the whole product give its potential estimate and, for the normalized enclosing-product comparison measure $\nu_{\mathcal{K}_t}$, the bound

$$\delta_t := \nu_{\mathcal{K}_t}(\mathcal{K}_t \setminus \mathcal{W}_t) \le 6\mathsf{b}_t e^{-p(t_t)^2/48}, \qquad \mathsf{b}_t \le C_J m^3.$$

Every ball of $\mathcal{W}_t$ has positive radius, so its volume is positive. Since V is finite on $\mathcal{K}_t$, we have $\int_{\mathcal{W}_t} e^{-V}\, dw > 0$, and hence $\nu_{\mathcal{K}_t}(\mathcal{W}_t) > 0$ and $0 \le \delta_t < 1$. This strict inequality concerns the actual missing mass; the displayed union-bound majorant need not be below one under the local hypotheses. For an empty free product, $\delta_t = 0$.

Since $0 \le \chi_t \le 1$, the right side of (21.32) is at most $P_t \int_{\mathcal{K}_t} e^{-V}$, and part (1) of Lemma 20.5 bounds the latter by $(1 - \delta_t)^{-1} \widetilde{F}_t$. No inclusion of $\mathcal{W}_t$ in $S_{c,b_{\mathrm{rec}}}$ is needed. The same reasoning applies if $P_t = 0$ or if the free list is empty. All constants arose from local path products, the fixed construction products, and their row-sum bounds. □

In the theorem below, E_t, R_t, and Λ_t are the effective classical action, the effective interaction, and the normalization constant at stage t; the last is the field-independent additive term in the log-density. Further, W_t is the product of the external weights (the factors of frozen variables that are not integrated), C_t is the reconstruction map, and ℓ_t is the level of the output of stage t. For the normalization comparison, $\Lambda_t^{\mathbb{T}}$ denotes the normalization constant of the corresponding recursion on the whole torus. Here H_t denotes the set of scalar Gaussian coordinates of stage t that are integrated in the corresponding renormalization group recursion on the whole torus but absent from the regional free list (it is not the Haar measure of Theorem 21.9), and $d_i(H_t)$ is the number of its elements at scale i. The numbers $N_{\mathrm{missing},t}$, $N_{\mathrm{bd},t}$, and $N_{\mathrm{freeze},t}$ count, on the lattices where they were created, the missing labels of field-independent generated terms, the labels of the fixed interface band, and the newly frozen analytic labels, as in Theorem 20.13.

Theorem 21.12. *Fix a large-field decomposition of Theorem 21.5, an initial measure ν (a stopped measure or the Wilson measure), an initial scale and a stopping scale differing by a whole number T of RG steps, and the cutoff domains and norm ball of Theorem 20.14. Every integrated group of averaging steps is a complete RG step, $s_t = J$. A remaining number $0 \le u_{\mathrm{ph}} < J$ of averaging steps within the given hierarchy is kept through the pullback $C \mapsto F(T_M^{u_{\mathrm{ph}}} C)$ of an observable F at the stopping scale; this requires $m_{\mathrm{stop}} = M^{u_{\mathrm{ph}}} m_{\mathrm{rem}}$ with $m_{\mathrm{rem}} \in 4\mathbb{N}$. For a fixed additional number $r_{\mathrm{stop}} \in \mathbb{N}_0$ of RG steps, the same condition is imposed with the total exponent $r_{\mathrm{stop}} J + u_{\mathrm{ph}}$, and all iterates must lie within the finite hierarchy. No recursion for normalization constants is asserted for an integrated group of fewer than J averaging steps. Assume the uniform incoming radii obtained by freezing every label of reduced radius, the boundary-distance comparison* (21.10)*, the conditional force conditions* (21.13) *and* (21.14)*, the cutoff radii of* (21.19)*, the initial norm bounds of Theorem 20.14, and the bounds* (21.8) *on frozen coordinates. Let $\mathcal{W}_t$ be the fluctuation cutoff domain* (21.31)*, which is the instance of Theorem 20.14 with common radius $p(t_t)$; the enclosing product domain $\mathcal{K}_t$ is used only in Lemma 21.11. Write Z_ν for the partition function of the initial measure, without centering: for a stopped measure*

$$Z_\nu = \int_{D_r} e^{-E_{d_0,\mathrm{sat}}/g_{\mathrm{base}}^2 - R_{d_0,\mathrm{sat}}}\, dH,$$

and $Z_\nu = Z_{m_{\mathrm{base}},\gamma}$ for the Wilson measure. Use the stage measures and density versions of Theorem 21.9. Then the following constructions and bounds hold at every finite depth and number of steps.

1. *(Analytic functions, from fine to coarse.) For every real value of the frozen coordinates satisfying* (21.8)*, the functions E_t, R_t, Λ_t, W_t, the classical objectives, the reconstruction maps C_t, and the auxiliary fluctuation integrals are defined on the full spatially varying radii by the recursion of Theorem 20.14, with the substitution of frozen coordinates of Lemma 21.10. This definition uses no density inequality and no choice of representatives.*

The effective interaction is centered only in its constant term, all its first derivatives are kept, and the full classical values are kept. For a stopped measure the normalization constant on the torus is $\Lambda_0^{\mathbb{T}} = -R_{d_0}(I)$*, and an initial freezing subtracts in addition the frozen value of the centered effective interaction. For the Wilson measure we use the exact split of Theorem 21.8(4), with its original external factor.*

2. *(Representatives satisfying the reconstruction identities, from coarse to fine.) Take all small top representatives in the coordinate domains of Theorem 21.8(1) whose frozen coordinates satisfy* (21.8)*, and construct such representatives downward with the maps of part (1). At a boundary with freezing, let* $\mathscr{D}_{t+1}$ *be the set of these representatives at the next stage, and define the set of output data satisfying the freezing and reconstruction identities*

$$\mathscr{P}_{t+1} = \mathcal{A}_t^{-1}(\mathscr{D}_{t+1}).$$

For each such datum, include every supported fiber point:

$$\mathscr{D}_t = \{(C_t(c,\zeta;b_{\mathrm{rec}}),b_{\mathrm{rec}}) : (c,b_{\mathrm{rec}}) \in \mathscr{P}_{t+1},\ \zeta \in \mathcal{Z}_{c,b_{\mathrm{rec}}}\},$$

where $\mathcal{Z}_{c,b_{\mathrm{rec}}}$ *is the set of supported fiber coordinates over* (c,b_{rec})*. At the last RG step, the set of output data consists of these small top representatives whose frozen coordinates satisfy* (21.8)*; every configuration in the support of the stage measure has such a representative by Theorem 21.5. Other representatives are compared only by the changes of Lemma 21.6(1)–(3) or by the pointwise invariance of Theorem 21.9. These sets contain all choices, and no probability law is assigned to a representative map.*

3. *(Density bounds, from fine to coarse.) For every real value of the frozen coordinates, every* $(c,b_{\mathrm{rec}}) \in \mathscr{P}_{t+1}$*, and every supported fiber coordinate* ζ *over it,*

$$\begin{aligned} p_t(C_t(c,\zeta;b_{\mathrm{rec}}),b_{\mathrm{rec}}) \le\ & A_t Z_v^{-1} e^{\Lambda_t(b_{\mathrm{rec}})} W_t(b_{\mathrm{rec}}) \\ & \times \exp\{-E_t(\mathrm{Log}\, C_t(c,\zeta;b_{\mathrm{rec}});b_{\mathrm{rec}})/g_{\ell_t}^2\} \\ & \times \exp\{-R_t(\mathrm{Log}\, C_t(c,\zeta;b_{\mathrm{rec}});b_{\mathrm{rec}})\}. \end{aligned}$$

Here $A_0 = 1$ *and*

$$A_{t+1} = A_t(1-\epsilon_t)^{-1}, \qquad \epsilon_t \le 6\mathsf{b}_t e^{-p(t_t)^2/48}, \quad \mathsf{b}_t \le C_J m_t^3, \qquad \log A_T \le C_\delta,$$

after the uniform choice of the minimal side in Lemma 20.5. Every step uses the exact Haar disintegration and then a single triangular change to normalized fluctuation variables, with determinant

$$\prod_{i=0}^{s_t-1} g_i^{3f_i} \det K_i(c_{i+1}(w_{>i});b_{\mathrm{rec}})^{-1/2}.$$

The resulting Borel set of fluctuation coordinates of supported points is contained in the enclosing product domain, and Lemma 21.11, with identical prefactors and the smaller cutoff

domain, gives the stated loss. The next stage evaluates the same configuration. The indicators are kept until this comparison, and no domination at arbitrary points of the enclosing product domain is required.

4. *(Normalization.) With* $\Delta\Lambda_t = \Lambda_t - \Lambda_t^{\mathbb{T}}$ *in the same centered renormalization group recursion on the whole torus, Theorem 20.13 gives*

$$\Delta\Lambda_{t+1} \le \Delta\Lambda_t + \sum_{i \text{ in } t} d_i(H_t)\log(1/g_i) + C_J(N_{\text{missing},t} + N_{\text{bd},t} + N_{\text{freeze},t}),$$

including the initial freezings. This comparison uses the same centered recursion on the whole torus and the same partition function Z_ν *throughout.*

5. *(External classical terms and the measure of frozen coordinates.) For the comparison of the output classical actions, the protected external classical exponents are recombined exactly once. At fixed frozen coordinates, with their original couplings included in* $S_{\text{ext}}(b_{\text{rec}})$,

$$e^{-S_{\text{ext}}(b_{\text{rec}})}e^{-E^{\text{int}}/g_t^2} = e^{-E^{\text{full}}/g_t^2}, \qquad E^{\text{full}} = E^{\text{int}} + g_t^2 S_{\text{ext}}(b_{\text{rec}}),$$

where E^{int} *is the effective classical action of the block region, and this factor is removed from the external weight. Under an RG step both the action and* g_t^2 *are multiplied by* M^{s_t}*, so each such exponent is preserved and counted once. At the top we keep the measure*

$$\rho_{\mathcal{X}}(db_{\text{rec}}) = w_{\mathcal{X}}(b_{\text{rec}})H_{\mathcal{X}}(db_{\text{rec}}) \le H_{\mathcal{X}}(db_{\text{rec}}), \qquad w_{\mathcal{X}} = I_{\mathcal{X}}^{\text{act}} I_{\mathcal{X}}^{\text{inv,end}},$$

on the frozen coordinates, where $H_{\mathcal{X}}$ *is their product Haar measure. The first indicator keeps every failure* $q_f(b_{\text{rec}}) \ge d_*$*, which is a function of the frozen coordinates since the whole dependence set of* f *was frozen. The second keeps any chosen invariant tests depending only on the frozen coordinates at the output. There is no second copy of the frozen-coordinate terms included in the full classical action. Optional noninvariant chart restrictions may be bounded by one.*

All local constants have the dependence stated at the beginning of this section, including independence of the later widths, while C_δ *has the dependence described in item (4) of Definition 4.14. No comparison of regional integrals from below, gauge covariance of auxiliary functions, or overlap identity for the classical action is part of this induction.*

Proof. Every integrated step has $s_t = J$, so $\ell_{t+1} = \ell_t + J$ and $g^2_{\ell_{t+1}} = Bg^2_{\ell_t}$. We reserve z_i for the free logarithmic coordinates and write $\zeta_i = g_i w_i$ for the scaled fluctuation arguments of C_t. All analytic functions below are functions of the identity-chart variables of the block region at fixed real (ξ, b_{rec}). We prove the five parts in order, followed by the statement on the remaining averaging steps.

Part (1): initialization. For a stopped measure, we set

$$r_{d_0} = R_{d_0} - R_{d_0}(I), \qquad \Lambda_0^{\mathbb{T}} = -R_{d_0}(I).$$

The partition function without centering then gives exactly $Z_\nu^{-1} e^{\Lambda_0^{\mathbb{T}}} e^{-E_{d_0}/g_{\mathrm{base}}^2 - r_{d_0}}$ at a small representative in D_r. In particular $\widehat{Z} = e^{R_{d_0}(I)} Z_\nu$ for the centered partition function in Theorem 21.5; we keep Z_ν throughout this proof. For an initial freezing at $\xi^\sharp$, we set

$$\begin{aligned} E_0(v; b_{\mathrm{rec}}) &= E_{d_0}(v \oplus \xi^\sharp), \\ R_0(v; b_{\mathrm{rec}}) &= r_{d_0}(v \oplus \xi^\sharp) - r_{d_0}(0 \oplus \xi^\sharp), \\ \Lambda_0(b_{\mathrm{rec}}) &= -R_{d_0}(I) - r_{d_0}(0 \oplus \xi^\sharp). \end{aligned} \tag{21.35}$$

Additional frozen coordinates are held as real parameters. For the Wilson measure, we set $E_0 = F_{\mathrm{bare}}$, $R_0 = 0$, $\Lambda_0 = 0$, and $W_0 = e^{-E_{\mathrm{hole}}/g_{\mathrm{base}}^2}$, together with any kept indicators at the output. The exact split in Theorem 21.8(4) implies this initialization with the partition function of the Wilson measure.

We verify the initial norm bounds. The initial analytic values obey (21.8), because $C_{\mathrm{conv},J} \geq C_{\mathrm{ad},J}$, which was fixed before Theorem 21.5, and the near values at the first step under the Wilson measure satisfy its conversion bound. For a stopped measure, the decomposition with zero completion has classical perturbation $P_0(v) = E_{d_0}(v \oplus \xi^\sharp) - E_{d_0}(v \oplus 0)$, including its constant. With the matched completion $\iota_{\xi^\sharp}$ of Theorem 19.9, this is exactly its boundary-completion difference, and the adjusted perturbation is $\overline{P}_0 = 0$. In the norm with zero completion, its nonconstant part is bounded by $C_{\mathrm{bc,cl}} E_{\mathrm{cl}} \beta_{\mathrm{rec}} / \rho_{\mathrm{cl}} \leq \sigma_*/4$, by (21.16). For the quantum input, splitting the centered function $r_{d_0}(v \oplus \xi^\sharp)$ into its restriction to the torus and its boundary-completion difference gives the bound $C_{\mathrm{bc,q}} E \beta_{\mathrm{rec}} / \rho \leq \sigma_*/4$. The constant in (21.35) is kept exactly and is not bounded by this norm.

At the first step under the Wilson measure, the plaquettes depending on integration variables use only the small near values of the initial good-cell complex. The zero-completed Wilson function evaluated at those data differs from the sum of these plaquette terms by plaquettes involving only frozen variables, which are constant in the integration variables. Hence the adjusted classical perturbation is constant at this step, and its nonconstant boundary-completion difference with zero completion obeys the same classical bound. These classical constants remain in F_{bare}, and the energy of the deep frozen group variables stays in W_0. The quantum input is zero. This proves $x_0, x_0^{\mathrm{cl}} \leq \sigma_*$ for either initial measure, on uniform radii of the remaining inputs. No deep frozen group variable has entered an analytic logarithm.

Part (1): the analytic recursion. At a later input, let D_{in} be the list of remaining analytic variables of the block region, with their original locations and volume factors; it does not include the frozen parameters. Since the preceding freezing of the union removed every label of reduced radius, the classical and quantum input radii are uniform by (21.15). The previous fixed complement and all earlier frozen basepoints obey (21.10). The initialization satisfies the same statement, with zero boundary-weighted input when

there is no incoming fixed complement, and additional excluded regions created by the tests preserve this inclusion. All completion adjustments use only newly frozen small analytic variables; previously nonintegrated torus variables remain zero, and the deep frozen group variables remain fixed external parameters.

We apply Theorems 19.9 and 20.14 inductively, with the fixed amplitude A_{w} and the coupling ceiling g_* chosen for it, to define the classical objective, the conditional minimizers for initial segments, their positive square roots, and the reconstruction map on the full radii. The hypotheses of each application are checked before any set of representatives is constructed. The input norm just restored bounds the adjusted perturbation by $2\sigma_*$. The images and every connecting segment lie strictly in the uniform input ball, by (21.17) and the fixed margin of the larger construction domain. The force and Hessian estimates, uniformly for $y \in \mathcal{T}_I$ for each initial segment I, followed by (21.14), give all conditional minimizers and sequential neighborhoods; these checks are Lemma 21.7. All perturbation derivatives are taken in the integration and free variables at fixed real b. The fixed rates and spatial margins are those of the common tuple of Theorem 20.14 and are not changed by freezing. The torus input is the member at accumulated classical depth $d_t = d_0 + tJ$ of its uniform analytic class, with ceiling E; a new nonconstant boundary term is accounted for by the two input norms rather than added to this ceiling. We include the exact boundary-completion difference when the unperturbed objective uses newly frozen input variables. By Theorem 19.9, this objective agrees on the connected chart with E_t evaluated at its reconstructed field; only the torus term uses compact overlap there, and the perturbation is evaluated at that field from the outset. The full outgoing action is defined to be the value at the conditional minimizer multiplied by M^{s_t}.

We next define the update of the effective interaction by an integral; this also fixes all normalization conventions. Let $J_t^0(c, b_{\mathrm{rec}})$ be the product of the Haar disintegration factors of the intermediate scales evaluated along the zero-fluctuation chain, and define

$$D_t^0(c, b_{\mathrm{rec}}) = J_t^0(c, b_{\mathrm{rec}}) \prod_i g_i^{3f_i} \det K_i(\widehat{c}_{i+1}; b_{\mathrm{rec}})^{-1/2}, \tag{21.36}$$

where $\widehat{c}_{i+1}$ denotes the corresponding higher argument at zero fluctuation. All field-independent constants of the Haar disintegration are included. Sequential minimization and normalization give the exact decomposition of the action: the output value divided by $g_{\ell_{t+1}}^2$, the quadratic term $\sum_i |w_i|^2/2$, and the higher classical remainders add up to the input classical exponent. Indeed, at each intermediate scale we subtract the conditional minimum and its quadratic Taylor term; the latter is $|w_i|^2/2$ by the definition of K_i, and the factor M in the minimum cancels the factor M in the next coupling. Repeating this over the s_t scales, we obtain the decomposition, including its constants. Adding the inherited difference of effective interactions, all logarithmic differences of the Haar disintegration factors, and all logarithmic differences of the determinants that depend on the

higher fluctuation variables, we obtain the conditional fluctuation potential $V_t(c, b_{\mathrm{rec}}; w)$, including its quadratic part; it is the potential of Theorem 20.14.

In this integral, we use the fluctuation cutoff domain (21.31): every radius is $p(t_t)$ with $t_t = \max_i g_{t,i}$. This is in the allowed logarithmic family; it is not the radius R_{en}/t_t of the enclosing product. The containment, positive denominator, interaction, and auxiliary half-disc conditions hold by (21.17) and (21.19); they are deterministic conditions on the parameters and on g_*, not restrictions on the support of the measure. On the fixed product $\mathcal{W}_t$, we define

$$\begin{aligned} \mathcal{I}_t(c; b_{\mathrm{rec}}) &= D_t^0(c, b_{\mathrm{rec}}) e^{-R_t(\mathrm{Log}\, C_t(c,0;b_{\mathrm{rec}});b_{\mathrm{rec}})} \int_{\mathcal{W}_t} e^{-V_t(c,b_{\mathrm{rec}};w)}\, dw, \\ Q_t(c; b_{\mathrm{rec}}) &= -\log \mathcal{I}_t(c; b_{\mathrm{rec}}), \\ R_t^{\mathrm{out}}(c; b_{\mathrm{rec}}) &= Q_t(c; b_{\mathrm{rec}}) - Q_t(0; b_{\mathrm{rec}}), \qquad \Lambda_t^{\mathrm{out}} = \Lambda_t - Q_t(0; b_{\mathrm{rec}}). \end{aligned} \tag{21.37}$$

The logarithm is real on real data, where it agrees with the real logarithm of the positive integral; its zero-free analytic continuation is supplied by Theorem 20.14, and its sign is unrestricted. The integrand and its domain are defined on the full radii before any support set is considered. We have the exact identity

$$Z_v^{-1} e^{\Lambda_t} W_t e^{-E_t^{\mathrm{out}}(c)/g_{\ell_{t+1}}^2} \mathcal{I}_t(c; b_{\mathrm{rec}}) = Z_v^{-1} e^{\Lambda_t^{\mathrm{out}}} W_t e^{-E_t^{\mathrm{out}}(c)/g_{\ell_{t+1}}^2 - R_t^{\mathrm{out}}(c;b_{\mathrm{rec}})}. \tag{21.38}$$

Changing the distribution of constant factors between D_t^0 and the definition of Q_t leaves this identity unchanged; we use the convention of Theorem 20.13, which assigns each field-independent factor once.

At a boundary we use the substitution of Lemma 21.10. This defines all functions at the next level for every real value of the frozen coordinates, independently of any density bound. The simultaneously frozen list is the union of the full boundary band of reduced radius, the removed band, the new boundary layers, and the based transports; the corresponding initial variables were included at the initial scale. Their analytic values satisfy (21.8) for both radii. At a representative of the next stage satisfying the reconstruction identities, the freezing identity inserts these values, not small values from a different frame, and the total boundary-completion difference obeys (21.16). The resulting norm bounds are exactly those of Theorem 20.14: the output ceilings before freezing are y_t and y_t^{cl}, the boundary-completion differences are at most $\sigma_*/4$, and the removed band makes each remaining term at most $\sigma_*/2$. With $\alpha_{\mathrm{q}} = \alpha$ and the corresponding classical rate, we have for both types

$$x_{t+1}^{\bullet} \le C_{\mathrm{bc},\bullet} E_{\bullet} \beta_{\mathrm{rec}}/\rho_{\bullet} + 2e^{-\alpha_{\bullet}(s_{\mathrm{er}}-1)} y_t^{\bullet} \le \sigma_*/4 + \sigma_*/2,$$

so $x_{t+1}, x_{t+1}^{\mathrm{cl}} \le 3\sigma_*/4$ whenever the input is in its ball. The output ceilings $y_t^{\bullet}$ are computed on the input ball before the width s_{er} is chosen. By induction from the initial

ball, we obtain the analytic recursion at every finite number of steps. It keeps the terms of degree one; no first derivative has been removed by recentering, and every restoration of the bounds happens at a complete RG step.

It remains to verify the Borel regularity in the real parameters required at each perturbation step. The initial coefficients and chart path products are Borel functions of the protected real frozen coordinates; the deep frozen group variables at the first step under the Wilson measure enter only the Borel external factor. Suppose this holds at an input. The fixed-point iterations for the conditional minimizers use Borel coefficients and converge uniformly on their fixed neighborhoods, so their limits are Borel in b. The positive matrix square roots and inverses are Borel as uniform limits of the matrix-function constructions. The resulting values, Haar disintegration determinants, and coefficients are Borel. By Tonelli's theorem, integration over the fixed finite product preserves Borel dependence; we apply it to the positive and negative parts and to the real and imaginary parts, which have finite integrals. The logarithm can be chosen jointly Borel without a branch choice depending on the frozen coordinates: on the star-shaped output domain,

$$\log \mathcal{I}_t(c;b) = \log \mathcal{I}_t(0;b) + \int_0^1 \frac{D_c \mathcal{I}_t(sc;b)[c]}{\mathcal{I}_t(sc;b)}\, ds,$$

where the first term is the real logarithm. Zero-freeness and holomorphy make this the required analytic branch, and the parameter integral is Borel. Finally, the substitution of frozen coordinates evaluates these Borel families at the Borel coordinates of the frozen values. This proves the Borel regularity inductively, without differentiating in a real frozen parameter.

Part (2): representatives satisfying the reconstruction identities. We start from all small representatives of top configurations, in the coordinate domains of Theorem 21.8(1), whose analytic frozen coordinates satisfy (21.8); they exist by Theorem 21.5. At a boundary with freezing, we pull the next set of representatives satisfying the reconstruction identities back by the freezing bijection $\mathcal{A}_t$; this defines $\mathscr{P}_{t+1}$, which is not enlarged to an arbitrary comparison set. For each such datum, we include every supported fiber coordinate, as in the definition of $\mathscr{D}_t$. Theorem 21.8, applied at this step of the descent, shows that each of them has its inverse normalized fluctuation coordinate in the interior half of the enclosing product, and that its representative has the correct target and protected frozen coordinates. This defines the whole finite family downward using only the maps defined by (21.37). The sets integrated below are the Borel sets of free coordinates of supported fiber points at fixed output data, so no measurable representative map is needed.

The bounds (21.8) persist along this descent, by Lemma 21.6(1)–(3) and, at a new boundary, the direct insertion of Lemma 21.10. Changes as in Lemma 21.6(4) are not

used to enlarge these sets. Over each output datum in $\mathscr{P}_{t+1}$, the set still contains every supported fiber point.

Part (3): density bounds. We use the densities of Theorem 21.9. For a stopped measure, the gauge-invariant density agrees with its analytic expression at each representative satisfying the reconstruction identities, and the indicators of the decomposition and of the support are between zero and one. Then (21.35) implies the claimed bound at the initial scale with $A_0 = 1$. For the Wilson measure, the exact split implies the same bound with the kept factor W_0. At a point outside the support, the density is zero, and no analytic identity is needed there.

Suppose that the inequality holds on $\mathscr{D}_t$, and fix an output datum $(c, b_{\mathrm{rec}}) \in \mathscr{P}_{t+1}$. We apply the exact Haar disintegration to the incoming density, keeping its tree variables at first. By Theorem 21.9, the covariance under based gauges makes their normalized Haar integrals equal to one. For this fixed target, the gauge transformation of Lemma 19.5 is a fixed gauge transformation, independent of the free variables and equal to I at the roots of the target and at every protected vertex. The invariance of the density therefore allows us to evaluate the integrand at $C_t(c, \zeta; b_{\mathrm{rec}})$ instead of at its representative before the gauge transformation, and the tests take the same values there. This changes neither the Haar disintegration nor any determinant, and it is not a covariance statement for the auxiliary functions on the right side of the inequality.

We now perform the single sequential change to normalized fluctuation variables for the classical objective. At scale i its derivative with respect to w_i is $g_i K_i^{-1/2}$, and its other dependence is on higher variables. Ordering the higher variables first makes the derivative block triangular, so its positive real determinant is exactly

$$\prod_{i=0}^{s_t-1} g_i^{3f_i} \det K_i(c_{i+1}(w_{>i}); b_{\mathrm{rec}})^{-1/2}. \tag{21.39}$$

In particular, the determinant at a varying higher argument is not replaced by its value at zero. Equation (21.36) and the corresponding logarithmic differences split this one determinant; they do not add a second copy. Injectivity and the inverse map on the supported domain follow from the branches for initial segments, with their positive margins, established before. As in the proof of Lemma 21.11, the image is a Borel set $S_{c,b_{\mathrm{rec}}}$ in the enclosing product, and the remaining indicators composed with the inverse form a Borel function χ_t on $\mathcal{K}_t$ with values in $[0,1]$. The potential has a finite nonzero integral over $\mathcal{K}_t$ at each fixed real datum, also for an empty product.

Every supported point of that domain belongs to $\mathscr{D}_t$. We insert the inductive bound there, and let $P_t^0(c, b_{\mathrm{rec}})$ be

$$Z_\nu^{-1} e^{\Lambda_t(b_{\mathrm{rec}})} W_t(b_{\mathrm{rec}}) D_t^0(c, b_{\mathrm{rec}}) e^{-E_t^{\mathrm{out}}(c;b_{\mathrm{rec}})/g^2_{\ell_{t+1}} - R_t(\mathrm{Log}\, C_t(c,0;b_{\mathrm{rec}});b_{\mathrm{rec}})}.$$

Tests depending only on the output datum are kept in this common factor. If this factor is zero, the outgoing upper bound is zero; otherwise it is finite and positive. With χ_t denoting the remaining indicators, the exact disintegration followed by the inductive bound gives

$$\begin{aligned} p_t^{\mathrm{out}}(c, b_{\mathrm{rec}}) &\le A_t P_t^0(c, b_{\mathrm{rec}}) \int_{S_{c,b_{\mathrm{rec}}}} \chi_t(w) e^{-V_t(w)}\, dw \\ &\le A_t P_t^0(c, b_{\mathrm{rec}}) \int_{\mathcal{K}_t} e^{-V_t(w)}\, dw \\ &\le \frac{A_t}{1-\epsilon_t} P_t^0(c, b_{\mathrm{rec}}) \int_{\mathcal{W}_t} e^{-V_t(w)}\, dw. \end{aligned} \tag{21.40}$$

Here ϵ_t is a common upper bound for the datum-dependent δ_t of Lemma 21.11 at stage t, over all admitted output data, after the uniform minimum-side choice in part (3) of Lemma 20.5. One may take $\epsilon_t = 6\mathsf{b}_t e^{-p(t_t)^2/48} \le 1/2$. The first inequality is the hypothesis (21.32) of that lemma with $\chi = 1$ and $P_t = A_t P_t^0$, and the remaining two inequalities are its conclusion. The middle step uses the enclosure of Theorem 21.8, positivity on the whole larger product, and only $0 \le \chi_t \le 1$. The last step is Lemma 20.5 with identical prefactors; its radii are the common logarithmic radii, enclosed by $t_t p(t_t) < R_{\mathrm{en}}$, and its Hessian and mean conditions hold by (21.19), in particular with mean at most $p(t_t)/(2\sqrt{3})$. The larger product $\mathcal{K}_t$ is used only in this comparison. This verifies the hypothesis of Lemma 21.11 at every later stage, with the incoming loss A_t in the common prefactor.

By (21.38), the last line of (21.40) is the analytic outgoing bound, defined independently, with the factor $A_{t+1} = A_t/(1-\epsilon_t)$. By Lemma 21.10, the inverse under freezing of a representative of the next stage is this output configuration. That lemma substitutes the based transports and frozen links directly, transfers $-R_t^{\mathrm{out}}(0 \oplus \xi^\sharp)$ to the normalization constant, and keeps the full classical value. This proves the incoming inequality at stage $t+1$ on exactly $\mathscr{D}_{t+1}$ and completes the induction.

There is one comparison per output datum, jointly over all components and scales of the step. The probability estimate used here is $\epsilon_t \le 6\mathsf{b}_t e^{-p(t_t)^2/48}$ with $\mathsf{b}_t \le C_J m_t^3$. Ordering the finite list of output data along the sequence of sides and taking the uniform minimal side of Lemma 20.5, we obtain

$$\log A_T = \sum_{t<T} -\log(1-\epsilon_t) \le 2 \sum_{t<T} \epsilon_t \le C_\delta.$$

Empty free products have determinant one, logarithmic determinant zero, and fluctuation integral one, and an empty block region has zero nonconstant norm. Such an empty step contributes no loss.

Part (4): normalization. Since $s_t = J$ and the initial and stopping scales differ by complete RG steps, every application below is within the scope of Theorem 20.13. The recursion just

constructed is the same centered recursion, with the same extraction of field-independent factors, as in that theorem. All its norm and domain hypotheses were verified in part (1), including the common logarithmic cutoffs and the freezing of the whole union. The column bound used for the analytic norm propagation in Theorem 20.10 is that of the perturbed zero-fluctuation map. Indeed, the doubled output radius and the inherited half radius are part of the two image conditions, and the differences with each index fixed in Theorem 19.9 give, in the same boundary-weighted sum over distinguished outputs,

$$K_{\mathrm{col},J}^{\mathrm{actual}} \le K_{\mathrm{col},J}^{0} + C_J \sigma_{0,J},$$

where $K_{\mathrm{col},J}^{\mathrm{actual}}$ and $K_{\mathrm{col},J}^{0}$ are the column ceilings of the perturbed and unperturbed maps. The fixed allocations of dependence neighborhoods and exponents are already included in C_J. More explicitly, the margin in the coefficient exponent, after the transfer of boundary distances in (21.10), leaves a positive exponent c' for summing over the incoming label at a fixed output, and this sum is bounded by $v_J \sum_{q\ge 0}(q+2)^3 e^{-c'q} < \infty$. The volume factors of the lattices where the labels were created are kept in this column sum. Deleting labels or adding excluded regions cannot increase this bound of bounded density. This proves that the enlargement has the dependence stated at the beginning of this section. We fix this enlarged ceiling on the whole larger perturbation domain before choosing s_{er} or later widths. In Theorem 20.10, its coefficient is $K_J = 4(\log 2) K_{\mathrm{col},J}$ for this enlarged ceiling; no column bound for the unperturbed map alone is substituted.

Applying the generated-increment comparison of Theorem 20.13 with the incoming $\Delta\Lambda_t = \Lambda_t - \Lambda_t^{\mathbb{T}}$, we obtain the increment in part (4), including the initial freezings. To check the sign of the dimension term, note that one scalar Gaussian coordinate integrated in the corresponding renormalization group recursion on the whole torus contributes a factor g_i. When that coordinate is absent from the regional free list, the logarithmic difference between the regional and torus terms is $-\log g_i = \log(1/g_i)$. Summing over the missing scalar coordinates, we obtain $d_i(H_t)\log(1/g_i)$, once for each scale. By that theorem, the remaining generated differences of Haar disintegration factors, minimizers, and cluster expansions, and the freezings, are bounded by C_J times the three label counts, taken on the lattices where the labels were created. This comparison is additional analytic information: neither the exact disintegration, nor (21.37), nor normalization would by itself bound these generated differences. The factor A_t remains separate and is not added again to Λ_t.

The remaining averaging steps. Let $a = \ell_T - \ell_0 = JT$ be the number of integrated averaging steps (here a is not a mesh), and let $\ell_{\max}$ be the last level of the given finite hierarchy. A remaining number $0 \le u_{\mathrm{ph}} < J$ of averaging steps is chosen only when it is available: at the stopping scale we require

$$m_{\mathrm{stop}} = M^{u_{\mathrm{ph}}} m_{\mathrm{rem}}, \qquad m_{\mathrm{rem}} \in 4\mathbb{N}, \qquad \ell_T + u_{\mathrm{ph}} \le \ell_{\max}.$$

For a fixed additional number $r_{\mathrm{stop}} \in \mathbb{N}_0$ of RG steps, we set $v = r_{\mathrm{stop}} J + u_{\mathrm{ph}}$ and require

$$m_{\mathrm{stop}} = M^v m_{\mathrm{rem}}, \qquad m_{\mathrm{rem}} \in 4\mathbb{N}, \qquad \ell_T + v \le \ell_{\max};$$

the case of u_{ph} alone is $r_{\mathrm{stop}} = 0$. For each $0 \le k \le v$, the intermediate side is $M^{v-k} m_{\mathrm{rem}} \in 4\mathbb{N}$, which is at least four. The initial side is $M^a m_{\mathrm{stop}}$, and the bound on the index keeps every intermediate level in the given hierarchy. Hence both T_M^v at the stopping scale and T_M^{a+v} at the initial scale exist; a lower bound on m_{stop} alone would not give these integer conditions. We work on whole configurations, before regional coordinates are introduced. The block averaging map with its Borel extension is Borel, and its iterates are compositions of that map, so for every initial configuration V, we have

$$F(T_M^{a+v} V) = (F \circ T_M^v)(T_M^a V),$$

and the function at the stopping scale is exactly $C \mapsto F(T_M^v C)$, in particular $C \mapsto F(T_M^{u_{\mathrm{ph}}} C)$ for u_{ph} alone. We define the measure $\mu_{a,\mathcal{X}} = (T_M^a)_{\#}(\mathbf{1}_{\mathcal{A}_{\mathcal{X}}} \nu)$ on the whole configurations at the stopping scale. For every nonnegative Borel F we have

$$\int \mathbf{1}_{\mathcal{A}_{\mathcal{X}}}(V) F(T_M^{a+v} V)\, d\nu(V) = \int (F \circ T_M^v)(C)\, d\mu_{a,\mathcal{X}}(C), \tag{21.41}$$

by the definition of the pushforward; the identity extends to integrable F through positive and negative parts. Each fixed additional number of steps uses the total exponent v whose existence was just checked, together with its finite enlarged dependence neighborhood. For the local link and plaquette observables of Theorem 21.5, these iterates use its already enlarged final dependence neighborhood. The decomposition keeps this observable on each piece. There is no Haar disintegration, change of variables, restoration of bounds, or update of normalization for v. When the integrated part of the decomposition is empty, the identity is the initial pushforward itself.

Part (5): external classical factors and failure indicators. At fixed frozen coordinates, let $S_{\mathrm{ext}}(b_{\mathrm{rec}})$ be the sum of the protected external classical exponents with their original couplings; for the Wilson measure it includes $E_{\mathrm{hole}}/g_{\mathrm{base}}^2$. The term $g_t^2 S_{\mathrm{ext}}$ is constant in all integration variables, so adding it to the full action of the block region changes no minimizer, Hessian, map, or nonconstant norm. We have the exact identity

$$e^{-S_{\mathrm{ext}}} e^{-E^{\mathrm{int}}/g_t^2} = e^{-(E^{\mathrm{int}} + g_t^2 S_{\mathrm{ext}})/g_t^2}.$$

We delete this external factor from W_t when the full classical action including the frozen-coordinate terms is used. After an RG step, the corresponding constant becomes $M^{s_t} g_t^2 S_{\mathrm{ext}} = g_{t+1}^2 S_{\mathrm{ext}}$, so its exponent is preserved exactly. At each classical freezing, the full value was kept. Induction over the finite decomposition shows that each frozen-coordinate term of the full classical action has one copy in the output action and none in

the remaining weight of the frozen coordinates. The constants from the freezing of the effective interaction remain separate exact terms of Λ.

For each failing plaquette f, the whole dependence set was frozen at the input of its RG step. Its value q_f is therefore a Borel function of the frozen coordinates on that lattice, computed with the same path products of the block averaging map, and later operations fix its marked data exactly. Its trace is invariant under the consistent endpoint action. We keep the product of all indicators $\{q_f \geq d_*\}$ as $I_{\mathcal{X}}^{\mathrm{act}}$, and any chosen invariant tests depending only on the frozen coordinates at the output as $I_{\mathcal{X}}^{\mathrm{inv,end}}$. Every other optional coordinate restriction is between zero and one and may be removed in an upper bound. After the classical recombination, this leaves exactly the measure on frozen coordinates in part (5), which is bounded by its product Haar measure. It contains no second copy of an energy that could be used for a lower bound on the output action or for an energy bound on failing plaquettes.

Every local bound has the dependence stated at the beginning of this section on the fixed larger domains, and only C_δ has the dependence of item (4) of Definition 4.14. □

SECTION 22

Exponential-moment bounds between renormalization scales

In this section, we prove exponential-moment bounds for sums of plaquette energies of block-averaged configurations. The bounds are uniform in the number of averaging steps between the lattice on which the measure is given and the lattice on which the energies are evaluated. The main result is Theorem 22.1. Under its hypotheses, fix a coupling ceiling $\Gamma > 0$ and take the smallest side $u \geq n_{\min}(\Gamma)$. Let $b \in J\mathbb{N}_0$ with $0 \leq b \leq j-1$, and let ν be either the Wilson measure on the lattice of side n_b or a normalized stopped measure there at a preceding depth in $J\mathbb{N}_0$. The theorem states that the exponential moments under ν of the sum $Q_j^{\mathcal{T}}$ of the energies of the predecessor plaquettes of a chessboard tiling, (22.2), are bounded by $\exp\{3C_v n_{j-1}^3 + C_s n_{j-1}^2 \log(1/g_{n_{j-1}}) + C_b\}$. The constants are independent of $\gamma \in (0, \Gamma]$, of the lattice sides, and of $j-1-b$, and the expectation contains no small-field or regularity indicator. We also prove a chessboard estimate in which the regularity indicators stay inside the root (Lemma 22.11). Finally, we compare the Wilson measure, restricted to the first a conditions of the small-field event, with the stopped measures; this bounds the probability that the next condition fails, without conditioning on later scales (Lemmas 22.12 and 22.13). The inputs are the large-field decomposition and the density bounds of Section 21 (Theorems 21.5, 21.9, and 21.12); the regional integration estimates of Section 20 (Theorems 20.13 and 20.14 and Lemma 20.5); the classical lower bound of Theorems 11.2 and 11.6; the energy transport and predecessor geometry of Theorem 7.3 and Lemma 7.4; the reference normalization of Theorem 14.8; the chessboard estimate of Theorem 6.6; and, for the comparison of restrictions, Theorems 7.7 and 14.7. The results are used in Section 23 to prove the bound on large fields, Theorem 2.7.

Section 22.1 states the main theorem and outlines its proof, Sections 22.2 to 22.6 prove the estimates for one large-field decomposition, Section 22.7 completes the proof, and Sections 22.8 and 22.9 contain the chessboard estimate and the comparison of restrictions.

22.1 Setting and the main estimate

Scales and couplings. Fix $L > 0$, an odd integer $M \geq 3$, an integer $J \geq 1$, and $B = M^J$. For $u \in 4\mathbb{N}$ and $K \in \mathbb{N}_0$ let $N = uB^K$, $n_i = N/M^i$, and $V^i = T_M^i U$ for $0 \leq i \leq JK$, where T_M is the block averaging map of Definition 4.3, including its Borel extension at

the exceptional values. Increasing i moves toward the infrared, and all the sides n_i are divisible by four. One application of T_M is an averaging step, and J consecutive averaging steps form an RG step. The levels $i \in J\mathbb{N}_0$ are the boundaries of RG steps. At side n the coupling is $h_n = g_n^2 = \gamma/n$, as in Definition 4.1, so that $h_{n_{i+1}} = M h_{n_i}$. All Haar measures in this section are probability measures.

Plaquette energies. For $A \in \mathrm{SU}(2)$ let $\rho_G(A) \in [0, 2\pi]$ be the distance from A to I in the bi-invariant metric of Section 4, and recall that $q(A) = 1 - (\operatorname{tr} A)/2$. On the whole group,

$$\frac{\rho_G(A)^2}{2\pi^2} \le q(A) \le \frac{\rho_G(A)^2}{8}, \qquad 0 \le q(A) \le 2. \tag{22.1}$$

Indeed, if $t = \rho_G(A)/4 \in [0, \pi/2]$, then $q(A) = 1 - \cos(2t) = 2\sin^2 t$ by (4.2), and $2t/\pi \le \sin t \le t$. For a set $\mathcal{P}$ of positive plaquettes at level i and a configuration V on the lattice of side n_i we write

$$\mathcal{S}_i^{\mathcal{P}}(V) = \frac{4}{h_{n_i}} \sum_{p \in \mathcal{P}} q(V_p).$$

If $\mathcal{P}$ is the set of all positive plaquettes, then $\mathcal{S}_i^{\mathcal{P}}(V) = S_W(V)/h_{n_i}$ is the Wilson exponent.

The plaquette-energy sum. For a set $\mathcal{A}$ of positive plaquettes at level $i+1$, let $\mathrm{Pa}(\mathcal{A})$ be the union, counted once, of the plaquettes at level i in the complete predecessor rectangles of the elements of $\mathcal{A}$ (Theorem 7.3). Let $1 \le j \le JK$. For each of the eight tilings $\mathcal{T}$ of the level-j lattice into cells of $2 \times 2 \times 2$ sites in Lemma 7.4, and each cell $C \in \mathcal{T}$, let $\mathcal{P}_{j-1}(C)$ be the union of the complete predecessor rectangles of the six internal level-j plaquettes of C, and let $\mathcal{P}_{j-1}^{\mathcal{T}} = \bigcup_{C \in \mathcal{T}} \mathcal{P}_{j-1}(C)$, counted once. By Lemma 7.4, $|\mathcal{P}_{j-1}(C)| \le 24M^3$. For a configuration V on the lattice of side n_{j-1} we set

$$Q_j^{\mathcal{T}}(V) = \frac{4}{h_{n_{j-1}}} \sum_{p \in \mathcal{P}_{j-1}^{\mathcal{T}}} q(V_p) = \mathcal{S}_{j-1}^{\mathcal{P}_{j-1}^{\mathcal{T}}}(V). \tag{22.2}$$

This is the function that enters the chessboard estimate of Section 22.8.

Initial measures. Every estimate of this section starts from a probability measure ν on the configurations of some side n_b of the hierarchy, which we call the initial measure. It is one of the following.

1. The Wilson measure $\nu = \mu_{n_b,\gamma}$, with partition function $Z_\nu = Z_{n_b,\gamma}$. It is not restricted to D_r.
2. A normalized stopped measure at a depth $d_0 \in J\mathbb{N}_0$,

$$d\nu = Z_\nu^{-1} \mathbf{1}_{D_r} e^{-E_{d_0,\mathrm{sat}}/h_{n_b} - R_{d_0,\mathrm{sat}}}\, dH_{n_b}, \qquad Z_\nu = \int_{D_r} e^{-E_{d_0,\mathrm{sat}}/h_{n_b} - R_{d_0,\mathrm{sat}}}\, dH_{n_b},$$

as in Definition 4.4 and Theorem 14.6. Here $E_{d,\mathrm{sat}}$ is the extension of the effective classical action E_d to D_ρ by gauge invariance (Theorem 11.6), and $R_{d,\mathrm{sat}}$ is the corresponding effective interaction. The partition function Z_ν is not centered: the value $R_{d_0}(I)$ is kept in it.

Large-field decompositions. We use the partition of Theorem 21.5. Given an initial measure ν and a stopping level, the support of ν is partitioned into finitely many Borel sets $\mathcal{A}_\mathcal{X}$, indexed by large-field decompositions $\mathcal{X}$. A decomposition is produced by testing the plaquettes of the iterates $T_M^\ell V$ in increasing order of the level ℓ, and in a fixed order within one level. A plaquette f at level ℓ_f is a recorded bad plaquette of $\mathcal{X}$ if $q_f \geq d_*$ and its full dependence set avoids the set excluded before it. The variables of that dependence set that are not yet frozen are then frozen at the beginning of the RG step containing the level ℓ_f, together with a neighborhood, the excluded neighborhood of f, which is enlarged at each later RG step. We write $n_f = n_{\ell_f}$ for the side on which f is recorded and $x_f = n_f/\gamma$. Away from the excluded regions, the renormalization group is run on block regions, in RG steps of J averaging steps each, from the initial level to the stopping level; both levels are boundaries of RG steps. At the stopping level, of side m, the decomposition leaves a stopping field $c \in \mathrm{SU}(2)^F$ on the set F of links of the block region at the stopping level. We write $H = \mathcal{E}_m \setminus F$ for the other links of the stopping lattice, including the links across the boundary of the block region. For $z \in \mathrm{SU}(2)^H$, we write $c \oplus z$ for the configuration on the stopping lattice that equals c on F and z on H, and we call it a completion of c. The frozen coordinates b_{rec} consist of all frozen group variables, each kept on the lattice of the scale at which it was frozen. The map $V \mapsto \mathscr{O}_T^\mathcal{X}(V) = (c, b_{\mathrm{rec}})$ records the stopping field and the frozen coordinates. For a nonnegative function Q and $s \geq 0$, we write

$$\eta_\mathcal{X} = (\mathscr{O}_T^\mathcal{X})_\#(\mathbf{1}_{\mathcal{A}_\mathcal{X}}\nu), \qquad \eta_\mathcal{X}^s = (\mathscr{O}_T^\mathcal{X})_\#(e^{sQ}\mathbf{1}_{\mathcal{A}_\mathcal{X}}\nu).$$

For a Wilson initial measure, the first RG step of Theorem 21.5 separates the frozen group variables adjacent to the block region from those deep inside the excluded regions. The latter are arbitrary elements of $\mathrm{SU}(2)$; they are never inserted into an analytic function and enter only through an exact Wilson factor.

The analytic estimates are applied at gauge representatives of the stopping field and the frozen coordinates that satisfy the domain conditions and the reconstruction identities of Theorem 21.12. They are obtained from the representatives with small frozen coordinates at the stopping level by applying the reconstruction maps of the successive RG steps, and they also satisfy the identities for the insertion of frozen coordinates stated there. Below, we call them representatives satisfying the reconstruction identities.

Table 22.1 lists the measures that occur in the proof of Theorem 22.1, with their total masses and normalizations. The measures $\eta_\mathcal{X}$, $\eta_\mathcal{X}^s$, and ξ_T are not renormalized; they keep the partition function Z_ν of the initial measure.

Table 22.1. Measures used in the proof of Theorem 22.1.

Measure	Space	Total mass	Normalization
Wilson initial measure $\mu_{n_b,\gamma}$	$\mathcal{U}_{n_b}$	1	$Z_{n_b,\gamma}$
Stopped initial measure $\eta_{\mathcal{X}}$	$D_r \subset \mathcal{U}_{n_b}$ stopping fields and frozen coordinates	1 $\nu(\mathcal{A}_{\mathcal{X}}) \le 1$	Z_ν, not centered that of ν
$\eta^s_{\mathcal{X}}$	same as $\eta_{\mathcal{X}}$	$\mathbb{E}_\nu[e^{sQ}; \mathcal{A}_{\mathcal{X}}]$	that of ν
Reference measure ξ_T (Theorem 22.4)	$D_r \subset \mathcal{U}_m$	$m_T^{\mathbb{T}} \le 1$	prefactor $Z_\nu^{-1} e^{\Lambda_T^{\mathbb{T}}}$
Comparison measure $\widetilde{\sigma}_{\lambda,d,g}$ (Theorem 22.10)	$\mathcal{U}_m$	finite	$\widehat{Z}_d(g)$, an integral over D_r
Frozen-coordinate measure $\rho_{\mathcal{X}} = w_{\mathcal{X}} H_{\mathcal{X}}$	frozen coordinates	≤ 1	Haar

Dependence of constants. The constants of the local analytic estimates have the dependence described in item (3) of Definition 4.14. They depend only on M, J, the larger construction domains and their radius ratios, the spatial and boundary decay rates, the density of variables, and the norm bounds. They are independent of L, γ, the lattice sides, the depth, the number of RG steps since a frozen coordinate was created, the shape and topology of the block regions, and the real values of the frozen coordinates in their domain. Where stated, they are also independent of the widths of the boundary layers and excluded neighborhoods chosen later; these widths enter only through explicit counts. The constants in the probability estimates have the dependence described in item (4) of Definition 4.14. They may in addition depend on L, a fixed coupling ceiling, the fixed parameters, and the finite family of stopping offsets, but not on the coupling below the ceiling, the sides, the depth, or the geometry, age, and frozen values of a decomposition. We claim no useful bound as $J \to \infty$.

Thresholds. Fix $d_{\mathrm{cut}} > 0$ and set

$$d_* = d_{\mathrm{cut}}/2, \qquad c_E = 1 + C_M \pi \sqrt{2 d_{\mathrm{cut}}},$$

where δ_* and C_M are the constants of Theorem 22.4(a). For the chessboard estimate of Lemma 22.11 we assume $\pi\sqrt{2d_{\mathrm{cut}}} \le \delta_*$. In Theorem 22.1, these numbers enter only through the range of s and the definition of the recorded bad plaquettes.

The main estimate. The constants $K_M, K_1, \kappa_*, \kappa_0, c_A^{\mathrm{act}}, \alpha_W$ in the following theorem are defined in Theorem 22.4; they depend only on M and on the fixed classical data.

Theorem 22.1. *Fix $L > 0$, an odd integer $M \geq 3$, an integer $J \geq 1$, and $B = M^J$, and fix parameters satisfying the hypotheses of Theorems 20.14, 21.5, and 21.12. These include the coefficient-norm bounds at initialization, both substitution bounds* (22.6)*, the boundary-distance comparison, and the product domains verified in Lemma 22.3. The cutoff amplitude A_{w} is fixed before the coupling ceiling $g_* < 1$. Fix a finite nonempty set $\mathscr{R} \subset \mathbb{N}_0$ of stopping offsets, all remainders $0 \leq u_{\mathrm{ph}} < J$, the buffers containing their full dependence sets, and the bound F_J of Theorem 21.5 for the number of affected source plaquettes. Fix $\chi_* \geq 1$ such that the ratio of every stopping side of this family to the requested side n_{j-1} is at most χ_*, and such that $n_b/n_{j-1} \leq \chi_*$ whenever the stopping level lies at or below the initial level. Every iterate of T_M that is used must belong to the given finite hierarchy, and only full RG steps are integrated.*

Let $K_M, K_1, \kappa_*, \kappa_0, c_A^{\mathrm{act}}, \alpha_W$ be as in Theorem 22.4, and put $K_{\mathrm{W}} = 48K_1/\alpha_{\mathrm{W}}$ and $\theta = 1/2$. Choose $s_0 > 0$, after F_J, such that

$$s_0 \leq \min\Big\{\frac{1}{2},\ \frac{\kappa_*}{2}c_E^{-(J-1)},\ \frac{1}{4K_W},\ \frac{\theta c_A^{\mathrm{act}} d_*}{16F_J},\ \frac{\kappa_0}{2K_M}\Big\}.$$

Any further fixed decrease of s_0 is allowed. Then for every $0 < \Gamma < \infty$ there exist $n_{\min} \in 4\mathbb{N}$ and finite nonnegative constants C_v, C_s, C_b with $C_s \geq 9\chi_*^2$, chosen before the coupling, the side, and the depth, such that the following holds.

Let $0 < \gamma \leq \Gamma$, $u \in 4\mathbb{N}$ with $u \geq n_{\min}$, $K \in \mathbb{N}_0$, $N = uB^K$, $n_i = N/M^i$, $1 \leq j \leq JK$, and $b \in J\mathbb{N}_0$ with $0 \leq b \leq j-1$. Let ν be either the Wilson measure $\mu_{n_b,\gamma}$ or a normalized stopped measure on $\mathcal{U}_{n_b}$ at a depth aJ, $a \in \mathbb{N}_0$. Then, for each of the eight tilings $\mathcal{T}$ and every $0 \leq s \leq s_0$,

$$\log \mathbb{E}_\nu \exp\{sQ_j^{\mathcal{T}}(T_M^{j-1-b}V)\} \leq 3C_v n_{j-1}^3 + C_s n_{j-1}^2 \log(1/g_{n_{j-1}}) + C_b.$$

This covers every remainder u_{ph}, stopping levels at or below the initial level, an empty block region at the stopping level, and decompositions whose block region becomes empty before the stopping level and which are continued by empty RG steps.

More precisely, a recorded bad plaquette f created at side n_f contributes at least $P_0 x_f$ to the classical part of the exponent, where $x_f = n_f/\gamma$ and $P_0 = 4\theta c_A^{\mathrm{act}} d_*$. The plaquette-energy sum costs at most $8sF_J x_f \leq P_0 x_f/4$ per recorded bad plaquette, and all the corrections assigned to f, from the normalization constants, the missing coordinates, the boundary bands, the substitutions, and the integration over the omitted links, are at most

$$C_{\mathrm{ch},J}^{\Gamma}(1 + \log x_f)^2 \leq P_0 x_f/4.$$

Here one may take $C_{\mathrm{ch},J}^{\Gamma} = (1 + \log_+ \Gamma) C_{\mathrm{ch},J}^{\mathrm{base}}$, where $C_{\mathrm{ch},J}^{\mathrm{base}}$ depends only on the fixed parameters and the family of stopping offsets. Each decomposition retains the factor $\prod_f e^{-a_{\mathrm{act}} n_f/\gamma}$, with $a_{\mathrm{act}} = P_0/2$, and the sum of these factors over all decompositions is at most

$$\exp\Big\{\sum_\ell 3n_\ell^3 e^{-a_{\mathrm{act}} n_\ell/\gamma}\Big\},$$

which is bounded uniformly in the depth once $u \geq n_{\min}$. At a stopping side $m = \chi n_{j-1}$ one has $g_m = g_{n_{j-1}}/\sqrt{\chi}$, and the only surface term is $9\chi^2 n_{j-1}^2 \log(1/g_{n_{j-1}})$.

The constants $n_{\min}, C_v, C_s, C_b$ have the dependence described in item (4) of Definition 4.14, with the fixed ceiling Γ, the fixed parameters, and the finite family of stopping offsets and remainders. They are independent of the coupling $\gamma \in (0, \Gamma]$, the sides, the depth, the position and the length $j - 1 - b$ of the range of scales, and the age, shape, topology, and frozen values of the decompositions. The constants of the local analytic estimates keep the dependence described in item (3) of Definition 4.14; the widths enter only through the displayed counts.

Remark 22.2. There is no restriction on $j - b$, and the expectation contains no indicator of a cell condition or of a condition of the small-field event. Taking $b = 0$ and $\nu = \mu_{N,\gamma}$ gives the estimate under the Wilson measure with its own partition function. The proof does not use the bounds on the Wilson measure at successive scales of Section 23, where the theorem is used in Theorems 23.2 and 23.6.

Outline of the proof. Fix j, b, and $\mathcal{T}$, and write $n = n_{j-1}$. If the planned stopping level lies at or below the initial level, then only a bounded number of averaging steps separates the initial lattice from level $j - 1$, and the estimate follows from the partition-function bounds on the initial lattice. Otherwise we integrate full RG steps from level b to a stopping level $t_{\text{stop}} \leq j - 1$ and keep the remaining $v = j - 1 - t_{\text{stop}}$ averaging steps inside the function $Q_j^{\mathcal{T}} \circ T_M^v$.

Step 1: classical lower bounds. Along a decomposition $\mathcal{X}$, the density of $\eta_{\mathcal{X}}$ at a representative satisfying the reconstruction identities is bounded by e^{-E_T/g_m^2} times normalization factors, where E_T is the effective classical action of the stopping field with all external classical exponents included (Theorem 21.12). We reconstruct one configuration U_* on the initial lattice with zero fluctuations. Using an energy transport estimate that is uniform in the number of averaging steps, we show that E_T/g_m^2 dominates both $\Psi_F(c)/g_m^2$, where $\Psi_F(c)$ is the minimum of $\alpha_W S_W(c \oplus z)$ over all values z of the links in H, and $A_{\mathcal{X}} = c_A^{\text{act}} \sum_f 4q_f/h_{n_f} \geq 4c_A^{\text{act}} d_* \sum_f x_f$ (Theorem 22.4). Since both lower bounds are gauge invariant, the density bound extends to all points (Theorem 22.10).

Step 2: the plaquette-energy sum. At every point of $\mathcal{A}_{\mathcal{X}}$, the plaquette-energy sum is at most $K_W \Psi_F(c)/g_m^2 + 8F_J \sum_f x_f$ (Lemma 22.8). Since $sK_W \leq 1/4$, the factor e^{sQ} is absorbed by the factor $e^{-\Psi_F(c)/(2g_m^2)}$, which leaves at least $e^{-\Psi_F(c)/(4g_m^2)}$. The minimum is then replaced by a Haar integral over the links in H, which adds $3|H| \log(1/(c_* g_m))$ to the exponent (Lemma 22.7).

Step 3: summation over decompositions. Each recorded bad plaquette contributes $-P_0 x_f$ to the exponent. All normalization corrections, boundary terms, substitution terms, and the correction from the integration over the omitted links can be assigned to recorded bad plaquettes, and the corrections assigned to f are at most $C(1 + \log x_f)^2$. For a large minimum side, they are absorbed by $P_0 x_f/4$. This leaves a factor $e^{-P_0 x_f/2}$ per recorded

bad plaquette, and the sum over decompositions converges uniformly in the depth. The remaining ratio of a Wilson integral to the reference partition function on the stopping lattice is at most $e^{Cm^3+9m^2\log(1/g_m)}$ (see Remark 22.5).

The number of ultraviolet scales causes no accumulated loss, for the following reason. A recorded bad plaquette created at side n_f has $q_f \geq d_*$, and therefore contributes at least a fixed multiple of $x_f = n_f/\gamma$ to the classical action. At each later RG step, its excluded neighborhood contains a number of variables bounded independently of the scale, and there are at most $O(1+\log n_f)$ later RG steps. Each missing Gaussian coordinate changes the normalization by $\log(1/g_i) = \log(n_i/\gamma)/2 \leq (\log x_f)/2 + O(1)$, and each other correction is bounded per variable. The total correction is therefore $O_\Gamma((1+\log x_f)^2)$, which is small compared to x_f once x_f is large.

We distinguish two sets attached to a recorded bad plaquette f; see Figure 22.1. The first is its energy-estimate predecessor set $\mathcal{B}_f$ on the initial lattice, which carries the classical lower bound for q_f. These sets are disjoint for recorded bad plaquettes at different levels and overlap at most 48 times at one level. The second is the full excluded neighborhood assigned to f, which is much larger and may overlap with the neighborhoods of other recorded bad plaquettes. Source plaquettes whose full dependence sets meet such a neighborhood are discarded, and their number per recorded bad plaquette is bounded by F_J.

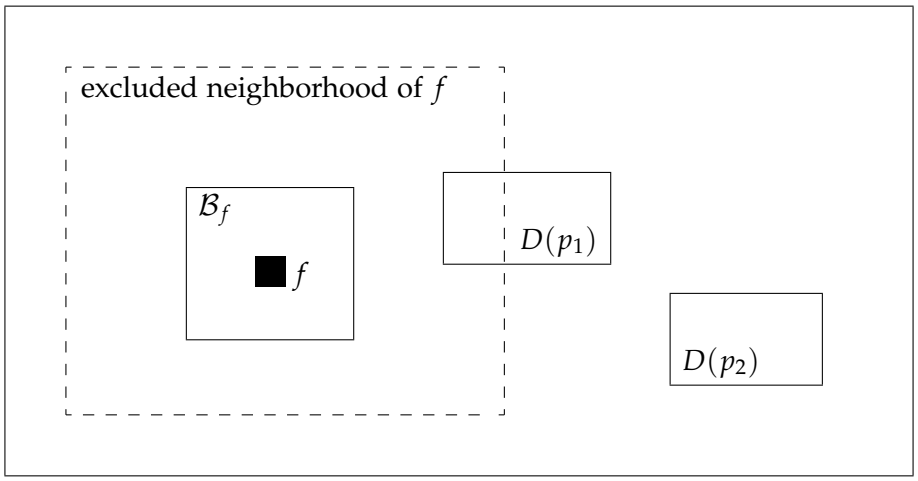

Figure 22.1. Schematic picture of the sets attached to a recorded bad plaquette f, drawn at one scale. The energy-estimate predecessor set $\mathcal{B}_f$ carries the lower bound for the action. The source plaquette p_1 is discarded because its full dependence set $D(p_1)$ meets the excluded neighborhood of f; the source plaquette p_2 is kept because $D(p_2)$ consists only of links of the block region at the stopping level.

22.2 Product domains along a large-field decomposition

The following lemma checks that the regional integration estimates of Section 20, on which the density bounds of Theorem 21.12 rest, apply along an arbitrary large-field decomposition. Only the small frozen coordinates are substituted into analytic functions (Theorems 21.5 and 21.12).

Lemma 22.3. *Fix $A_{\mathrm{w}} \geq 1$ first, and then fix parameters satisfying the hypotheses of Theorems 20.14 and 21.5, including the product domains and the coefficient-norm bounds at initialization in Theorem 21.12. Let $\mathcal{X}$ be a large-field decomposition whose initial and stopping levels are boundaries of RG steps, with T integrated RG steps. Then every integrated step consists of J averaging steps, the total number of integrated averaging steps is JT, and Theorems 20.13 and 20.14 and Lemma 20.5 apply at the gauge representatives of $\mathcal{X}$ satisfying the domain conditions and reconstruction identities of Theorem 21.12, with the frozen coordinates satisfying the bounds of Theorem 21.5. In each such application the fluctuation cutoff domain is*

$$\mathcal{W}_t = \prod_{i=0}^{J-1} \prod_{e} \{|w_{i,e}| \leq p(t_t)\}, \qquad t_t = \max_i g_{t,i}, \qquad p(t) = A_{\mathrm{w}} \log(1/t), \tag{22.3}$$

where $g_{t,i}$ is the coupling of the i-th averaging step of the t-th RG step. The coupling ceiling may depend on the fixed amplitude A_{w}; this does not change the constants of the local analytic estimates or the bounds that are uniform before J is chosen. The conclusion is uniform in the number of RG steps since the creation of the frozen coordinates and in the real values of the frozen coordinates in their stated domain, including the first step for a Wilson initial measure. No derivative with respect to a frozen coordinate is involved.

Proof. The cutoff amplitude is fixed before the coupling ceiling of Theorem 20.14 is chosen. By Theorem 21.12, every integrated step has J averaging steps, and (22.3) holds. If m_t is the output side of an RG step, then

$$t_t^2 = \gamma/(Mm_t), \qquad g_{t,i} = t_t M^{(i-J+1)/2} \quad (0 \leq i < J).$$

In particular, the radii $p_{t,i} = p(t_t)$ used in the small-field event belong to the family of radii allowed in Theorem 20.14,

$$p(t_t) \leq p_{t,i} \leq p(t_t) + c_J^{\log}, \qquad c_J^{\log} = \tfrac{1}{2} A_{\mathrm{w}} (J-1) \log M.$$

The larger enclosing product domain is used only in the comparison of Lemma 20.5; its radii do not replace the radii $p(t_t)$.

We now check the conditions on the coupling for this logarithmic family, which contains the common radius as a special case. Let $p^+(t) = p(t) + c_J^{\log}$. The condition that the cutoff domain lies in the enclosing product domain is $tp^+(t) < R_{\mathrm{en}}$. With the local

constants of Theorem 20.14, and with $E + \sigma_*$ for the norm bound of the input effective interaction, the small-interaction condition and the condition on the auxiliary complex parameter domain required there read

$$C_J t p^+(t) \le \tfrac{1}{2}, \qquad \frac{C_J t[(p^+(t))^3 + p^+(t) + (E+\sigma_*)p^+(t)]}{1 - C_J t p^+(t)} \le \epsilon_J, \qquad 2t[(p^+(t))^3 + p^+(t) + (E+\sigma_*)p^+(t)] \le c_{z,J}. \tag{22.4}$$

These are the expansion conditions of Theorem 20.14, and by the same choice of parameters the denominators of its rational image bounds are positive on the outer product domains. With $v = \log(1/t)$, every term of the form $t^k(p^+(t))^q$ with $k > 0$ equals $e^{-kv}(A_{\mathrm{w}} v + c_J^{\log})^q$, which tends to zero as $v \to \infty$. Hence one fixed ceiling on t gives the containment, all the inequalities (22.4), and the required smallness of the perturbative term

$$C_J t^2 (E+\sigma_*)\big[(p^+(t))^4 + (E+\sigma_*)(p^+(t))^2\big].$$

This ceiling is one of the fixed parameters. Since $g_* < e^{-1}$ and $A_{\mathrm{w}} \ge 1$, the radii $p(t_t)$ are at least one. At each fixed value of the frozen coordinates, the bound for the conditional mean in Lemma 20.5 stays uniformly below the cutoff radius: the ratio of the mean bound to $p(t)$ is at most $C_1 t(\mathcal{L}_V + 2)/p(t)$, which tends to zero. Together with the containment, this verifies the hypotheses of the tail estimate of Lemma 20.5 on the chosen cutoff domain.

We also verify the measure-theoretic hypotheses of that comparison, at every fixed real value of the frozen coordinates and every fixed coarse background. The enclosing product domain $\mathcal{K}_t$ is a finite product of closed balls of positive radius in $\mathbb{R}^3$, so it is Borel, compact, and of finite positive Lebesgue volume. The conditional fluctuation potential V given by Theorem 20.14 is real and of class C^2 on a neighborhood of $\mathcal{K}_t$, because the image bounds keep its inverse maps, Jacobians, and positive Hessian determinants within their domains. Thus there exist finite real numbers $v_- \le v_+$, which may depend on the fixed background and frozen coordinates, such that $v_- \le V \le v_+$ on $\mathcal{K}_t$. In particular,

$$0 < e^{-v_+}|\mathcal{K}_t| \le Z_{\mathcal{K}_t} = \int_{\mathcal{K}_t} e^{-V}\, dw \le e^{-v_-}|\mathcal{K}_t| < \infty. \tag{22.5}$$

The set S of supported fluctuation coordinates is the inverse image under a Borel coordinate map of the finitely many tests of the decomposition and of the coordinate domains, and the cutoff domain $\mathcal{W}_t$ is defined by finitely many inequalities; both are Borel. Every indicator or optional test $0 \le \chi \le 1$ that is kept is Borel, and e^{-V} is positive and Borel. The Haar disintegration, Gaussian, and constant prefactors are identical on both sides of the comparison. Since these checks are made at each fixed preceding output point and fixed frozen coordinates, no uniform bound on $v_\pm$ is needed. If there are no fluctuation

blocks, the product domain is a point of mass one; its partition function is positive and finite, its determinant is one, and its logarithmic determinant is zero.

For the substitution of frozen coordinates into analytic functions, Theorem 21.5 includes the initial bound for finite products of links and all conversion constants in $C_{\mathrm{conv},J} \geq C_{\mathrm{ad},J}$. At the representatives of the lemma, we have, at each scale at which variables are frozen and for both spatially varying radii $\phi_{\mathrm{cl}}, \phi_{\mathrm{q}}$,

$$|c_j^\sharp| \leq \min\{\beta_{\mathrm{rec}}, \phi_\bullet(j)/4\}, \qquad C_{\mathrm{bc},\bullet} E_\bullet \beta_{\mathrm{rec}}/\rho_\bullet \leq \sigma_*/4, \qquad \bullet \in \{\mathrm{cl}, \mathrm{q}\}. \tag{22.6}$$

For a frozen group variable b_j kept on the lattice where it was frozen, we have $c_j^\sharp = \operatorname{Log} b_j$ in the identity chart, and hence $|c_j^\sharp| = \rho_G(b_j)$. A longer fixed product of links uses the conversion included in $C_{\mathrm{conv},J}$, which is fixed before β_{rec} and r. At initialization, for a stopped initial measure, we use the bound by r coming from D_r, together with $C_{\mathrm{ad},J} r < \beta_{\mathrm{rec}}$; for a Wilson initial measure, the bound for the frozen variables adjacent to the block region is the other initialization clause of Theorem 21.5. The bound (22.6) covers all frozen variables, including the boundary band, the boundary neighborhoods, the links across the boundary of the block region, and the initialization, and its constant $C_{\mathrm{bc},\bullet}$ includes the sum over all these types. The arbitrary frozen group variables deep inside excluded regions are fixed external parameters and are not inserted into analytic functions.

All variables in the band of reduced analytic radius are frozen. Thus every variable that remains in the incoming block region $D_{\mathrm{in},t}$ has the classical radius ρ_{cl}, and the incoming norm of the classical perturbation in the coefficient-norm bounds is evaluated at that radius; the spatially varying radius is used only for the output. By Theorem 21.5, the old fixed complement and the points of creation of frozen variables remain in the fixed complement of the next block region, up to the fixed buffer of the finite link products. In the current units, the incoming and current distances to the fixed complement satisfy

$$d_{D_{\mathrm{in},t}}(i) \geq B d_{\mathrm{current}}(e) - B \operatorname{dist}(e, i/B) - C_{\mathrm{buf},J},$$

where i is the point of creation of an incoming variable, e is a current point, and $C_{\mathrm{buf},J}$ is the fixed buffer constant. This is the boundary-distance comparison required in Theorem 21.12 (compare Theorem 19.9); enlarging the fixed complement preserves the inclusion, and at initialization there is no boundary. The uniform bound on the conditional force kept in that induction is the following condition on the same product domains:

$$\begin{gathered} \delta_{V,t} = \max_I \sup_{y \in \mathcal{T}_I} \left\| A_I^{-1} V_I(c, a_I(c, y; \xi), y) \right\|_{\mathrm{coeff}}, \\ C_{\mathrm{seq},J}(2\delta_{V,t} + r_q) < \tfrac{1}{2}\varepsilon_{\mathrm{tube}}. \end{gathered} \tag{22.7}$$

Here I runs over the finitely many initial segments of the conditional integrations, A_I is the positive reference block of the segment I, a_I is its conditional constrained minimizer

without perturbation, V_I is the z_I-derivative, in the original free coordinates, of the added force V of (21.12), $\mathcal{T}_I$ is the domain of the remaining parameters, and r_q is the fixed radius of the free coordinates. The coefficient norm includes the common product domain of the coarse fields, uniformly at fixed real frozen coordinates. The condition (22.7) is a hypothesis on the product domains in Theorem 21.12 (see Lemma 19.3), uniform on the prescribed ball of classical perturbations; it is part of the fixed parameters and is verified in Section 23, see (23.29). The supremum is over every remaining parameter used in the sequential construction, not only over the point with zero fluctuations, and all real frozen coordinates are held fixed. Hence the image bounds and the sequential containment used in the induction hold on their stated domains.

Finally, $x_0, x_0^{\mathrm{cl}} \le \sigma_*$ are the coefficient-norm hypotheses of the induction at initialization, including the substitution at initialization. Its constants are those of the perturbed maps: $K_{\mathrm{col},J}$ in Theorem 20.14 bounds the columns of the perturbed zero-fluctuation map uniformly on the larger perturbation domain, and we use the resulting K_J in the output bound of that theorem and in its choice of the width s_{er} of the boundary layer removed at each step. By the substitution bounds (22.6), we have $z_t, z_t^{\mathrm{cl}} \le \sigma_*/4$, and the choice of s_{er} gives $2e^{-\alpha(s_{\mathrm{er}}-1)} y_t \le \sigma_*/2$, with the same inequality for the classical output bound. Thus both incoming norms at the next boundary are at most $3\sigma_*/4 < \sigma_*$, and by induction the coefficient-norm hypothesis holds after any number of RG steps. Since every integrated step is a full RG step, Theorem 20.13 applies at every step, including its incoming value and the initialization.

The sets of such representatives in Theorem 21.12 start from the representatives at which the bounds on the frozen coordinates just checked hold, and they contain every supported fiber point over each preceding output point. A gauge transformation acting independently at the endpoints of the frozen variables need not preserve the bound on their logarithms. We therefore use analytic estimates only on these sets, and we use the pointwise gauge covariance of Theorem 21.9 only after a gauge-invariant upper bound has been obtained. This verifies the hypotheses for both initial measures. □

22.3 Energy transport, feasible configurations, and the reference normalization

The next theorem collects the classical estimates: (a) is used in Sections 22.5 and 22.8, (b) in Section 22.6, and (c) in Section 22.7.

Theorem 22.4. *Fix an odd integer $M \ge 3$.*

(a) There are $\delta_*(M) > 0$ and $C_M < \infty$, depending only on M, such that for every level i, every set $\mathcal{P}'$ of positive plaquettes at level $i+1$, every configuration V at level i, and every δ,

$$\max_{p \in \mathrm{Pa}(\mathcal{P}')} \rho_G(V_p) \le \delta \le \delta_* \quad \Longrightarrow \quad \mathcal{S}_{i+1}^{\mathcal{P}'}(T_M V) \le (1 + C_M \delta)\, \mathcal{S}_i^{\mathrm{Pa}(\mathcal{P}')}(V).$$

Under this hypothesis no based loop holonomy in these predecessor rectangles equals $-I$, so all the logarithms in the definition of T_M there are the analytic ones. Define

$$B_* = \min\Big\{ \frac{\delta_*^2}{\pi^2}, \Big[\frac{(\sqrt{M}-1)\log 2}{\pi C_M} \Big]^2 \Big\}, \qquad \sigma(b) = \frac{\pi C_M \sqrt{b}}{\sqrt{M}-1}.$$

Let $\ell \ge 0$ be such that the side at level ℓ is at least four, let $\mathcal{P}_\ell$ be a set of positive plaquettes at level ℓ, and let $\mathcal{P}_i = \mathrm{Pa}(\mathcal{P}_{i+1})$ for $0 \le i < \ell$; we call the $\mathcal{P}_i$ the energy-estimate predecessor sets of $\mathcal{P}_\ell$. Then for every configuration U at level 0 and every $0 < b \le B_*$,

$$\mathcal{S}_\ell^{\mathcal{P}_\ell}(T_M^\ell U) \le \max\{ e^{\sigma(b)}, 8|\mathcal{P}_\ell|/b \}\, \mathcal{S}_0^{\mathcal{P}_0}(U). \tag{22.8}$$

This holds for every holonomy and with the Borel extension of T_M. If $\mathcal{S}_0^{\mathcal{P}_0}(U) \le b/h_{n_\ell}$, then for $0 \le i \le \ell$ every plaquette in $\mathcal{P}_i$ has angle at most $\pi\sqrt{b}\, M^{-(\ell-i)/2}$, and the factor in (22.8) *can be replaced by $e^{\sigma(b)} \le 2$. If $q < d_{\mathrm{cut}}$ for every plaquette in $\mathcal{P}_\ell$, then $8|\mathcal{P}_\ell|/b$ may be replaced by $4|\mathcal{P}_\ell| d_{\mathrm{cut}}/b$. Let $p_M \le 24M^3$ be the largest number of plaquettes in a set $\mathcal{P}_{j-1}(C)$, and put*

$$K_M = \max(2, 8p_M/B_*), \qquad K_1 = \max(2, 8/B_*).$$

Then for $0 \le k \le j-1$ and every configuration V at level k, and for every depth ℓ,

$$Q_j^{\mathcal{T}}(T_M^{j-1-k} V) \le K_M \frac{S_W(V)}{h_{n_k}}, \qquad \frac{S_W(T_M^\ell U)}{h_{n_\ell}} \le 48 K_1 \frac{S_W(U)}{h_{n_0}}.$$

These constants are independent of the depth, the side, J, L, γ, and the geometry. The factor K_M may be replaced by 2 only if $q < d_{\mathrm{cut}}$ for all the relevant plaquettes at level $j-1$ and $4p_M d_{\mathrm{cut}} \le B_*$.

(b) Let $\mathcal{X}$ be a large-field decomposition as in Theorem 21.12, with ℓ integrated averaging steps and stopping side m, and let $g_{\mathrm{base}}^2 = \gamma/n_b$ be the coupling of the initial lattice. At every representative $(\widehat{c}, \widehat{b_{\mathrm{rec}}})$ satisfying the domain conditions and reconstruction identities of Theorem 21.12, the zero-fluctuation reconstructions of the successive RG steps, with the frozen coordinates inserted at the scales at which they were frozen, give one configuration U_* on the initial lattice such that

$$(T_M^\ell U_*)|_F = \widehat{c}, \qquad \frac{E_T(\widehat{c}; \widehat{b_{\mathrm{rec}}})}{g_m^2} = \frac{\mathcal{E}_{\mathrm{base}}(U_*)}{g_{\mathrm{base}}^2}, \qquad g_m^2 = M^\ell g_{\mathrm{base}}^2.$$

Here E_T is the effective classical action of the stopping field after all external classical exponents have been incorporated once into the classical exponent. For a stopped initial measure, $U_* \in D_\rho$ and $\mathcal{E}_{\text{base}} = E_{d_0,\text{sat}}$ on this larger gauge-invariant domain; for a Wilson initial measure, U_* is a configuration in $\mathcal{U}_{n_b}$ and $\mathcal{E}_{\text{base}} = S_W$. Consequently

$$E_T(\widehat{c};\widehat{b_{\text{rec}}}) \geq M^\ell \inf\{\mathcal{E}_{\text{base}}(U) : U \in \mathcal{S},\ (T_M^\ell U)|_F = \widehat{c}\},$$

where $\mathcal{S} = D_\rho$ or $\mathcal{S} = \mathcal{U}_{n_b}$, respectively. No minimizer in D_r is asserted.
Let $\kappa_* > 0$ be such that $E_{d,\text{sat}} \geq \kappa_* S_W$ on D_ρ for every depth $d \geq 0$ (Theorems 11.2 and 11.6), and set

$$\kappa_0 = \min(1, \kappa_*), \qquad c_A^{\text{act}} = \alpha_W = \frac{\kappa_0}{48K_1}, \qquad \mathcal{V}_m = \alpha_W S_W.$$

The two names c_A^{act} and α_W denote the same number, in its two roles below. For $c \in \mathrm{SU}(2)^F$ and for frozen coordinates b_{rec} put

$$\Psi_F(c) = \mathcal{V}_{m;F}(c) = \min_{z \in \mathrm{SU}(2)^H} \mathcal{V}_m(c \oplus z), \qquad A_{\mathcal{X}}(b_{\text{rec}}) = c_A^{\text{act}} \sum_{f \in \mathcal{X}} \frac{4q_f(b_{\text{rec}})}{h_{n_f}},$$

where $q_f(b_{\text{rec}})$ is the energy of the recorded bad plaquette f, a function of the frozen coordinates because the full dependence set of f is frozen. Then, at the same representative,

$$\frac{E_T}{g_m^2} \geq \frac{\Psi_F(\widehat{c})}{g_m^2}, \qquad \frac{E_T}{g_m^2} \geq A_{\mathcal{X}}(\widehat{b_{\text{rec}}}), \tag{22.9}$$

and

$$A_{\mathcal{X}}(b_{\text{rec}}) \geq 4c_A^{\text{act}} d_* \sum_{f \in \mathcal{X}} \frac{n_f}{\gamma} \qquad \text{on } I_{\mathcal{X}}^{\text{act}} = \{q_f(b_{\text{rec}}) \geq d_* \text{ for all } f \in \mathcal{X}\}.$$

(c) Use the full-torus recursion of the stopped measures (Theorem 14.6) with the same RG steps as the decomposition; we call it the reference recursion. At a depth $d \geq 0$ of the reference recursion on the stopping lattice put

$$\widehat{Z}_d(g) = \int_{D_r} e^{-E_{d,\text{sat}}/g^2 - [R_{d,\text{sat}} - R_d(I)]}\, dH_m, \qquad g^2 = \gamma/m.$$

The restriction of the initial measure to the small-field conditions of the reference recursion and its pushforward to the stopping lattice has the form

$$d\xi_T = Z_\nu^{-1} e^{\Lambda_T^{\mathbb{T}}} \mathbf{1}_{D_r} e^{-E_{d,\text{sat}}/g^2 - [R_{d,\text{sat}} - R_d(I)]}\, dH_m,$$

where $\Lambda_T^{\mathbb{T}}$ is the normalization constant of the reference recursion; for a Wilson initial measure, only this reference measure is restricted to D_r at the start. With $m_T^{\mathbb{T}} = \xi_T(1) \leq 1$, one has exactly

$$\frac{e^{\Lambda_T^{\mathbb{T}}}}{Z_\nu} = \frac{m_T^{\mathbb{T}}}{\widehat{Z}_d(g)} \leq \widehat{Z}_d(g)^{-1}. \tag{22.10}$$

All Haar disintegration, Gaussian, cluster expansion, and substitution constants are included in $\Lambda_T^{\mathbb{T}}$, and for a stopped initial measure $\Lambda_0^{\mathbb{T}} = -R_{d_0}(I)$.
For every fixed $0 < \lambda_0 \le \lambda_1 < \infty$ there are $C, C', C'' < \infty$, uniform in the depth d of the reference recursion, in m, and in $0 < g \le g_* < 1$, such that

$$\widehat{Z}_d(g) \ge e^{-C3m^3} g^{3(2m^3+1)}, \qquad \int e^{-\lambda \mathcal{V}_m/g^2}\, dH_m \le e^{C'3m^3} g^{3(2m^3-3m^2+1)}$$

for $\lambda \in [\lambda_0, \lambda_1]$ with $4\lambda\alpha_W/g^2 \ge 1$. Consequently the logarithm of the ratio of these two integrals is at most $C''3m^3 + 9m^2\log(1/g)$. The normalized stopped measure $\widehat{\nu}$ on the stopping lattice, with the same support D_r, satisfies

$$\log \mathbb{E}_{\widehat{\nu}} e^{vS_W/g^2} \le C''3m^3 + 9m^2\log(1/g), \qquad 0 \le v \le \kappa_*/2.$$

For fixed $0 < \lambda_0 \le 1$, the quantity

$$\widehat{Z}_d(g)^{-1} \int_{D_r} e^{-\lambda(E_{d,\mathrm{sat}}/g^2 + R_{d,\mathrm{sat}} - R_d(I)) + vS_W/g^2}\, dH_m, \qquad \lambda \in [\lambda_0, 1], \quad 0 \le v \le \lambda_0\kappa_*/2,$$

satisfies the same bound with a larger volume constant. In each of these ratios the boundary correction $9m^2\log(1/g)$ occurs once. The denominator is always the integral over exactly D_r; the periodic boundary plaquettes are deleted only in the upper bound for the numerator.

The constants of the reconstruction and of the normalization constants have the dependence described in item (3) of Definition 4.14, excluding the widths chosen later. The constants in (c) depend on the fixed domains on the torus, r, the norm bounds, and the interval $[\lambda_0, \lambda_1]$ of action coefficients, not on the depth, the side, or the coupling. Applications to probability estimates have the dependence described in item (4) of Definition 4.14.

Remark 22.5. The factor g^{-9m^2} in (c) comes from a count of independent coordinates. The periodic lattice of side m has $3m^3$ links and m^3 sites, so the complement of a spanning tree has $2m^3 + 1$ links; restricting each of them to a ball of radius proportional to g in SU(2), a group of dimension three, gives the lower bound $g^{3(2m^3+1)}$ for $\widehat{Z}_d(g)$. The open cube with m sites per side, used for the numerator, has $3m^2(m-1)$ links and m^3 sites, hence $2m^3 - 3m^2 + 1$ links outside a spanning tree, which give the upper bound $g^{3(2m^3-3m^2+1)}$. The difference $3[(2m^3+1) - (2m^3 - 3m^2 + 1)] = 9m^2$ is a boundary correction in an inequality; it is not an identification of a physical quantity. At a side $m = \chi n$ it becomes $9\chi^2 n^2 \log(1/g_n) + (9/2)\chi^2 n^2 \log\chi$. Gauge fixing along a tree, deleting nonnegative plaquette terms, and factorizing one-plaquette integrals are elementary stability arguments in the tradition of Faria da Veiga and O'Carroll [64, 65]; the precise periodic and open counts used here are proved in Theorem 14.8, with the open-cube estimate of Lemma 6.10.

Proof of Theorem 22.4(a). We write $h_i = h_{n_i}$ within this proof.

Transport over one averaging step. Multiplying the restricted conclusion of Theorem 7.3 by four and dividing by $h_{i+1} = Mh_i$, we obtain the displayed implication. Its hypotheses are local: the maximum is over the union of the complete predecessor rectangles, and the side at level $i+1$ is at least four. We may decrease $\delta_*(M)$ so that the exceptional based loop holonomies are excluded as well. To check this, note that a contour $F_{c,x}C_c^{-1}$ in (4.3) is filled by moving its straight segment of length M across the coordinate segments of the path $\sigma_{v,x}$. At most $M\sum_{k=1}^{3}|x_k - v_k| \le 3M(M-1)/2$ elementary moves across one plaquette are needed, and each move inserts a conjugate of a plaquette transport or of its inverse. All these plaquettes belong to the complete predecessor rectangle, so by the bi-invariant triangle inequality the distance of this based loop holonomy from I is at most $3M^2\delta$. If we also require $3M^2\delta_* < 2\pi$, then this holonomy is not $-I$, and its logarithm is the analytic one. This decrease of δ_* changes only a constant depending on M.

Transport over many averaging steps. Let $V^i = T_M^i U$ and write

$$e_i = \mathcal{S}_i^{\mathcal{P}_i}(V^i), \qquad \delta_i = \max_{p\in\mathcal{P}_i} \rho_G(V_p^i), \qquad \Pi_i = \prod_{k<i}(1 + C_M\delta_k).$$

For an empty set of plaquettes we set the maximum to zero; the corresponding energy is also zero. Suppose first that $e_0 \le b/h_\ell$. We prove by induction on $i \le \ell$ that the first i steps satisfy

$$e_i \le \Pi_i e_0, \qquad \Pi_i \le \exp\Big\{\pi C_M\sqrt{b}\sum_{k<i} M^{-(\ell-k)/2}\Big\} \le 2. \tag{22.11}$$

The case $i = 0$ is immediate. Suppose that (22.11) holds for some i. Since all plaquette energies are nonnegative, (22.1) implies that, for every $p \in \mathcal{P}_i$,

$$\rho_G(V_p^i)^2 \le 2\pi^2 q(V_p^i) \le \frac{\pi^2 h_i}{2} e_i \le \frac{\pi^2}{2}\Pi_i b M^{-(\ell-i)} \le \pi^2 b M^{-(\ell-i)},$$

where we used $h_i/h_\ell = M^{-(\ell-i)}$ and $\Pi_i \le 2$. For $i < \ell$ this is at most $\pi^2 b \le \delta_*^2$. Then the transport over one averaging step applies with $\mathrm{Pa}(\mathcal{P}_{i+1}) = \mathcal{P}_i$; it gives $e_{i+1} \le (1 + C_M\delta_i)e_i$ and excludes all exceptional values used in that step. Further,

$$\log\Pi_{i+1} \le C_M\sum_{k\le i}\delta_k \le \pi C_M\sqrt{b}\sum_{r\ge 1} M^{-r/2} = \sigma(b) \le \log 2.$$

This closes the induction (22.11). The bound on individual plaquettes also holds at $i = \ell$, and no further transport step is needed there. This proves all the stated conclusions under the hypothesis $e_0 \le b/h_\ell$, including the case $\ell = 0$.

If instead $e_0 > b/h_\ell$, then since $q \le 2$, we have $e_\ell \le 8|\mathcal{P}_\ell|/h_\ell < (8|\mathcal{P}_\ell|/b)e_0$. If every plaquette of $\mathcal{P}_\ell$ has $q < d_{\mathrm{cut}}$, the upper bound is $4|\mathcal{P}_\ell|d_{\mathrm{cut}}/h_\ell$. These two cases prove (22.8) for arbitrary configurations. Since no logarithm is taken in the second case, the exceptional values of the Borel extension cause no difficulty. If $q < d_{\mathrm{cut}}$ for all the relevant

plaquettes and $4p_M d_{\mathrm{cut}} \le B_*$, we may choose $b = 4p_M d_{\mathrm{cut}}$; then for every cell the second factor in (22.8) is at most one and the first is at most two.

Cells and all plaquettes. We apply (22.8) with $b = B_*$ separately to the set $\mathcal{P}_{j-1}(C)$ of each cell, with level k in place of level 0. Each such set has at most p_M plaquettes, so the factor is at most K_M. By Lemma 7.4, the energy-estimate predecessor sets at level k of distinct cells of one tiling are disjoint, and the sum of their energies is therefore at most $S_W(V)/h_{n_k}$. This proves the bound with K_M. For an arbitrary set of plaquettes at level ℓ, we apply (22.8) to each plaquette separately, with $|\mathcal{P}_\ell| = 1$ and factor at most K_1. By the same lemma, a plaquette of the initial lattice lies in at most 48 of these predecessor sets, and summation gives the factor $48K_1$. Both arguments apply with any intermediate level as initial level. □

Proof of Theorem 22.4(b). The effective classical action along the decomposition. By Theorem 21.12, the initial and stopping levels are boundaries of RG steps, and there are T integrated RG steps of J averaging steps each; thus $\ell = JT$. The logarithmic product domains, the bounds on the frozen coordinates that are inserted into analytic functions, the coefficient-norm bounds, and the representatives are those checked in Lemma 22.3. For the t-th RG step, let C_t^0 be its reconstruction map with every normalized fluctuation variable set to zero, that is, its zero-fluctuation reconstruction. By the definition of the classical part of its objective, the outgoing effective classical action is

$$E_{t+1}^{\mathrm{out}}(c; b_{\mathrm{rec}}^{(t)}) = B\, E_t\big(C_t^0(c; b_{\mathrm{rec}}^{(t)}); b_{\mathrm{rec}}^{(t)}\big), \qquad B = M^J. \tag{22.12}$$

If new coordinates $c^\sharp$ are frozen at the end of the step, the next incoming action is

$$E_{t+1}(v; b_{\mathrm{rec}}^{(t)}, c^\sharp) = E_{t+1}^{\mathrm{out}}(v \oplus c^\sharp; b_{\mathrm{rec}}^{(t)}).$$

Thus freezing is a direct substitution in this identity; in particular, the value at $v = 0$ is kept together with the nonconstant part. For an external classical exponent S_{ext}, the convention of Theorem 21.12 is the exact identity

$$e^{-S_{\mathrm{ext}}} e^{-E_t^{\mathrm{int}}/g_t^2} = e^{-[E_t^{\mathrm{int}} + g_t^2 S_{\mathrm{ext}}]/g_t^2}.$$

It adds the term once to the effective classical action and removes it from the weight of the frozen coordinates. Under (22.12) the added action and g_t^2 are both multiplied by B, which leaves the exponent unchanged.

One feasible configuration. We start from such a representative at which the bounds on the frozen coordinates hold. We insert the frozen coordinates at each preceding scale at which they were frozen, and apply the maps C_t^0 downward. The reconstruction identities and the protection of all stored endpoints in Theorems 21.5 and 21.12 ensure that each insertion gives back the coordinate of the preceding output point, that each reconstruction

solves its block averaging constraint exactly, and that every older frozen dependence is preserved. The image bounds of Theorem 20.14, applied with the hypotheses verified in Lemma 22.3, keep this downward sequence of reconstructions in its product domains. For a stopped initial measure, the resulting representative on the initial lattice lies in the larger common chart, so its configuration U_* lies in D_ρ; this uses the larger image domain, not membership in D_r. For a Wilson initial measure, the frozen variables deep inside excluded regions remain arbitrary group elements, and the initial classical exponent is exactly $S_W(U_*)$. Composing the constraint identities, we obtain $(T_M^\ell U_*)|_F = \widehat{c}$. Dividing (22.12) by $g_{t+1}^2 = B g_t^2$ and iterating over the T RG steps gives the identity for E_T/g_m^2, and $JT = \ell$ implies $g_m^2 = M^\ell g_{\text{base}}^2$. Since U_* belongs to the constrained set, the lower bound by the infimum follows; no interchange of minima is involved.

The first lower bound. By the lower bound of Theorem 11.2 on the common radius ρ, transported by the fixed gauge transformation of a representative on the initial lattice (Theorem 11.6), we have

$$\frac{\mathcal{E}_{\text{base}}(U_*)}{g_{\text{base}}^2} \geq \kappa_0 \frac{S_W(U_*)}{g_{\text{base}}^2}. \tag{22.13}$$

The radius is within the domain of Theorem 11.2, and the constant κ_* there is valid for every integer depth, whether or not an effective interaction is attached to that depth, as also stated in Theorem 14.8; for a Wilson initial measure (22.13) holds with constant one. Combining this with the bound for all plaquettes in (a), we obtain

$$\frac{E_T}{g_m^2} \geq \frac{\kappa_0}{48K_1} \frac{S_W(T_M^\ell U_*)}{g_m^2} \geq \frac{\Psi_F(\widehat{c})}{g_m^2}.$$

In the last inequality we used that $T_M^\ell U_* = \widehat{c} \oplus z$ for some $z \in \mathrm{SU}(2)^H$, and that Ψ_F minimizes over all such z.

The second lower bound. For a recorded bad plaquette f, let $\mathcal{B}_f$ be the energy-estimate predecessor set of $\{f\}$ on the initial lattice. We first justify disjointness at different levels. On the input lattice of the RG step in which f is recorded, the endpoints of its full dependence list cover every vertex of the four centered blocks obtained by pulling back the corners of f to that input lattice. Indeed, each one-step formula reads the root paths $\sigma_{a,x}$ for every vertex x of each endpoint block; their trees span those blocks, and the same assertion follows recursively from the centered nesting identity. For a plaquette at the input level, its four boundary links already cover its four corner vertices. By Lemma 7.4, every plaquette of $\mathcal{B}_f$ lies in the centered preimages of these blocks.

All these dependence variables are frozen together with their excluded neighborhood by Definition 21.4(2). The neighborhood includes the protected endpoint margins, so it excludes the incident dependence links as well as the marked vertices; the endpoint protection rule of Theorem 21.3(4) preserves this exclusion at later scales. Suppose that f and f' are recorded at levels $\ell_f < \ell_{f'}$ and that their initial energy-estimate predecessor

sets share a plaquette. The centered partitions are nested. A shared vertex therefore places a marked vertex from a corner block of f in a corner block of f', when both are read on the input lattice where f was recorded. If the two tests belong to the same RG step, the full dependence list of f' meets the excluded neighborhood just added for f. If they belong to different RG steps, the centered ancestor of that mark is excluded by the endpoint protection rule, and again the full dependence list of f' meets the earlier excluded set. Both cases contradict the rule that a recorded test avoid that set. Thus the sets $\mathcal{B}_f$ at different levels are disjoint. This argument uses endpoint coverage and the protected neighborhoods; it does not require the minimal list of read links to contain every link of an energy-estimate patch.

At one level, a plaquette lies in at most 48 of the sets $\mathcal{B}_f$ by Lemma 7.4. Since plaquette energies are nonnegative, we have

$$\frac{S_W(U_*)}{g_{\mathrm{base}}^2} \geq \frac{1}{48} \sum_f \mathcal{S}_0^{\mathcal{B}_f}(U_*).$$

The comparison (22.8) for one plaquette and arbitrary configurations, proved in (a), applies at the level ℓ_f of each f with constant K_1. Since the feasible configuration U_* preserves every frozen dependence, the energy of f in it is $q_f(\widehat{b_{\mathrm{rec}}})$. Thus

$$\frac{S_W(U_*)}{g_{\mathrm{base}}^2} \geq \frac{1}{48K_1} \sum_f \frac{4q_f(\widehat{b_{\mathrm{rec}}})}{h_{n_f}}.$$

Multiplying by κ_0 and using (22.13), we find $E_T/g_m^2 \geq A_{\mathcal{X}}(\widehat{b_{\mathrm{rec}}})$. On $I_{\mathcal{X}}^{\mathrm{act}}$ we have $q_f \geq d_*$ and $h_{n_f} = \gamma/n_f$ for every f, which gives the lower bound for $A_{\mathcal{X}}$. □

Proof of Theorem 22.4(c). The reference identity. We apply the identity at the end of Theorem 14.8 to the same reference operators and the same partition function Z_ν as in Theorem 21.12. Every reference operator is a full RG step on the same levels. The depth d_0 of a stopped initial measure is a multiple of J, and the depth at the stopping level is $d = d_0 + JT$, with $d_0 = 0$ for a Wilson initial measure. Thus the reference recursion lies within the scope of Theorem 14.8. The stopping side is m, the preceding depth is d, and the centered effective interaction is $R_{d,\mathrm{sat}} - R_d(I)$. Restriction and pushforward give a subprobability measure, also for a Wilson initial measure. Its density is the displayed ξ_T, with mass at most one. Integrating it, we obtain (22.10). The initial value $\Lambda_0^{\mathbb{T}} = -R_{d_0}(I)$ for a stopped initial measure holds because Z_ν is not centered. All later constants are those of this one recursion.

The partition-function bounds. These are the bounds of Theorem 14.8 on the lattice of side m, with $D = 3m^3$. The trial configurations of that theorem have $2m^3 + 1$ links outside a spanning tree, each with logarithm of norm at most $a_0 g < \min(r/2, 1)$, and the tree

variables have Haar integral one. The bounds on the action and the effective interaction on this set, together with the volume of a ball in SU(2), give

$$\widehat{Z}_d(g) \geq \Big(\frac{a_0 g - \sin(a_0 g)}{2\pi}\Big)^{2m^3+1} e^{-C3m^3} \geq e^{-C_L 3m^3} g^{3(2m^3+1)},$$

where we used $x - \sin x \geq x^3/8$ for $0 \leq x \leq 1$ and included the powers of a_0 in C_L. This lower bound is an integral over exactly D_r. The upper bound for $\int e^{-\lambda \mathcal{V}_m/g^2}\, dH_m = \int e^{-\lambda \alpha_W S_W/g^2}\, dH_m$ is the bound for Wilson numerators in Theorem 14.8, with $\alpha_0 = \alpha_W$, $s = 0$, and inverse coupling $4\lambda\alpha_W/g^2 \geq 1$. In its proof, the plaquettes crossing the periodic boundary are deleted from the numerator, the unused links integrate to one, and on the remaining open cube with m sites per side the $2m^3 - 3m^2 + 1$ plaquettes selected along an axial tree have independent Haar-distributed transports; the one-plaquette bound $\int e^{-\beta q}\, dH \leq \sqrt{2/\pi}\, \beta^{-3/2}$ of Lemma 6.10 then gives the factor $g^{3(2m^3-3m^2+1)}$. Dividing by the lower bound for $\widehat{Z}_d(g)$ leaves $3[(2m^3+1) - (2m^3 - 3m^2 + 1)] = 9m^2$ powers of $1/g$.

The bound for the stopped measure is the exponential-moment bound of Theorem 14.8, with $\lambda_{\mathrm{en}} = \kappa_*/2$. It can also be read off from the same calculation: on D_r its integrand satisfies

$$e^{-E_{d,\mathrm{sat}}/g^2 - [R_{d,\mathrm{sat}} - R_d(I)] + vS_W/g^2} \leq e^{C3m^3} e^{-(\kappa_* - v)S_W/g^2}, \qquad \kappa_* - v \geq \kappa_*/2,$$

where we used $E_{d,\mathrm{sat}} \geq \kappa_* S_W$ and the bound on the oscillation of the centered effective interaction. For the quantity with the coefficient λ we replace the coefficient by $\lambda\kappa_* - v \geq \lambda_0\kappa_*/2$, and we bound the centered effective interaction by its uniform oscillation bound from Theorem 14.8. Both estimates then follow from the upper bound for the Wilson numerator and the single lower bound for the denominator. If the ceiling g_* has not yet been reduced so that the inverse coupling of these two numerators is at least one, then on the remaining range of g, below g_* and above that threshold, $\log(1/g)$ is bounded by a fixed constant; enlarging the volume constant gives the same bounds there. Alternatively, one may make the common reduction of the ceiling in Theorem 14.8. □

22.4 The minimum of the Wilson action over omitted links

The density bounds of Section 22.6 contain the factor $e^{-\lambda \Psi_F(c)/g^2}$, a minimum over all values of the links in H, which we compare with a Haar integral over these links. The comparison is a lower bound of Laplace type that uses only stationarity at a minimizer, an upper bound on the second derivative, and the Haar volume of a small ball; no nondegenerate Hessian is needed. We first record the continuity and gauge invariance of the minimum and of the corresponding integral.

Throughout this section $m \geq 4$, $H \subset \mathcal{E}_m$ is a set of positive links, $F = \mathcal{E}_m \setminus H$, and for $c \in \mathrm{SU}(2)^F$ and $z \in \mathrm{SU}(2)^H$ we write $c \oplus z$ for the configuration on Λ_m that equals c on

F and z on H. We write H_H for the product Haar measure on $\mathrm{SU}(2)^H$, and $\mathcal{V}_m = \alpha_W S_W$ and $\Psi_F(c) = \min_z \mathcal{V}_m(c \oplus z)$ for a fixed $\alpha_W > 0$, as in Theorem 22.4(b).

Lemma 22.6. *For $\lambda > 0$ and $g > 0$ let*

$$I_{\lambda,g}(c) = \int_{\mathrm{SU}(2)^H} e^{-\lambda \mathcal{V}_m(c \oplus z)/g^2}\, dH_H(z).$$

The functions Ψ_F and $I_{\lambda,g}$ are continuous on $\mathrm{SU}(2)^F$. Let $k \in \mathrm{SU}(2)^{\Lambda_m}$ be a lattice gauge transformation and let c^k be the transformed field on F, which depends only on the values of k at the endpoints of the links in F. Then $\Psi_F(c^k) = \Psi_F(c)$ and $I_{\lambda,g}(c^k) = I_{\lambda,g}(c)$. In particular, Ψ_F and $I_{\lambda,g}$ are invariant under every gauge transformation of the endpoints of the links in F, extended arbitrarily to the other sites, and the result does not depend on the extension.

Proof. For $c, c' \in \mathrm{SU}(2)^F$ we have

$$|\Psi_F(c) - \Psi_F(c')| \le \alpha_W \sup_{z \in \mathrm{SU}(2)^H} |S_W(c \oplus z) - S_W(c' \oplus z)|.$$

Since S_W is uniformly continuous on the compact group $\mathrm{SU}(2)^{\mathcal{E}_m}$, the right side tends to zero as $c' \to c$. The same argument, applied to the integrand, shows that $I_{\lambda,g}$ is continuous. Let k be a gauge transformation, and write $z \mapsto z^k$, $(z^k)_{xy} = k_x z_{xy} k_y^{-1}$, for its action on the links in H. This map is a bijection of $\mathrm{SU}(2)^H$ that acts on each factor by a fixed left and a fixed right translation, so it preserves H_H. Since $(c \oplus z)^k = c^k \oplus z^k$ and S_W is gauge invariant, we have

$$\mathcal{V}_m(c^k \oplus z^k) = \mathcal{V}_m(c \oplus z), \qquad dH_H(z^k) = dH_H(z).$$

Taking the minimum over z and changing variables in the integral, we conclude that Ψ_F and $I_{\lambda,g}$ are invariant. If a gauge transformation is given only at the endpoints of the links in F, any two extensions to the other sites give bijections of the whole product $\mathrm{SU}(2)^H$ as above, so the result does not depend on the extension. □

Lemma 22.7. *For every $m \ge 4$, every set $H \subset \mathcal{E}_m$ of positive links, $F = \mathcal{E}_m \setminus H$, every $c \in \mathrm{SU}(2)^F$, and every fixed $\alpha_W > 0$, the function $z \mapsto \mathcal{V}_m(c \oplus z) = \alpha_W S_W(c \oplus z)$ has a minimizer z_* on $\mathrm{SU}(2)^H$, and it is stationary at z_* in all directions of the links in H. For $X = (X_e)_{e \in H} \in \mathfrak{su}(2)^H$ and the curve $z_e(t) = z_{*,e} e^{tX_e}$,*

$$\Big| \frac{d^2}{dt^2} S_W(c \oplus z(t)) \Big| \le 16 \sum_{e \in H} |X_e|^2.$$

Hence, for every $0 < g \le 1$, the product neighborhood $\{z_{*,e} e^{X_e} : |X_e| < g \text{ for all } e \in H\}$ has Haar mass at least

$$(c_* g)^{d_H}, \qquad d_H = 3|H|, \qquad c_* = (16\pi)^{-1/3},$$

and on it $\mathcal{V}_m(c \oplus z) - \Psi_F(c) \le 8\alpha_W |H| g^2$. *For* $0 < \lambda_0 \le \lambda \le \lambda_1 < \infty$,

$$e^{-\lambda \Psi_F(c)/g^2} \le (c_* g)^{-d_H} e^{8\lambda\alpha_W |H|} \int_{\mathrm{SU}(2)^H} e^{-\lambda \mathcal{V}_m(c \oplus z)/g^2} \, dH_H(z),$$

and the exponential factor may be enlarged to $e^{8\lambda_1 \alpha_W |H|}$. *These bounds hold for arbitrary links across the boundary of the block region, arbitrary values of* c, *and arbitrary shape, topology, age, and depth; the displayed constants do not depend on these parameters or on the coupling. If* H *is empty, equality holds. No regularity, uniqueness, or measurable choice of a minimizer is required.*

Proof. The function $z \mapsto \mathcal{V}_m(c \oplus z)$ is continuous on the compact product $\mathrm{SU}(2)^H$, so it attains its minimum. Every curve $t \mapsto z_{*,e} e^{tX_e}$ through the minimizer stays in this product for both signs of t, and differentiating at $t = 0$ proves stationarity in all directions of the links in H.

We extend X by zero on F. Along the curve, the transport around a positive plaquette is a product of four unitary factors. A factor $z_{*,e} e^{tX_e}$ has first and second derivatives of operator norm at most $|X_e|/2$ and $|X_e|^2/4$, since $\|X_e\|_{\mathrm{op}} = |X_e|/2$ with our normalization of the inner product; an inverse factor $e^{-tX_e} z_{*,e}^{-1}$ has the same bounds. By the product rule, $|\mathrm{tr}\, A|/2 \le \|A\|_{\mathrm{op}}$, and the Cauchy–Schwarz inequality for four terms,

$$\Big| \frac{d^2}{dt^2} q\big((c \oplus z(t))_p\big) \Big| \le \frac{1}{4} \Big(\sum_{e \in \partial p} |X_e| \Big)^2 \le \sum_{e \in \partial p} |X_e|^2.$$

Here the sum is over the positive links underlying the oriented boundary of p; for $m \ge 4$ they are distinct. Since each positive link lies in exactly four positive plaquettes and $S_W = 4 \sum_p q(U_p)$, the second derivative of S_W is bounded by $16 \sum_{e \in H} |X_e|^2$ everywhere along the curve. By Taylor's formula with integral remainder, whose weight $\int_0^1 (1 - t)\, dt$ equals $1/2$, and stationarity at $t = 0$, we have

$$\mathcal{V}_m(c \oplus z_* e^X) - \Psi_F(c) \le 8\alpha_W \sum_{e \in H} |X_e|^2.$$

Thus on the product of balls of radius g the increase is at most $8\alpha_W |H| g^2$.

The Haar probability measure on $\mathrm{SU}(2)$ has radial density $(2/\pi) \sin^2 \vartheta \, d\vartheta$ in the angle $\vartheta = |X|/2$. Thus the ball $\{e^X : |X| < g\}$ has mass $(g - \sin g)/(2\pi)$. Taylor's formula for the sine gives, for $0 \le g \le 1$,

$$g - \sin g \ge g^3/6 - g^5/120 \ge g^3/8.$$

The exponential map is injective on this ball since $g \le 1 < 2\pi$. By translation invariance of Haar measure and the product structure, the product neighborhood has mass at least $(g^3/(16\pi))^{|H|} = (c_* g)^{d_H}$. On this neighborhood the integrand $e^{-\lambda \mathcal{V}_m(c \oplus z)/g^2}$ is at least $e^{-\lambda \Psi_F(c)/g^2 - 8\lambda\alpha_W |H|}$. Integrating over the neighborhood, enlarging the domain of

integration to the whole product, and rearranging, we obtain the displayed inequality. Replacing λ by λ_1 in the positive exponential only enlarges the right side. If H is empty, all products have mass one and the additional exponents vanish. Each bound is uniform on the whole compact group, and a minimizer was used separately for each c, not as a measurable function of c. □

22.5 Domination of the plaquette-energy sum by the Wilson minimum

Along a large-field decomposition, the function $Q_j^{\mathcal{T}} \circ T_M^{j-1-b}$ need not be a function of the stopping field and the frozen coordinates alone: some requested plaquettes may have dependence sets that meet excluded neighborhoods. The next lemma shows that this does not matter for an upper bound: the bound holds for every completion $c \oplus z$, and we may then take the infimum over completions.

Lemma 22.8. *Fix an odd integer $M \geq 3$, an integer $J \geq 1$, $B = M^J$, and the fixed analytic, geometric, and buffer data of Theorems 21.5 and 21.12. Fix a finite family of stopping offsets and remainders, with total exponents $v = r_{\mathrm{stop}} J + u_{\mathrm{ph}}$ and $0 \leq u_{\mathrm{ph}} < J$, and fix the corresponding enlargement F_J of the bound for the number of affected source plaquettes in Theorem 21.5, before the interval of s or any minimum side is chosen. Let $K_1, \alpha_W > 0$ be as in Theorem 22.4 and put $K_W = 48K_1/\alpha_W$.*

Let $L > 0$ and $\gamma > 0$, and let a finite hierarchy of sides in $4\mathbb{N}$, an initial measure (stopped, at a depth $d_0 \in J\mathbb{N}_0$, or Wilson), a large-field decomposition $\mathcal{X}$ from its initial level to its stopping level with $\ell \in J\mathbb{N}_0$ averaging steps, and an exponent v of the family be given. Write $m = M^v n_{\mathrm{req}}$ for the stopping side, where $n_{\mathrm{req}} \in 4\mathbb{N}$ is the requested side; every iterate that is used must belong to the finite hierarchy. Let F be the set of links of the block region at the stopping level, $H = \mathcal{E}_m \setminus F$, and let $\mathcal{P}_{\mathrm{orig}}$ be the requested list of plaquettes at side n_{req}, a union of the sets $\mathcal{P}_{j-1}(C)$ of cells, counted once. Set

$$Q_{\mathrm{orig}}(V) = \frac{4}{h_{n_{\mathrm{req}}}} \sum_{p \in \mathcal{P}_{\mathrm{orig}}} q\big((T_M^{\ell+v} V)_p\big), \qquad g_m^2 = \gamma/m, \qquad D_{\mathcal{X}} = 8F_J \sum_{f \in \mathcal{X}} \frac{n_f}{\gamma}.$$

Then every point $V \in \mathcal{A}_{\mathcal{X}}$, with $(c, b_{\mathrm{rec}}) = \mathcal{O}_T^{\mathcal{X}}(V)$, and every $z \in \mathrm{SU}(2)^H$ satisfy

$$Q_{\mathrm{orig}}(V) \leq 48K_1 \frac{S_W(c \oplus z)}{g_m^2} + D_{\mathcal{X}}. \tag{22.14}$$

Consequently, at every point of $\mathcal{A}_{\mathcal{X}}$,

$$Q_{\mathrm{orig}}(V) \leq \frac{K_W}{g_m^2} \min_{z \in \mathrm{SU}(2)^H} \{\alpha_W S_W(c \oplus z)\} + 8F_J \sum_{f \in \mathcal{X}} \frac{n_f}{\gamma} = \frac{K_W \Psi_F(c)}{g_m^2} + D_{\mathcal{X}}. \tag{22.15}$$

The minimum Ψ_F is continuous and invariant under gauge transformations of the endpoints of the links in F (Lemma 22.6). For either initial measure ν, with its partition function Z_ν, which is not centered, let $\eta_{\mathcal{X}}$ and $\eta_{\mathcal{X}}^s$ be as in Section 22.1, with $Q = Q_{\mathrm{orig}}$. For every $s \geq 0$,

$$\eta_{\mathcal{X}}^s(dc\, db_{\mathrm{rec}}) \leq e^{sK_W \Psi_F(c)/g_m^2 + sD_{\mathcal{X}}}\, \eta_{\mathcal{X}}(dc\, db_{\mathrm{rec}}). \tag{22.16}$$

This includes decompositions without recorded bad plaquettes, an empty set F, and decompositions whose block region becomes empty before the planned stopping level, continued by empty RG steps. No small-field event, support, or partition function is changed, and no smallness of the coupling is needed beyond the existence of the decomposition. The constant K_W depends only on M and on the fixed classical lower bound and its domain; it does not depend on the side, L, the coupling, the depth, the geometry, the age, or the frozen values. The constant F_J keeps the explicit polynomial dependence on the widths in Theorem 21.5, and its coefficient has the dependence described in item (3) of Definition 4.14, independently of the widths chosen later. The constants of later probability estimates have the dependence described in item (4) of Definition 4.14.

Proof. We fix the decomposition and the requested list first.

Step 1: dependence sets. For each requested plaquette p, let $D_m(p)$ be the full set of links of the stopping lattice on which $C \mapsto q((T_M^v C)_p)$ depends. It contains the links of the four boundary transports of p and, recursively, all reference paths, relative contours, filling plaquettes, and branch tests of every entry read in the v averaging steps; the clause on complete predecessor sets in Lemma 7.4 supplies these finite dependence sets. We also trace them to every scale of the integrated decomposition at which variables were frozen. We keep p only if $D_m(p) \subset F$ and the traced dependence sets avoid all the full excluded neighborhoods assigned in Theorem 21.5: the neighborhoods of the recorded bad plaquettes with their buffers, the adjacent cells, the frozen boundary bands, the links across the boundary of the block region, the enlarged earlier excluded regions, the buffers protecting earlier stored endpoints, and the protective sets of the first step for a Wilson initial measure. Their levels of creation and their assignment to recorded bad plaquettes are kept. The smaller energy-estimate predecessor sets $\mathcal{B}_f$ would not suffice for this definition.

Step 2: kept plaquettes are determined by the stopping field. If two configurations on the stopping lattice agree on $D_m(p)$, then for every entry needed in the first averaging step they read identical path products and identical branch tests. A regular entry has the same analytic logarithm in both configurations, and an exceptional entry has the same reference-path value. By induction over the v averaging steps, the final plaquette transports agree, and hence so do their traces. This proves locality for all group values, including the exceptional branches; for $v = 0$ it is the equality of the four boundary links.

By the identity for the observation map in Theorems 21.5 and 21.9, we have $(T_M^{\ell} V)|_F = c$, and therefore, for every completion $C = c \oplus z$,

$$\frac{4}{h_{n_{\mathrm{req}}}} \sum_{p \text{ kept}} q\big((T_M^{\ell+v} V)_p\big) = \frac{4}{h_{n_{\mathrm{req}}}} \sum_{p \text{ kept}} q\big((T_M^{v} C)_p\big).$$

This equality concerns the point V itself; no auxiliary feasible configuration or representative has been substituted.

Step 3: discarded plaquettes. We assign each discarded requested plaquette to the first full excluded neighborhood that its dependence set meets, ordering first by the level of creation and then by the fixed order of the tests. If $D_m(p) \not\subset F$, an omitted link lies in an excluded neighborhood at the stopping level; otherwise the exclusion comes from an earlier traced intersection. The counting clause of Theorem 21.5, enlarged for the finite family of stopping offsets and remainders, bounds the number of plaquettes assigned to each recorded bad plaquette f by F_J. The deterministic assignment to a single f is needed only because the neighborhoods may overlap; we never use disjointness of the full neighborhoods. Since $n_{\mathrm{req}} \le n_f$ and $0 \le q \le 2$, each discarded plaquette contributes at most $8n_{\mathrm{req}}/\gamma \le 8n_f/\gamma$ to Q_{orig}. Summing over the discarded plaquettes, we find, for every $C = c \oplus z$,

$$Q_{\mathrm{orig}}(V) \le \frac{4}{h_{n_{\mathrm{req}}}} \sum_{p \text{ kept}} q\big((T_M^{v} C)_p\big) + D_{\mathcal{X}} \le \frac{4}{h_{n_{\mathrm{req}}}} \sum_{p} q\big((T_M^{v} C)_p\big) + D_{\mathcal{X}},$$

where the last sum is over all positive plaquettes at side n_{req}.

Step 4: the Wilson action of a completion. We apply the bound for all plaquettes and arbitrary configurations in Theorem 22.4(a) with initial configuration C at side m and depth v. Its initial exponent is $S_W(C)/g_m^2$, and $h_{n_{\mathrm{req}}} = M^v g_m^2$. Together with Step 3, this gives (22.14), with no additional factor m/n_{req} and no regularity test at the requested level. The bound applies to every completion, whatever its holonomies or exceptional values. Taking the infimum over the whole compact product $\mathrm{SU}(2)^H$, we obtain (22.15). By continuity of S_W and compactness, the infimum is attained, but no measurable choice of a minimizer is needed. Continuity and invariance of Ψ_F are proved in Lemma 22.6.

Step 5: empty cases. If $\mathcal{X}$ has no recorded bad plaquettes, there are no excluded neighborhoods and $D_{\mathcal{X}} = 0$. If F is empty, then no plaquette is kept, since the dependence set of every plaquette is nonempty on sides at least four, and the assignment of Step 3 gives $Q_{\mathrm{orig}} \le D_{\mathcal{X}}$ directly; in this case $\Psi_{\varnothing} = 0$, attained by the identity configuration. If the block region becomes empty before the planned stopping level, we carry the frozen coordinates unchanged through the remaining RG steps. For these steps the fluctuation integral and the determinant equal one, the nonconstant norm is zero, and the simultaneous replacement $E \mapsto BE$, $g^2 \mapsto Bg^2$ leaves the exponent unchanged. The recurrence

$R_{t+1}(f) \le B^{-1}R_t(f) + C_J(W + R_{\mathrm{cell}} + 1)$ for the radii of the excluded neighborhoods in Theorem 21.5 still assigns every later omitted link to the same neighborhoods, even when their union is the whole torus. The finite dependence range of the requested plaquettes at the stopping level is included in F_J. Thus the same assignment and the same bound hold at the planned stopping level. These empty steps use only the clauses on empty products and on normalization constants in Theorems 20.13 and 20.14 and the partition of Theorem 21.5.

Step 6: integration. For a nonnegative Borel function $\varphi(c, b_{\mathrm{rec}})$, we integrate $\varphi(\mathscr{O}_T^{\mathcal{X}}(V))e^{sQ_{\mathrm{orig}}(V)}$ against $\mathbf{1}_{\mathcal{A}_{\mathcal{X}}}\, d\nu(V)$ and insert (22.15). The right side becomes the integral of $\varphi e^{sK_W\Psi_F/g_m^2 + sD_{\mathcal{X}}}$ against $\eta_{\mathcal{X}}$, which proves (22.16). Both sides carry the same factor Z_ν^{-1}. All integrands are nonnegative, the spaces are finite-dimensional, and Q_{orig} is bounded on them. The dependence of the constants follows from the bound for all plaquettes and from the explicit count F_J. □

The same argument applies to the Wilson exponent of all plaquettes at the requested side, with a larger bound for the number of affected plaquettes. This version is used in Section 23 for exponential moments of the full blocked action.

Corollary 22.9. *In the setting of Lemma 22.8, let the requested function at side n instead be $\mathcal{Q}_n(V) = S_W(T_M^{\ell+v}V)/g_n^2$, where $m = M^v n$, v belongs to a fixed finite family of exponents, and all iterates are available. Enlarge the bound for the number of affected plaquettes to a bound F_J^{A} for the list of all positive plaquettes, before choosing any interval of s. Then at every point of $\mathcal{A}_{\mathcal{X}}$ and for every completion z,*

$$\mathcal{Q}_n(V) \le 48K_1\frac{S_W(c\oplus z)}{g_m^2} + 8F_J^{\mathrm{A}}\sum_f \frac{n_f}{\gamma}, \qquad \text{hence} \qquad \mathcal{Q}_n(V) \le \frac{K_W\Psi_F(c)}{g_m^2} + 8F_J^{\mathrm{A}}\sum_f \frac{n_f}{\gamma}.$$

The corresponding inequality for the pushforward measures, analogous to (22.16)*, holds with the same partition function. This includes Wilson initial measures, empty sets F, and decompositions continued by empty RG steps. One may take $F_J^{\mathrm{A}} = C_J^{\mathrm{A}}(W + R_{\mathrm{cell}} + 1)^3$; this bound has the same polynomial dependence on the widths, and its coefficient the same dependence, as F_J, and K_W is unchanged.*

Proof. Steps 1, 2, and 4–6 of the proof of Lemma 22.8 apply verbatim with the list of all positive plaquettes at side n in place of $\mathcal{P}_{\mathrm{orig}}$, with n in place of n_{req}, and with F_J^{A} in place of F_J. In Step 3, each discarded plaquette still contributes at most $8n/\gamma \le 8n_f/\gamma$, since the recorded bad plaquette to which it is assigned lies at a level finer than the requested side. In Step 4, the Wilson exponent of $T_M^v(c\oplus z)$ at side n is bounded by Theorem 22.4(a) with no factor depending on the ratio of the sides.

It remains to justify the count in Step 3. We check explicitly that the counting clause of Theorem 21.5 extends to the list of all plaquettes. The family of exponents v

is finite, and each exponent has a finite fixed dependence range. A neighborhood of radius R is met by the dependence sets of at most a fixed multiple of $(R+1)^3$ positive plaquettes. The recurrence for the radii in Theorem 21.5 bounds R by a fixed multiple of $W + R_{\mathrm{cell}} + 1$ at later outputs, and the enlargement at the input of the RG step of creation is already included in the count at creation, which carries the factor B. Thus passing to all plaquettes changes only this incidence constant, and unions and overlaps are handled by subadditivity and by the assignment to a single recorded bad plaquette. This proves the bound $F_J^{\mathrm{A}} = C_J^{\mathrm{A}}(W + R_{\mathrm{cell}} + 1)^3$, with the enlargement for the finite family of exponents; the number of RG steps of the decomposition does not occur. □

22.6 Gauge-invariant domination of the densities

We now combine the density bound of Theorem 21.12, which holds at representatives satisfying the reconstruction identities, with the classical lower bounds of Theorem 22.4(b). Since the resulting bound has only gauge-invariant factors, the pointwise gauge covariance of the density in Theorem 21.9 extends it to every point.

Theorem 22.10. *Let $\mathcal{X}$ be a large-field decomposition for a stopped or a Wilson initial measure as in Theorem 21.12, with stopping side m, $g^2 = \gamma/m$, and $0 < g \le 1$. Whenever the uniform bounds of Theorem 22.4(c) on the stopping lattice are used, impose also their fixed ceiling on g. Let F be the set of links of the block region at the stopping level, H the set of all other links of the stopping lattice, including the links across the boundary of the block region, and $d_H = 3|H|$. Let $p_{\mathcal{X}}(c, b_{\mathrm{rec}})$ be the density of $\eta_{\mathcal{X}}$ with respect to $H_F \otimes H_{\mathcal{X}}$ given by Theorem 21.9, where H_F and $H_{\mathcal{X}}$ are the product Haar measures on the stopping field and on the frozen coordinates. Let $w_{\mathcal{X}}$ be the gauge-invariant weight of the frozen coordinates and $\rho_{\mathcal{X}} = w_{\mathcal{X}} H_{\mathcal{X}}$, as in Theorem 21.12; they keep the indicator $I_{\mathcal{X}}^{\mathrm{act}}$ of the tests of all recorded bad plaquettes. Fix $0 < \theta < 1$, put $\lambda = 1 - \theta$, and use the constants of Theorem 22.4.*

At every representative $(\widehat{c}, \widehat{b_{\mathrm{rec}}})$ in the support satisfying the domain conditions and reconstruction identities of Theorem 21.12, the density bound of Theorem 21.12 and its estimate for the normalization constant give

$$p_{\mathcal{X}}(\widehat{c}, \widehat{b_{\mathrm{rec}}}) \le \widehat{Z}_d(g)^{-1} e^{L_{\mathcal{X}}(\widehat{b_{\mathrm{rec}}})} w_{\mathcal{X}}(\widehat{b_{\mathrm{rec}}}) e^{-E_T(\widehat{c};\widehat{b_{\mathrm{rec}}})/g^2}, \qquad L_{\mathcal{X}} \le \overline{L}_{\mathcal{X}}.$$

One may take

$$L_{\mathcal{X}} = \log A_T + \Lambda_T - \Lambda_T^{\mathbb{T}} + C_{\mathrm{osc},J} m^3, \qquad \overline{L}_{\mathcal{X}} = C_\delta + 3C_J m^3 + C_\partial \,\mathrm{Surf}_{\mathcal{X}} + \sum_{f \in \mathcal{X}} \overline{\mathrm{ch}}_f.$$

Here Λ_T is the normalization constant of the regional recursion along $\mathcal{X}$, $\Lambda_T^{\mathbb{T}}$ is that of the reference recursion, and A_T is the accumulated comparison constant of Theorem 21.12. Further, $\mathrm{Surf}_{\mathcal{X}}$ is the number of variables in the boundary bands that enter the normalization constant, and

$\overline{\mathrm{ch}}_f$ *is the sum of the nonnegative upper bounds, assigned to* f *by Theorem 21.5, for the corrections from missing Gaussian coordinates, from missing constant terms of fluctuation integrals, and from substitutions of frozen coordinates. Each missing Gaussian coordinate contributes its own* $\log(1/g_i)$*, and each other such variable contributes a fixed bound* C_J*, including the variables at initialization. These are deterministic bounds in terms of the geometry and the couplings, independent of the chosen representative. The identity* (22.10) *supplies only the prefactor* $\widehat{Z}_d(g)^{-1}$*; the bound for* $\Lambda_T - \Lambda_T^{\mathbb{T}}$ *comes from the increment estimate of Theorem 20.13.*

Applying both lower bounds (22.9) *at the same representative gives a gauge-invariant upper bound which is defined everywhere. At every point* (c, b_{rec})*, with the density of Theorem 21.9, which vanishes off the gauge saturation of these representatives,*

$$p_{\mathcal{X}}(c, b_{\mathrm{rec}}) \le \widehat{Z}_d(g)^{-1} e^{\overline{L}_{\mathcal{X}}} w_{\mathcal{X}}(b_{\mathrm{rec}}) \exp\bigl\{-\lambda \Psi_F(c)/g^2 - \theta A_{\mathcal{X}}(b_{\mathrm{rec}})\bigr\}.$$

The minimum Ψ_F *and the corresponding integral over* H *are invariant under every gauge transformation of the endpoints of the links in* F*, extended to the other sites. The tests of the recorded bad plaquettes and the other tests in* $w_{\mathcal{X}}$ *are invariant under the action of consistent endpoint gauge transformations at all scales. Hence the pointwise covariance of Theorem 21.9 applies to this bound. Define the finite measure, which is in general not normalized,*

$$d\widetilde{\sigma}_{\lambda,d,g}(C) = \widehat{Z}_d(g)^{-1} e^{-\lambda \mathcal{V}_m(C)/g^2}\, dH_m(C),$$

and let $\widetilde{\sigma}_{\lambda,d,g;F}$ *be its marginal on the links of* F*. Integrating the Wilson factor over the links in* H *gives*

$$\begin{aligned}\eta_{\mathcal{X}}(dc\, db_{\mathrm{rec}}) \le\ & \exp\bigl\{\overline{L}_{\mathcal{X}} + d_H \log(1/(c_* g)) + 8\lambda \alpha_W |H| - \theta A_{\mathcal{X}}(b_{\mathrm{rec}})\bigr\} \\ & \times [\widetilde{\sigma}_{\lambda,d,g;F} \otimes \rho_{\mathcal{X}}](dc\, db_{\mathrm{rec}}).\end{aligned}$$

For $\theta = \lambda = 1/2$*, let* Q_{orig} *be a requested plaquette-energy sum as in Lemma 22.8, and let* $\eta_{\mathcal{X}}^s = (\mathscr{O}_T^{\mathcal{X}})_{\#}(e^{sQ_{\mathrm{orig}}} \mathbf{1}_{\mathcal{A}_{\mathcal{X}}} \nu)$*. For* $0 \le s \le (4K_W)^{-1}$ *and* $\lambda_s = 1/2 - sK_W \in [1/4, 1/2]$*,*

$$\eta_{\mathcal{X}}^s \le \exp\bigl\{\overline{L}_{\mathcal{X}} + sD_{\mathcal{X}} + d_H \log(1/(c_* g)) + 8\lambda_s \alpha_W |H| - A_{\mathcal{X}}(b_{\mathrm{rec}})/2\bigr\}\, [\widetilde{\sigma}_{\lambda_s,d,g;F} \otimes \rho_{\mathcal{X}}]. \tag{22.17}$$

The function Q_{orig} *need not be a function of the observation* (c, b_{rec})*, and the same partition function* Z_ν *and the same centered denominator* $\widehat{Z}_d(g)$ *are used for all* s*.*

All external classical exponents occur once in E_T *and are absent from* $\rho_{\mathcal{X}}$*. The intermediate auxiliary actions and effective interactions need only be defined at the analytic arguments given by these representatives; no global auxiliary density is asserted or integrated. The local constants in the bounds for the normalization constant and for the oscillation have the dependence described in item (3) of Definition 4.14, independently of the widths chosen later. The explicit counts contain the dependence on the geometry, and uniform probability constants have the dependence described in item (4) of Definition 4.14.*

Proof. We first check the hypotheses of the imported estimates, then bound the density at such a representative, extend the bound to every point by gauge invariance, and finally integrate over the omitted links.

Step 1: hypotheses. The decomposition in Theorem 21.12 has its initial and stopping levels at boundaries of RG steps and integrates only full RG steps. By Lemma 22.3, its logarithmic product domains satisfy the containment and the expansion conditions, its frozen coordinates satisfy the one-quarter radius bounds and the substitution bounds, and its coefficient norms at initialization remain within the same bounds. Here A_{w} is fixed before the ceiling, and (22.5) gives measurability and a positive finite partition function for every comparison with the enclosing product domain. This verifies the hypotheses of the integration estimate and of the comparison at every step, with all frozen coordinates real.

Step 2: the bound at a representative. We choose such a representative at which the bounds on the frozen coordinates hold, and let Z_ν be the partition function of Theorem 21.12. At this representative, after the external classical exponents have been incorporated once, the induction of that theorem gives

$$p_{\mathcal{X}}(\widehat{c}, \widehat{b_{\mathrm{rec}}}) \le A_T Z_\nu^{-1} e^{\Lambda_T(\widehat{b_{\mathrm{rec}}})} w_{\mathcal{X}}(\widehat{b_{\mathrm{rec}}}) e^{-E_T/g^2 - R_T(\widehat{c};\widehat{b_{\mathrm{rec}}})}.$$

The regional effective interaction R_T is centered at the origin of the block region at the stopping level. By Theorem 20.14, its part coming from the full torus and its boundary correction satisfy the oscillation bound

$$|R_T(v; b_{\mathrm{rec}})| \le \rho^2 \Big[E|\Omega_T| + y_* \sum_{i \in \Omega_T} e^{-\alpha d_{\Omega_T}(i)} \Big] \le C_{\mathrm{osc},J} m^3,$$

where Ω_T is the list of scalar variables of the block region at the stopping level, $d_{\Omega_T}(i)$ is the distance of i to its complement, and y_* is the fixed output bound of Theorem 20.14, which is used because no boundary layer is removed after the last RG step. There are at most $9m^3$ scalar variables. In the last inequality, we used $e^{-\alpha d} \le 1$, which avoids any assumption on the shape of the boundary. The linear terms are included in this oscillation bound. The constants are evaluated on the fixed analytic domains, before the widths are chosen.

Step 3: the normalization constants. Inserting (22.10), that is $e^{\Lambda_T^{\mathbb{T}}}/Z_\nu \le \widehat{Z}_d(g)^{-1}$, into this density bound, we obtain the stated expression for $L_{\mathcal{X}}$. To bound it, we sum over the RG steps the increment inequality of Theorem 20.13, as recorded in Theorem 21.12. Every summand comes from a full RG step, and the column bounds of the perturbed maps and all the product conditions have been checked in Lemma 22.3. At initialization the normalization constant equals the constant of the reference recursion plus the

increment from the substitution at initialization. Each missing scalar Gaussian coordinate contributes $\log(1/g_i)$, and each missing constant term of a fluctuation integral and each substituted variable contributes its fixed bound C_J. Using Theorem 21.5, we assign these nonnegative bounds to the recorded bad plaquette whose assigned neighborhood contains the variable. Variables in the boundary bands contribute $C_\partial \operatorname{Surf}_{\mathcal{X}}$. A variable that lies in several neighborhoods is assigned to the first recorded bad plaquette in the fixed order of the tests, and is therefore counted once, or overcounted by a bounded positive amount. Variables at initialization are assigned in the same way. Thus

$$\Lambda_T - \Lambda_T^{\mathbb{T}} \le C_\partial \operatorname{Surf}_{\mathcal{X}} + \sum_f \overline{\mathrm{ch}}_f,$$

after a fixed bound for the bulk at the stopping level has been absorbed into $3C_J m^3$; the same C_J may include $C_{\mathrm{osc},J}/3$. Finally, $\log A_T \le C_\delta$ by Theorem 21.12 and Lemma 20.5. These estimates prove the bound by $\overline{L}_{\mathcal{X}}$, in which only counts of geometric objects and the given couplings g_i occur, and no value at the representative.

Step 4: the classical lower bounds. At the same representative, by Theorem 22.4(b), we have $E_T/g^2 \ge \Psi_F(\widehat{c})/g^2$ and $E_T/g^2 \ge A_{\mathcal{X}}(\widehat{b_{\mathrm{rec}}})$. Multiplying these inequalities by λ and θ, respectively, adding them, and using $\lambda + \theta = 1$, we obtain

$$\frac{E_T}{g^2} \ge \frac{\lambda \Psi_F(\widehat{c})}{g^2} + \theta A_{\mathcal{X}}(\widehat{b_{\mathrm{rec}}}).$$

Inserting this into the bound of Step 2, we find the pointwise upper bound at every such representative.

Step 5: extension to every point. By Lemma 22.6, Ψ_F and the integral $I_{\lambda,g}$ are continuous and invariant under gauge transformations of the endpoints of the links in F, extended to the other sites. Each value $q_f(b_{\mathrm{rec}}) = 1 - \operatorname{tr}(U_f(b_{\mathrm{rec}}))/2$ of a recorded bad plaquette is computed from the transport $U_f(b_{\mathrm{rec}})$ around f, using its frozen full dependence set and the Borel extension of T_M; under an endpoint gauge transformation the intermediate endpoint factors cancel and the final transport is conjugated. Thus $A_{\mathcal{X}}$ and all tests in $w_{\mathcal{X}}$ are invariant under the action of consistent endpoint gauge transformations in Theorem 21.9. The bound $\overline{L}_{\mathcal{X}}$ is gauge invariant, since it depends only on the geometry and the couplings. It follows that the right side of the bound is a gauge-invariant Borel function G defined everywhere. For a point $x = (c, b_{\mathrm{rec}})$ in the gauge saturation of these representatives, we choose such a representative $\widehat{x} = x^k$ at which the bounds on the frozen coordinates hold; it exists by Theorem 21.5, and the bounds of Steps 2–4 hold at $\widehat{x}$. The endpoint action on arbitrary frozen variables need not preserve the bound on their logarithms, but G is defined by invariant factors only. By the pointwise covariance of the density in Theorem 21.9, we have

$$p_{\mathcal{X}}(x) = p_{\mathcal{X}}(\widehat{x}) \le G(\widehat{x}) = G(x).$$

This is a pointwise statement for each x, and the gauge transformation k may depend on x; neither a random choice according to Haar measure nor an integration over the set of representatives is needed. Off the gauge saturation the density vanishes, and the inequality holds there as well.

Step 6: integration over the omitted links. It remains to integrate the Wilson factor, which is now defined globally. The hypothesis of Lemma 22.7 is $0 < g \le 1$, which we have assumed; hence that lemma applies with the fixed λ. This condition at the stopping side is separate from the ceiling on the largest coupling of an integrated RG step: at the output of a full RG step, $g = \sqrt{M}\, t_{\max}$. The reference identity used in Step 3 needs no uniform bound on the ratio of partition functions; whenever that bound is used, its fixed ceiling is imposed as well, as required in the statement. Multiplying by $\widehat{Z}_d(g)^{-1}\, dH_F(c)$ gives exactly

$$\widehat{Z}_d(g)^{-1}\Big[\int_{\mathrm{SU}(2)^H} e^{-\lambda \mathcal{V}_m(c\oplus z)/g^2}\, dH_H(z)\Big]\, dH_F(c) = d\widetilde{\sigma}_{\lambda,d,g;F}(c).$$

All these are finite nonnegative integrals over compact products. Multiplying the pointwise inequality by $dH_F(c)\, dH_{\mathcal{X}}(b_{\mathrm{rec}})$ proves the inequality for $\eta_{\mathcal{X}}$, with $w_{\mathcal{X}}\, dH_{\mathcal{X}} = d\rho_{\mathcal{X}}$. Every external classical exponent has entered E_T exactly once. The invariant indicators of the recorded bad plaquettes remain in $\rho_{\mathcal{X}}$; hence $q_f \ge d_*$ holds at every point of integration used later. No global value or covariance property of E_T or R_T was used. The dependence of the constants follows from the local bounds for the oscillation and the normalization constant and from the displayed counts.

Step 7: the weighted measures. For the last assertion, we take $\theta = \lambda = 1/2$ and apply (22.16) to the bound for $\eta_{\mathcal{X}}$ obtained in Step 5, before the integration over H. This changes $-\Psi_F/(2g^2)$ into $-\lambda_s \Psi_F/g^2$ and adds $sD_{\mathcal{X}}$ to the exponent. We then apply Lemma 22.7 to this Wilson factor with $\lambda = \lambda_s$. Its constants are uniform for $\lambda_s \in [1/4, 1/2]$, and the marginal is exactly $\widetilde{\sigma}_{\lambda_s,d,g;F}$. This proves (22.17). Since the multiplication by $e^{sQ_{\mathrm{orig}}}$ was made before the integration over H, no two partition functions are compared. □

22.7 Summation over large-field decompositions

We now prove Theorem 22.1, following the outline in Section 22.1. The method of absorbing the normalization losses of excluded regions into the action of the large fields goes back to Bałaban's treatment of large fields [20, 21]; the decomposition, the frozen coordinates, and the constants used here are those of Section 21.

Proof of Theorem 22.1. Steps 1 and 2 fix the ceilings and the stopping level, Steps 3–6 treat a stopping level above the initial level, and Step 7 treats the remaining case.

Step 1: ceilings and the minimum side. We write $n = n_{j-1}$. The parameters, the buffers, and the count F_J are fixed first. We choose the coupling bound $g_{\mathrm{anc}} > 0$ for the bounds in Theorem 22.4(c), uniformly for $\lambda \in [1/4, 1/2]$, and impose

$$g_{\mathrm{end}} \le \min\{1, g_*, g_{\mathrm{anc}}, \sqrt{\alpha_W}, \sqrt{2\kappa_*}\}, \qquad n_{\min} \ge \max\{e\Gamma, \Gamma/g_{\mathrm{end}}^2, \Gamma/(Mg_*^2)\}. \tag{22.18}$$

We also include every fixed minimum side required by the geometry and by the first step for a Wilson initial measure in Theorem 21.5. Then, for every stopping side $m \ge n_{\min}$, we have $g_m \le 1$, as required in Lemma 22.7. Each ratio of partition functions satisfies its own coupling bound, the inverse-coupling conditions $4\lambda\alpha_W/g_m^2 \ge 1$ for $\lambda \ge 1/4$ and $2\kappa_*/g_m^2 \ge 1$ hold, and a full RG step with output side m has $t_{\max}^2 = \gamma/(Mm) \le g_*^2$. The identity $g_m = \sqrt{M}\, t_{\max}$ shows why the condition at the stopping side is checked separately. No restriction on γ enters a local estimate.

Step 2: the stopping level. Let $t_0 = J\lfloor (j-1)/J \rfloor$ and $u_{\mathrm{ph}} = j - 1 - t_0$. For a given $r_{\mathrm{stop}} \in \mathscr{R}$, we set $t_{\mathrm{stop}} = t_0 - r_{\mathrm{stop}} J$. If $t_{\mathrm{stop}} > b$, we integrate the $(t_{\mathrm{stop}} - b)/J$ full RG steps of the decomposition. The function at their endpoint is exactly

$$C \longmapsto Q_j^{\mathcal{T}}(T_M^v C), \qquad v = r_{\mathrm{stop}} J + u_{\mathrm{ph}} = j - 1 - t_{\mathrm{stop}}, \qquad m = n_{t_{\mathrm{stop}}} = M^v n. \tag{22.19}$$

Here $0 \le b < t_{\mathrm{stop}} \le j - 1 < JK$, and therefore all v iterates are available and all their sides are multiples of four. The depth $aJ + t_{\mathrm{stop}} - b$ of the reference recursion is a multiple of J. If $t_{\mathrm{stop}} \le b$, we use the initial measure directly: $j - 1 - b$ is an available nonnegative exponent, bounded by $J \max \mathscr{R} + J - 1$, and $n_b/n \le \chi_*$. This treats all remainders without integrating a partial RG step. Steps 3–6 concern the case $t_{\mathrm{stop}} > b$.

Step 3: one decomposition. We use the Borel partition of Theorem 21.5 and the density induction of Theorem 21.12. For a Wilson initial measure, the first step covers all of $\mathcal{U}_{n_b}$ and does not first restrict the Wilson measure to D_r. By Lemma 22.3, the product domains, the coefficient norms, the bounds on the frozen coordinates, and the boundary comparisons hold for every finite decomposition, without a bound on its number of RG steps.

Fix one decomposition $\mathcal{X}$. Let $\Psi_F = \min_z \alpha_W S_W(c \oplus z)$, and let $H_{\mathcal{X}} = \sum_f x_f$. In Steps 3–6, $H_{\mathcal{X}}$ denotes this scalar sum, not the product Haar measure on the frozen coordinates. At the observation, by Lemma 22.8, we have $Q_{\mathrm{orig}} \le K_W \Psi_F/g_m^2 + 8F_J H_{\mathcal{X}}$. We apply the bound of Theorem 22.10 with $\theta = 1/2$, before the integration over H. Multiplication by $e^{sQ_{\mathrm{orig}}}$ is justified by the inequality (22.16) between pushforward measures, without assuming that Q_{orig} is a function of the observation. With $\lambda_s = 1/2 - sK_W \in [1/4, 1/2]$, the exponent before the integration over H satisfies

$$sQ_{\mathrm{orig}} - \frac{\Psi_F}{2g_m^2} - \frac{A_{\mathcal{X}}}{2} \le -\frac{\lambda_s \Psi_F}{g_m^2} - (P_0 - 8sF_J)H_{\mathcal{X}}.$$

Indeed, by Theorem 22.4(b) and the invariant indicators of the recorded bad plaquettes, we have $A_{\mathcal{X}}/2 \geq 2c_A^{\mathrm{act}} d_* H_{\mathcal{X}} = P_0 H_{\mathcal{X}}$, and the condition $s \leq \theta c_A^{\mathrm{act}} d_*/(16F_J)$ gives $8sF_J \leq P_0/8 \leq P_0/4$. We integrate the Wilson minimum once over H by Lemma 22.7, which adds $3|H|\log(1/(c_* g_m)) + 8\lambda_s \alpha_W |H|$ to the exponent. The centered reference denominator and the partition function Z_ν of the initial measure are the same for every s.

Step 4: assignment of the corrections. We enlarge the local counting constant to account for the directions, the colors, the links across the boundary of the block region, and the finite family of remainders, and set

$$D_0 = C_J(BW + R_{\mathrm{cell}} + 1)^3, \qquad D_1 = C_J(W + R_{\mathrm{cell}} + 1)^3.$$

By Theorem 21.5, every variable outside the bulk that enters the normalization constant is assigned to a recorded bad plaquette at whose creation it was produced, and the assignment is subadditive when neighborhoods merge. At most D_0 variables are assigned to f at its creation, and at most D_1 at each later RG step. At creation their integration side is at most Bn_f, and the sides at later steps decrease by the factor B. We absorb the finite factors coming from the stopping offsets and the finite link products into a constant $\chi_{\mathrm{lay}} \geq 1$. For every missing Gaussian coordinate assigned to f,

$$\log(1/g_i) = \tfrac{1}{2}\log(n_i/\gamma) \leq \tfrac{1}{2}\log x_f + \tfrac{1}{2}\log \chi_{\mathrm{lay}}. \tag{22.20}$$

By Theorems 20.13 and 21.12, all other corrections per variable have fixed bounds. Thus a constant C_{lab}, with the dependence described in item (3) of Definition 4.14, bounds the correction of each variable by $C_{\mathrm{lab}}(1 + \log x_f)$. The dependence on the widths is entirely in D_0, D_1, and the fixed counts of affected plaquettes.

Let H_f be the number of RG steps after the creation of f, including empty steps. Counting the decreasing sides down to four, we find

$$H_f + 1 \leq C_{\mathrm{lay},J} + \#\{q \in \mathbb{N}_0 : 4B^q \leq \chi_{\mathrm{lay}} n_f\} \leq C'_{\mathrm{lay},J}(1 + \log n_f).$$

The finite additive term includes the conventions at creation and at the stopping level; the number of RG steps of the decomposition does not occur. Since $x_f \geq e$ and $\gamma \leq \Gamma$, we have $1 + \log n_f \leq (1 + \log_+ \Gamma)(1 + \log x_f)$. We write H_f^{term} for the set of omitted links at the stopping level assigned to f. The deterministic assignment of Theorem 21.5, to the first recorded bad plaquette in the fixed order of the tests, partitions H into these sets, and $|H_f^{\mathrm{term}}| \leq D_1$. The corrections assigned to f are listed in Table 22.2. For the integration over H we also used that $m \leq n_f$, so that $\log(1/(c_* g_m)) \leq \log(1/c_*) + (\log x_f)/2$.

The numbers of nonempty and of empty later RG steps in the table add up to at most H_f, so no step contributes twice. At the first RG step at which the block region is empty, all omitted variables are covered by assigned neighborhoods, and the recurrence $R_{t+1}(f) \leq B^{-1} R_t(f) + C_J(W + R_{\mathrm{cell}} + 1)$ of Theorem 21.5 continues to cover

Table 22.2. All corrections assigned to one recorded bad plaquette f created at side n_f. Here $L_f = 1 + \log x_f$, and the later RG steps include empty steps.

Stage	Corrections included, and where they are bounded	Bound
Creation	Missing Gaussian coordinates, missing constant terms of the Haar disintegration and fluctuation integrals, substitutions at initialization and at creation; Theorems 20.13 and 21.12	$D_0 C_{\mathrm{lab}} L_f$
Later nonempty RG steps	Missing coordinates and constant terms, boundary bands, and every later substitution, at the couplings of their integration; the same increment estimate	$D_1 C_{\mathrm{lab}} L_f$ per step
Integration over H	Omitted links, including links across the boundary of the block region: $3\lvert H_f^{\mathrm{term}}\rvert \log(1/(c_* g_m)) + 8\lambda_s \alpha_W \lvert H_f^{\mathrm{term}}\rvert$; Lemma 22.7	$D_1 C_{\mathrm{com}} L_f$, once
Empty RG steps	Determinant and fluctuation integral equal one; logarithmic determinant and centered effective interaction vanish. Missing reference variables use the same increment estimate	at most $D_1 C_{\mathrm{lab}} L_f$ per empty step
External exponents	Incorporated once into the classical exponent; the weight of the frozen coordinates is a subprobability; Theorem 21.12	no further positive correction
Plaquette-energy sum	Discarded plaquettes keep the coefficient $4/g_n^2$; Lemma 22.8	$8 s F_J x_f \le P_0 x_f / 4$

their coarse images, including the full finite dependence range, even when the union of the neighborhoods is the whole torus. We carry the frozen coordinates by the identity through the remaining full RG steps; both the effective classical action and g^2 acquire the factor B, which leaves each external exponent unchanged. The clauses on empty products in Theorems 20.13 and 20.14 therefore justify the row for empty steps.

Combining the first four rows of the table, we find

$$C_\partial \operatorname{Surf}_{\mathcal{X}} + \sum_f \overline{\mathrm{ch}}_f + 3|H| \log(1/(c_* g_m)) + 8\lambda_s \alpha_W |H| \le \sum_f C^{\Gamma}_{\mathrm{ch},J} (1 + \log x_f)^2. \tag{22.21}$$

For example, one may take for $C^{\mathrm{base}}_{\mathrm{ch},J}$ a fixed multiple of $(D_0 + D_1)(1 + C'_{\mathrm{lay},J})(C_{\mathrm{lab}} + C_{\mathrm{com}})$. The bulk term $3C_J m^3$ and the single comparison constant C_δ of Theorem 22.10 remain as explicit prefactors at the stopping level; they are not generated again at each step.

Step 5: absorption and the bound for one decomposition. For $x \ge e$, the function $(1 + \log x)^2/x$ decreases to zero. We increase the minimum side so that $C^{\Gamma}_{\mathrm{ch},J}(1 + \log x)^2 \le P_0 x/4$ for every $x \ge n_{\min}/\Gamma$. Since $n_f \ge m \ge u \ge n_{\min}$ and $\gamma \le \Gamma$, every x_f is in this range, and by Steps 3 and 4 at least $P_0 x_f/2$ of the classical lower bound remains for each recorded bad plaquette. By Theorem 21.12, the weight of the frozen coordinates, after the removal of the incorporated external exponents, has mass at most one. The marginal $\widetilde{\sigma}_{\lambda_s, d, g_m; F}$ has the mass of the whole Wilson numerator, $\widehat{Z}_d(g_m)^{-1} \int e^{-\lambda_s \mathcal{V}_m / g_m^2}\, dH_m$. Using the bound for the single ratio in Theorem 22.4(c), uniform for $\lambda_s \in [1/4, 1/2]$, we conclude that

$$\mathbb{E}_\nu \big[e^{sQ_{\mathrm{orig}}}; \mathcal{A}_{\mathcal{X}} \big] \le e^{3C_T m^3 + 9m^2 \log(1/g_m) + C_\delta} \prod_f e^{-a_{\mathrm{act}} n_f/\gamma}, \tag{22.22}$$

where C_T collects C'' of Theorem 22.4(c) and C_J. Only the reference integral in the denominator is restricted to D_r.

Step 6: summation over decompositions. Since the sets $\mathcal{A}_{\mathcal{X}}$ partition the support of ν, $\mathbb{E}_\nu e^{sQ_{\mathrm{orig}}}$ is the sum of the left sides of (22.22) over all decompositions. By Theorem 21.5, there is at most one decomposition for each attainable set of recorded bad plaquettes, and there are at most $3n_\ell^3$ positive plaquettes at level ℓ. Hence

$$\sum_{\mathcal{X}} \prod_f e^{-a_{\mathrm{act}} n_f/\gamma} \le \prod_\ell \big(1 + e^{-a_{\mathrm{act}} n_\ell/\gamma}\big)^{3n_\ell^3} \le \exp\Big\{ \sum_\ell 3 n_\ell^3 e^{-a_{\mathrm{act}} n_\ell/\gamma} \Big\},$$

which is the bound in the theorem. To bound its logarithm, we include all levels, also those inside RG steps, so that consecutive sides differ by the factor M, and note that

$$\frac{(Mm')^3 e^{-a_{\mathrm{act}} M m'/\gamma}}{m'^3 e^{-a_{\mathrm{act}} m'/\gamma}} = M^3 e^{-a_{\mathrm{act}}(M-1)m'/\gamma} \le \frac{1}{2}$$

for all sides m' above a fixed further minimum side, uniformly for $\gamma \le \Gamma$. We also require $n_{\min} \ge 3\Gamma/a_{\mathrm{act}}$, so that $x \mapsto x^3 e^{-a_{\mathrm{act}} x/\gamma}$ decreases for $x \ge n_{\min}$, and $6n_{\min}^3 e^{-a_{\mathrm{act}} n_{\min}/\Gamma} \le 1$.

Since all sides n_ℓ that occur are at least $u \geq n_{\min}$, the sum in the exponent is at most twice its first term, hence at most one, for every finite depth. Since $m = \chi n$, the remaining exponent is

$$3C_T\chi^3 n^3 + 9\chi^2 n^2 \log(1/g_n) + \tfrac{9}{2}\chi^2 n^2 \log\chi + C_\delta + 1.$$

The fixed term containing $\log\chi$ is absorbed into the volume constant, and the condition $C_s \geq 9\chi_*^2$ accommodates the single surface term.

Step 7: stopping level at or below the initial level. In this case $Q_{\mathrm{orig}} = Q_j^{\mathcal{T}} \circ T_M^{j-1-b}$, and by the bound for cells in Theorem 22.4(a), we have $Q_{\mathrm{orig}} \leq K_M S_W(V)/h_{n_b}$. For a stopped initial measure, the bound for stopped measures in Theorem 22.4(c) applies, because $sK_M \leq \kappa_0/2 \leq \kappa_*/2$. For a Wilson initial measure, we have $sK_M \leq 1/2$, and the moment is at most

$$\frac{\int e^{-(1-sK_M)S_W/h_{n_b}}\, dH_{n_b}}{\int e^{-S_W/h_{n_b}}\, dH_{n_b}}.$$

We use the integral over D_r of the reference recursion at depth zero only to bound the denominator from below, and the Wilson integral over the whole configuration space, with coefficient $1 - sK_M \in [1/2, 1]$, in the numerator. The same calculation of Theorem 22.4(c), that is, of Theorem 14.8, bounds this ratio by $e^{3C_T n_b^3 + 9n_b^2 \log(1/g_{n_b})}$. We convert units using $n_b/n \leq \chi_*$, as in Step 6. Finally, we enlarge the constants C_v, C_s, C_b to cover the finite family of stopping offsets and remainders, which proves the theorem. All increases of the minimum side are made after Γ is fixed and before the coupling is chosen. No step used a bound on $j - b$ or a bound on the probability, under the Wilson measure, of the complement of a small-field event. □

22.8 Chessboard estimates with regularity indicators

The chessboard estimate converts the exponential-moment bound of Theorem 22.1 into a bound for the probability that a given cell contains a bad plaquette at level j, given regularity at finer levels inside the cells. Reflection positivity of the Wilson measure with respect to reflections in lattice planes is due to Osterwalder and Seiler [134], and systematic treatments of reflection positivity and chessboard estimates were given by Fröhlich, Israel, Lieb, and Simon [92, 93]. We use the functional form of the chessboard estimate in [29, Theorem 5.8, (5.34)–(5.35)]. It applies to the algebra of bounded gauge-invariant functions of the links on one side of a lattice plane through links, and to the pullbacks of such functions by the block averaging maps with their Borel extension, as verified in Theorem 6.6. In the form proved there, it states the following. Let $\mu^{(\ell)}$ be the pushforward of the Wilson measure to level ℓ, tile the lattice at level ℓ into cells Q_t of $2 \times 2 \times 2$ sites, $\mathfrak{m}$ in number, and let ϑ_t denote the reflected placements in the cells. Then

for nonnegative bounded gauge-invariant functions $f_1, \dots, f_k$ of the links of one cell and distinct cells $t_1, \dots, t_k$,

$$\mathbb{E}_{\mu^{(\ell)}} \prod_{i=1}^{k} \vartheta_{t_i} f_i \le \prod_{i=1}^{k} \Big[\mathbb{E}_{\mu^{(\ell)}} \prod_{t} \vartheta_t f_i \Big]^{1/\mathfrak{m}},$$

and the same holds for each of the eight shifted tilings. Reflection positivity is used only for the Wilson measure and its pushforwards under the block averaging maps; a measure restricted to a fiber of the block averaging map or to a small-field event need not be reflection positive.

Lemma 22.11. *Let $N = uB^K$ with $u \in 4\mathbb{N}$, and let $1 \le j \le JK$. For each of the eight tilings at level j, let $\mathfrak{m}_j = n_j^3/8$ be the number of its disjoint cells of $2 \times 2 \times 2$ sites. All events below are gauge-invariant functions of the links of one cell, at the respective levels, pulled back to the fine lattice by the block averaging maps with their Borel extension, and they are considered under the Wilson measure $\mu = \mu_{N,\gamma}$. For two such events R_0 and I_0 attached to one cell, let $\vartheta_t R_0$ and $\vartheta_t I_0$ be their reflected placements in the cells t of the tiling, and set*

$$R = \bigcap_t \vartheta_t R_0, \qquad I_{\mathrm{all}} = \bigcap_t \vartheta_t I_0.$$

Then

$$\mu(R \cap I_0) \le \mu(R \cap I_{\mathrm{all}})^{1/\mathfrak{m}_j} \mu(R)^{1-1/\mathfrak{m}_j}, \qquad \mu(R_0 \cap I_0) \le \mu(R \cap I_{\mathrm{all}})^{1/\mathfrak{m}_j}.$$

If $\mu(R) > 0$, this gives $\mu(I_0 \mid R) \le \mu(I_{\mathrm{all}} \mid R)^{1/\mathfrak{m}_j}$.

Now let $R_0 = R_{<j}(C; d_{\mathrm{cut}})$ be the event of Lemma 7.4 that $q < d_{\mathrm{cut}}$ for exactly those plaquettes at finer levels whose full dependence sets lie in the cell C, and let $I_0 = I_j(C; d_*)$ be the event that at least one internal level-j plaquette of C has $q \ge d_*$, where $d_* = d_{\mathrm{cut}}/2$. The event R imposes no condition on plaquettes whose dependence sets cross the boundaries of the cells. Assume $\pi\sqrt{2d_{\mathrm{cut}}} \le \delta_*$, and let $c_E = 1 + C_M \pi \sqrt{2d_{\mathrm{cut}}}$. On $R \cap I_{\mathrm{all}}$, the function (22.2) *of the configuration at level $j-1$ satisfies*

$$Q_j^{\mathcal{T}} \ge \frac{4 d_* \mathfrak{m}_j}{c_E h_{n_j}}.$$

Consequently, for every $s > 0$,

$$\log \mu_{N,\gamma}(R_0 \cap I_0) \le -\frac{4 s d_* n_j}{c_E \gamma} + \mathfrak{m}_j^{-1} \log \mathbb{E}_{\mu_{N,\gamma}} \big[e^{s Q_j^{\mathcal{T}}}; R \big].$$

The expectation on the right is restricted to the event R and taken with the partition function of the Wilson measure. If its logarithm is at most $3C_v n_{j-1}^3 + C_s n_{j-1}^2 \log(1/g_{n_{j-1}}) + C_b^\circ$, then dividing this bound by $\mathfrak{m}_j$ gives, at $m = n_j$, exactly

$$\mathcal{A}_\gamma(m) = 24 C_v M^3 + \frac{4 C_s M^2}{m} \log(Mm/\gamma) + \frac{8 C_b^\circ}{m^3}.$$

No division by the probability of a regularity event occurs. Regularity of all plaquettes at finer levels implies the event R, but R implies neither regularity of the plaquettes whose dependence sets cross cell boundaries nor any condition of the small-field event. The inequalities contain no constant depending on the depth, the geometry, or the coupling, apart from c_E.

Proof. Each indicator of an event in a cell used below is bounded by one and Borel: its list of plaquettes is finite, q is continuous, and every iterate of the block averaging map with its Borel extension is Borel. Since it is gauge invariant and depends only on links internal to its cell, it belongs to the algebra of Theorem 6.6; the support condition, the reflection geometry for odd M, and the exact number of cells needed there are given by Lemma 7.4. In the functional inequality we place $\mathbf{1}_{R_0\cap I_0}$ in the distinguished cell and $\mathbf{1}_{R_0}$ in every other cell. Placing the first function at all reflected translates gives $\mathbf{1}_{R\cap I_{\mathrm{all}}}$, and placing each of the other functions at all reflected translates gives $\mathbf{1}_R$. The product on the left is $\mathbf{1}_{R\cap I_0}$. This proves the first inequality, including the case of zero probabilities. Applying the same inequality to the single function $\mathbf{1}_{R_0\cap I_0}$, with the constant function one in the other cells, proves the second inequality. If $\mu(R) > 0$, dividing the first inequality by $\mu(R)$ gives the conditional form, with the normalization still inside the root.

For the event R, every plaquette in a complete predecessor rectangle of an internal level-j plaquette is tested, since these lists are included in the tests of Lemma 7.4. By (22.1), the angles of these plaquettes at level $j-1$ are at most $\pi\sqrt{2d_{\mathrm{cut}}} \le \delta_*$. Applying the transport estimate over one averaging step in Theorem 22.4(a) to the union of the internal level-j plaquettes, we obtain

$$\frac{4}{h_{n_j}} \sum_{\text{internal } P} q(V_P^j) \le c_E Q_j^{\mathcal{T}}.$$

On I_{all} every cell has at least one internal plaquette with $q \ge d_*$. The internal plaquettes of distinct cells are distinct, so the sum on the left is at least $4d_*\mathfrak{m}_j/h_{n_j}$. This proves the lower bound for $Q_j^{\mathcal{T}}$. For $s > 0$, the exponential Markov inequality under the Wilson measure implies that

$$\mu(R\cap I_{\mathrm{all}}) \le \exp\bigl\{-4sd_*\mathfrak{m}_j/(c_E h_{n_j})\bigr\}\mathbb{E}_{\mu_{N,\gamma}}\bigl[e^{sQ_j^{\mathcal{T}}}; R\bigr].$$

Taking the $\mathfrak{m}_j$-th root, using the second chessboard inequality, and taking logarithms, with $\log 0 = -\infty$, we obtain the stated bound, since $h_{n_j} = \gamma/n_j$. Only one factor $d_* = d_{\mathrm{cut}}/2$ occurs.

Finally, we have $n_{j-1} = Mm$, $\mathfrak{m}_j = m^3/8$, and $\log(1/g_{n_{j-1}}) = \log(Mm/\gamma)/2$. Dividing the three terms of the assumed bound by $m^3/8$ gives $24C_vM^3$, $4C_sM^2\log(Mm/\gamma)/m$, and $8C_b^\circ/m^3$, respectively, which is $\mathcal{A}_\gamma(m)$. Regularity of all plaquettes at finer levels implies the event R by inclusion of the lists of plaquettes, while R omits every finer plaquette whose full dependence set crosses the boundary of its cell. □

22.9 Domination of successive small-field restrictions

The next lemma is the input for the second term in the bound on large fields, Theorem 2.7, which concerns configurations whose curvature is small at every scale but for which some fluctuation cutoff or coordinate-domain condition fails. The probability of the preceding conditions is multiplied, never divided, and no condition at later scales enters. The restricted measures and their dominations are indexed by $0 \le a \le K$, and quantities involving the next RG step by $0 \le a < K$.

Lemma 22.12. *Fix the small-field event of Definitions 4.4 and 14.4, with its prefactors and its fixed local parameters, together with $L > 0$, M, J, and $0 < \gamma_0 \le 1$. For $N = uB^K$ and $0 \le a \le K$, let S^a be the event consisting of the initial condition $U \in D_r$ and precisely the conditions of the first a RG steps in* (4.6)*, and put*

$$\eta_a = (T_M^{aJ})_{\#}(\mathbf{1}_{S^a}\mu_{N,\gamma}), \qquad \zeta_a = (T_M^{aJ})_{\#}\big(\mathbf{1}\{V^{bJ} \in D_r \text{ for } 0 \le b \le a\}\,\mu_{N,\gamma}\big).$$

For $0 \le a < K$, at the output side $m = n_{(a+1)J}$ of the next RG step, set

$$t_a^2 = \gamma/(Mm), \qquad \delta_a = 6\mathsf{b}_a e^{-m_{\mathrm{w}} p(t_a)^2/24}, \qquad z_a = 6\mathsf{b}_a e^{-m_{\mathrm{w}} Q_{\mathrm{DB}}^2/(24t_a^2)},$$
$$\epsilon_a = \delta_a/(1-z_a), \qquad \mathsf{b}_a \le C_J m^3,$$

where $p(t) = A_{\mathrm{w}} \log(1/t)$ and $a_{\mathrm{w}} = m_{\mathrm{w}} A_{\mathrm{w}}^2/24$. Here b_a is the number of three-dimensional fluctuation blocks of the RG step, $Q_{\mathrm{DB}} > 0$ is the radius denoted Q_{phys} in Definition 14.4, whose product of balls of radius Q_{DB}/t_a lies inside the supported fiber coordinates, and $m_{\mathrm{w}} > 0$ is the lower bound for the Hessian of the conditional fluctuation potential; neither Q_{DB} nor m_{w} is related to the plaquette-energy sum or to the logarithmic cutoff. Above the common minimum side described below, the comparison of Theorem 14.7, with identical unnormalized prefactors, gives

$$\mathbf{1}_{D_r}(T_M^J)_{\#}\eta_a \le (1-\epsilon_a)^{-1}\eta_{a+1}, \qquad \zeta_a \le \prod_{b<a}(1-\epsilon_b)^{-1}\eta_a.$$

It also gives the following bound for the failure of the next condition:

$$\mu_{N,\gamma}(S^a \cap A_m \cap W_m^c) \le \epsilon_a \mu_{N,\gamma}(S^a) \le C_J m^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mm/\gamma}},$$

where $A_m = \{V^{(a+1)J} \in D_r\}$ and $W_m = \mathcal{A}_{a,J} \cap \{\max_{i,e}|w_{a,i,e}| \le p(t_a)\}$ is the condition of the next RG step on the coordinate domains and the fluctuation cutoff, so that $S^{a+1} = S^a \cap A_m \cap W_m$. This bound keeps only the preceding conditions and the condition on the target; there is no conditioning on regularity at later scales.

There is one minimum side, valid simultaneously for all $0 < \gamma \le \gamma_0$ and every finite depth, above which $z_a, \epsilon_a \le 1/2$ and the product is at most e^{C_δ}; the logarithm of the product can be made at most one. Every event S^a has positive probability. Let $\widehat{\nu}_a = \eta_a/\mu_{N,\gamma}(S^a)$ be the normalized stopped measure. If $G_{\le aJ}$ is an event of regularity of the curvature which, by Theorem 7.7, implies

the conditions $V^{bJ} \in D_r$ for $0 \le b \le a$, then for every nonnegative Borel function F of the configuration at level aJ,

$$\mathbb{E}_{\mu_{N,\gamma}}[F(V^{aJ}); G_{\le aJ}] \le e^{C_\delta} \mu_{N,\gamma}(S^a) \mathbb{E}_{\widehat{\nu}_a} F \le e^{C_\delta} \mathbb{E}_{\widehat{\nu}_a} F.$$

This is a multiplicative domination, valid also for test functions with exponentially large values on the finite lattice; the probability $\mu_{N,\gamma}(S^a)$ is not inverted. It does not identify a stopped measure with a marginal of the conditioned Wilson measure.

The same minimum side can be chosen so that, in addition, any fixed finite collection of the following inequalities holds: for $k \in \{1, 2\}$, fixed $C < \infty$, and fixed $\varepsilon > 0$,

$$C[1 + \log(m/\gamma)]^k \le \varepsilon m/\gamma \qquad (m \ge n_0,\ 0 < \gamma \le \gamma_0).$$

For the event $\mathrm{FF}_0 = \{\max_p q(U_p) \ge d_*\}$ that some plaquette of the fine lattice has $q(U_p) \ge d_*$, the following bound holds at every $N \in 4\mathbb{N}$ with $\beta_N = 4N/\gamma \ge 2$:

$$\mu_{N,\gamma}(\mathrm{FF}_0) \le 3N^3 \exp\Big\{ \frac{\mathrm{C_{LT}} + 36 \log \beta_N / N}{8} - \frac{\beta_N d_*}{16} \Big\},$$

where $\mathrm{C_{LT}} = \max\{C_0 + 24 \log 2, 0\}$, with C_0 the constant of Theorem 6.6, is independent of N, β_N, and γ. Since

$$\sup_{\beta \ge 4N/\gamma_0} \frac{\mathrm{C_{LT}} + 36 \log \beta / N}{\beta} \le \frac{\mathrm{C_{LT}} \gamma_0}{4N} + \frac{9 \gamma_0 \log(4N/\gamma_0)}{N^2} \longrightarrow 0,$$

one obtains, above the common minimum side,

$$\mu_{N,\gamma}(\mathrm{FF}_0) \le 3N^3 e^{-d_* N/(8\gamma)}.$$

The bound for the supremum is used for $4N/\gamma_0 \ge e$. The numbers of free blocks can always be kept in the form $\mathsf{b} \le C_J m^3$; in terms of $t^2 = \gamma/(Mm)$ this also gives $\mathsf{b} \le C_J \gamma_0^3 t^{-6}/M^3$. All minimum sides and all constants of absorption and of the products have the dependence described in item (4) of Definition 4.14; they are independent of the coupling, the side, the depth, and the geometry and age of decompositions. The correction $36 \log \beta_N / N$ is kept exactly until the minimum side, uniform in the coupling, has been chosen.

Proof. Restricted measures are indexed by $0 \le a \le K$, and quantities of a transition by $0 \le a < K$. We first choose the common minimum side, so that all positivity conditions on denominators hold before a quantitative comparison is applied.

Step 1: measure-theoretic hypotheses. The amplitude $A_{\mathrm{w}} \ge 1$ is fixed before its coupling ceiling and before n_0. The product domains on the torus here are the instances of Lemma 22.3 without boundary. In particular, their sets of supported fluctuation coordinates, their cutoff domains, and their tests are Borel, the conditional fluctuation potential

is smooth on a neighborhood of the compact enclosing product domain, and (22.5) gives a positive finite partition function at each fixed target satisfying the coordinate-domain conditions. The initial Wilson density is positive, and every identical prefactor carries the normalization of the Wilson measure. These facts verify the measure-theoretic hypotheses of the comparison in Lemma 20.5 whenever its conclusion for products over endpoints is used below.

Step 2: the common minimum side. We choose all minimum sides uniformly in the coupling. Set

$$z(m,\gamma) = \tfrac{1}{2}\log(Mm/\gamma), \qquad a_{\mathrm{w}} = m_{\mathrm{w}}A_{\mathrm{w}}^2/24 > 0.$$

Since $p(t) = A_{\mathrm{w}}\log(1/t)$ and $\log(1/t_a) = z(m,\gamma)$, the errors satisfy

$$\delta_a \le C_J m^3 e^{-a_{\mathrm{w}} z(m,\gamma)^2}, \qquad z_a \le C_J m^3 e^{-b_{\mathrm{DB}} m/\gamma}, \qquad b_{\mathrm{DB}} = m_{\mathrm{w}} M Q_{\mathrm{DB}}^2/24 > 0.$$

For any fixed $R > 1$, the exponential envelope has ratio

$$R^3 e^{-b_{\mathrm{DB}}(R-1)m/\gamma} \le R^3 e^{-b_{\mathrm{DB}}(R-1)n_0/\gamma_0}$$

between the sides Rm and m, for $m \ge n_0$ and $\gamma \le \gamma_0$. For the envelope $W(m,\gamma) = C_J m^3 e^{-a_{\mathrm{w}} z(m,\gamma)^2}$, let $\Delta_R = (\log R)/2$. Since $z(Rm,\gamma) = z(m,\gamma) + \Delta_R$, its ratio is exactly

$$\frac{W(Rm,\gamma)}{W(m,\gamma)} = R^3 e^{-a_{\mathrm{w}}(2\Delta_R z + \Delta_R^2)},$$

and the right side decreases in z. Also

$$\frac{\partial \log W}{\partial \log m} = 3 - a_{\mathrm{w}} z, \qquad \frac{\partial \log W}{\partial \log \gamma} = a_{\mathrm{w}} z > 0 \quad \text{when } z > 0.$$

Thus, for $m \ge n_0$ and $0 < \gamma \le \gamma_0$, one sufficiently large n_0 makes both ratios at $R = B$ at most $1/2$. Both envelopes then decrease in m, they are maximized in the coupling at γ_0, and their first terms tend to zero as $n_0 \to \infty$. The same holds for each ratio in a fixed finite family of remainders, after taking the maximum of the required minimum sides.

We increase this minimum side until $z_a \le 1/2$ for every a and $W(n_0,\gamma_0) \le 1/4$. Then

$$z_a \le \tfrac{1}{2} < 1, \qquad \delta_a \le \tfrac{1}{4} < 1, \qquad \epsilon_a = \frac{\delta_a}{1 - z_a} \le \tfrac{1}{2} < 1 \qquad (0 \le a < K). \tag{22.23}$$

Thus the hypotheses $d_t < 1$ and $\epsilon_t < 1$ of Theorem 14.7 both hold before any error bound or reciprocal bound is used. We set $D_a = \prod_{0 \le b < a}(1 - \epsilon_b)^{-1}$ for $0 \le a \le K$, with $D_0 = 1$. The output sides of the RG steps of a finite sequence, ordered increasingly, form a segment of the sequence $m, mB, mB^2, \dots$, where $m \ge n_0$. Using $\epsilon_a \le 2\delta_a$ and $-\log(1-x) \le 2x$ for $0 \le x \le 1/2$, we obtain

$$\sum_a \epsilon_a \le 4W(n_0,\gamma_0), \qquad \log D_a \le 2\sum_b \epsilon_b \le 8W(n_0,\gamma_0).$$

Increasing n_0 makes the last quantity at most one, or arbitrarily small. This proves the assertion on C_δ and the bound by the exponential envelope, with an enlarged fixed C_J. The argument is an explicit instance of the conclusion for products over endpoints in Lemma 20.5.

Step 3: positivity. The events S^a have positive probability. Initially, D_r contains a product neighborhood of the identity of positive Haar measure, on which the Wilson density is positive. At each further RG step on the torus, the cutoff domain has positive volume and the integrand is real and positive. The recursion for the stopped measures used in Theorems 14.8 and 21.12 therefore multiplies a positive constant by a positive integral at the stopping level, which is bounded below by its strictly positive trial integral over D_r. By induction, $\mu_{N,\gamma}(S^a) > 0$ for every $0 \le a \le K$. The normalized pushforward is exactly the stopped measure $\widehat{\nu}_a$, at the preceding depth aJ.

Step 4: one RG step. At the initial side, $\eta_0 = \zeta_0 = \mathbf{1}_{D_r}\mu_{N,\gamma}$. The density of η_a is the unnormalized density of the stopped measure, including the probability of the preceding conditions and all its constant factors. For $0 \le a < K$, at a target of side $m = n_{(a+1)J}$ satisfying the coordinate-domain conditions, we apply Theorem 14.7 to this density. Its functions G and $\widetilde{F}$ have identical Haar disintegration, Gaussian, and constant prefactors, and multiplying both by the probability of the preceding conditions preserves their ratio. The quantities Q_{phys} and m_{cv} of that theorem are the present Q_{DB} and m_{w}. Its number of blocks is the number $\mathsf{b}_a \le C_J m^3$ of blocks of the RG step, its largest integrated coupling is $t_a^2 = \gamma/(Mm)$, and its logarithmic cutoff is the common $p(t_a)$ at every averaging step of this RG step. The condition $t_a p(t_a) < R_{\mathrm{en}}$ follows from the fixed ceiling for the logarithmic family, and the enclosing product domain is that of the fixed parameters of the stopped measures. The exact identity $\widetilde{F}_a/G_a = \kappa_c^{\mathrm{old}}(\Omega_p^{\mathrm{w}})$ needs no smallness of the errors. Its consequence for the tail uses $d_{t_a} = z_a < 1$ from (22.23) and gives, on D_r,

$$\widetilde{F}_a/G_a \ge 1 - \epsilon_a, \qquad \epsilon_a = \delta_a/(1 - z_a), \tag{22.24}$$

with the displayed δ_a and z_a. The reciprocal bound also uses $\epsilon_a < 1$ from (22.23). The ratio bound holds at every target satisfying the coordinate-domain conditions, and integrating it, we obtain $\mathbf{1}_{D_r}(T_M^J)_{\#}\eta_a \le (1-\epsilon_a)^{-1}\eta_{a+1}$. This comparison includes the coordinate-domain conditions of the next RG step, as required in $\widetilde{F}_a$.

Step 5: induction and the failure bound. For $0 \le a < K$, if $\zeta_a \le D_a\eta_a$, then, since pushforward and restriction preserve inequalities between measures,

$$\zeta_{a+1} = \mathbf{1}_{D_r}(T_M^J)_{\#}\zeta_a \le D_a \mathbf{1}_{D_r}(T_M^J)_{\#}\eta_a \le D_a(1-\epsilon_a)^{-1}\eta_{a+1}.$$

By induction, the stated domination holds for every $0 \le a \le K$. For $0 \le a < K$, the failure bound follows from the other consequence of (22.24), namely $G_a - \widetilde{F}_a \le \epsilon_a G_a$ on

D_r. Integrating over the targets in D_r, we obtain

$$\mu_{N,\gamma}(S^a \cap A_m \cap W_m^c) \le \epsilon_a \mu_{N,\gamma}(S^a \cap A_m) \le \epsilon_a \mu_{N,\gamma}(S^a).$$

Step 6: regular events and test functions. For $0 \le a \le K$, by the hypothesis on $G_{\le aJ}$, the deterministic inclusion of Theorem 7.7 places every configuration V^{bJ}, $0 \le b \le a$, on this event in D_r. Its hypotheses include the fixed threshold for the plaquette energies and the minimum side of that theorem, and arbitrary holonomies of flat connections are allowed. Thus the pushforward of the restriction of $\mu_{N,\gamma}$ to $G_{\le aJ}$ is bounded by ζ_a. For every nonnegative bounded Borel function F, the domination implies that

$$\mathbb{E}_{\mu_{N,\gamma}}[F(V^{aJ}); G_{\le aJ}] \le D_a \int F \, d\eta_a = D_a \mu_{N,\gamma}(S^a) \mathbb{E}_{\widehat{\nu}_a} F.$$

For an arbitrary nonnegative Borel function F, we apply this to $\min(F, k)$ and let $k \to \infty$. This proves the stated inequality also when the test function has exponentially large values on the finite lattice. The probability $\mu_{N,\gamma}(S^a)$ is at most one and may be dropped, without being inverted. When $K = 0$ there is only $\eta_0 = \zeta_0 = \mathbf{1}_{D_r} \mu_{N,\gamma}$ and $D_0 = 1$, and no transition error, next target, or failure event occurs.

Step 7: absorption of logarithms. For the remaining minimum sides, we set $x = m/\gamma \ge n_0/\gamma_0$. For $k = 1, 2$, we have

$$\frac{d}{dx} \frac{(1 + \log x)^k}{x} = \frac{(1 + \log x)^{k-1}(k - 1 - \log x)}{x^2}.$$

Thus this ratio decreases to zero once $x \ge e^{k-1}$. For a given finite collection of C, k, and ε, we choose n_0 so that the ratio at n_0/γ_0 is at most ε/C for each entry. This proves all the displayed absorptions simultaneously.

Step 8: the fine lattice. Finally, we use the bound of Theorem 6.6 for exponential moments of arbitrary sets of plaquettes at the fine scale, with a single plaquette and its parameter $s = 1/2$. At $\beta_N = 4N/\gamma \ge 2$ it reads

$$\mathbb{E}_{\mu_{N,\gamma}} e^{\beta_N q(U_p)/16} \le \exp\{[C_0 + 24 \log 2 + 36 \log \beta_N / N]/8\}.$$

By the exponential Markov inequality and a union bound over the $3N^3$ positive plaquettes, we obtain the displayed bound with $C_{\mathrm{LT}} = C_0 + 24 \log 2$, enlarged to be nonnegative if necessary. For $4N/\gamma_0 \ge e$, both $1/\beta$ and $(\log \beta)/\beta$ decrease on the ray $\beta \ge 4N/\gamma_0$; evaluating each at the left endpoint gives the displayed bound for the supremum. Its right side tends to zero as $N \to \infty$, independently of the coupling. We choose the common minimum side so that it is at most $d_*/4$ for every larger N. Then the positive part of the exponent is at most $\beta_N d_*/32$, which leaves

$$-\frac{\beta_N d_*}{16} + \frac{\beta_N d_*}{32} = -\frac{\beta_N d_*}{32} = -\frac{d_* N}{8\gamma}.$$

This is the asserted bound, in which the exact correction $36 \log \beta_N / N$ was kept until this absorption, which is uniform in the coupling.

Solving $t^2 = \gamma/(Mm)$ gives $m^3 = \gamma^3 t^{-6}/M^3 \le \gamma_0^3 t^{-6}/M^3$, which proves the last counting formula. Taking the maximum of the finitely many minimum sides constructed above, and rounding up to an element of $4\mathbb{N}$, proves the claim on the common minimum side, with the dependence stated in the lemma. □

The next lemma extends these conclusions to an arbitrary finite coupling ceiling Γ, which is the form used in Theorem 23.5.

Lemma 22.13. *Fix $0 < \Gamma < \infty$ and the parameters, the buffers, the count of affected plaquettes, the finite family of stopping offsets and remainders, and the interval of s of Theorem 22.1. The exponential-moment bounds and the conclusions on decompositions of that theorem hold for $0 < \gamma \le \Gamma$. Above one further minimum side, all conclusions of Lemma 22.12 on successive restrictions, on nonnegative test functions, and on the fine lattice also hold for $0 < \gamma \le \Gamma$, with the same small-field event and identical unnormalized prefactors. One may require*

$$m \ge \max\{e\Gamma, \Gamma/g_{\mathrm{end}}^2, \Gamma/(Mg_*^2)\},$$

with g_{end} as in (22.18)*, and $C_{\mathrm{ch},J}^{\Gamma} = (1 + \log_+ \Gamma) C_{\mathrm{ch},J}^{\mathrm{base}}$. In particular, for $0 \le a < K$, with $m = n_{(a+1)J}$ and with A_m and W_m as in Lemma 22.12,*

$$\mu_{N,\gamma}(S^a \cap A_m \cap W_m^c) \le \epsilon_a \mu_{N,\gamma}(S^a) \le C_J m^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mm/\gamma}}.$$

There is no conditioning on the curvature at later scales. All constants have the dependence described in item (4) of Definition 4.14, with the fixed ceiling Γ; the constants of the local estimates and the intervals of s and of the action coefficients do not change when the ceiling is increased.

Proof. The assertion on exponential moments was proved in Theorem 22.1 for the whole interval $0 < \gamma \le \Gamma$. For the assertions on successive restrictions, we use Theorem 14.7 with the same unnormalized prefactor and the count $\mathsf{b}_a \le C_J m^3$. With $t_a^2 = \gamma/(Mm)$, its cutoff and exterior errors are exactly $\delta_a = 6\mathsf{b}_a e^{-m_{\mathrm{w}} p(t_a)^2/24}$ and $z_a = 6\mathsf{b}_a e^{-m_{\mathrm{w}} Q_{\mathrm{DB}}^2/(24 t_a^2)}$. The bounds for a finite coupling ceiling in Lemma 20.15 make $z_a \le 1/4$, $\epsilon_a = \delta_a/(1 - z_a) \le 1/2$, and the logarithm of every reciprocal product at most one, above a minimum side independent of $\gamma \in (0, \Gamma]$. All transitions have $a < K$. Every finite sequence of satisfied conditions has positive probability. Indeed, at the identity configuration its coordinate-domain conditions hold strictly and its normalized fluctuation variables vanish; thus a finite intersection of neighborhoods of the identity on which the conditions hold has positive Haar measure, and the Wilson density is positive. Iterating the comparison of one RG step as in Steps 4–6 of the proof of Lemma 22.12, we obtain the domination and every consequence for nonnegative test functions. Multiplying the failure bound for one

RG step by the probability of the preceding conditions proves the displayed bound; the event keeps only the preceding conditions and the target.

The estimate on the fine lattice from Theorem 6.6, in the form used in Step 8 of the proof of Lemma 22.12, is

$$\mu(\mathrm{FF}_0) \le 3N^3 \exp\bigl\{(C_{\mathrm{LT}} + 36\log\beta/N)/8 - \beta d_*/16\bigr\}, \qquad \beta = 4N/\gamma.$$

For $4N/\Gamma \ge e$, the monotonicity of $1/\beta$ and $\log\beta/\beta$ implies that

$$\frac{C_{\mathrm{LT}} + 36\log\beta/N}{\beta} \le \frac{C_{\mathrm{LT}}\Gamma}{4N} + \frac{9\Gamma\log(4N/\Gamma)}{N^2} \longrightarrow 0.$$

We choose the minimum side so that this is at most $d_*/4$. The exponent is then at most $-\beta d_*/32 = -d_* N/(8\gamma)$, which proves the same bound on the fine lattice uniformly for $0 < \gamma \le \Gamma$. □

SECTION 23

Uniform bounds for the small-field event

This section proves that the small-field event $S_{N,u,\gamma}$ of Definition 4.4 has probability close to one under the Wilson measure, uniformly in the number of renormalization group (RG) steps and in the coupling below a fixed ceiling. The main result is Theorem 23.10. For every $0 < \Gamma < \infty$ it provides an integer J, with $B = M^J$, and all remaining parameters of the small-field event, chosen before the coupling, such that

$$\mu_{uB^K,\gamma}\big(S^c_{uB^K,u,\gamma}\big) \le C' u^3 e^{-\bar{c}u/\gamma} + C_{\mathrm{w}} u^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mu/\gamma}} \tag{23.1}$$

for all $0 < \gamma \le \Gamma$, all coarse sides $u \in 4\mathbb{N}$ above a threshold n_Γ, and all $K \ge 0$. The first term bounds the probability that some averaged configuration $V^j = T_M^j U$ has a plaquette whose energy exceeds a fixed threshold d_*. The second term bounds the probability that the curvature is small at every scale, but the coordinate-domain conditions or the cutoffs $|w_{k,i,e}| \le A_{\mathrm{w}} \log(1/t_k)$ on the normalized fluctuation variables fail in some RG step. This is the bound on large fields, Theorem 2.7, which lets us pass from the conditioned Wilson measure $\nu_{N,u,\gamma}$ to the Wilson measure by (3.1).

Two regimes of (23.1) are used later. For a fixed coarse side u, the probability of S^c is smaller than every power of γ as $\gamma \to 0$, uniformly in K (Corollary 23.11); this is used in the weak-coupling analysis. For a fixed ceiling Γ, it tends to zero as $u \to \infty$ through the sides nB^a, uniformly in $\gamma \in (0, \Gamma]$ and K; this is used to remove the conditioning in the construction of the continuum measure. The logarithmic cutoff limits the rate: by Theorem 23.12, at a fixed coarse side, $\sup_K \mu(S^c)$ is of order $\exp(-c \log^2(1/\gamma))$, and a matching lower bound holds already for one RG step.

The principal antecedent of the present construction is Bałaban's proof of ultraviolet stability for three-dimensional lattice gauge theories [15]. The estimate proved here concerns the probability of the specific event $S_{N,u,\gamma}$. Its proof has two independent parts: a bound on large curvature under the Wilson measure itself, and a bound on the first failure of a coordinate-domain condition or of a cutoff. Both are described at the beginning of Section 23.4.

The other task of this section is the choice of parameters. The integer J, the analytic radii, the support radius r of B_r and D_r, the widths of the boundary layers of the large-field decompositions, the cutoff amplitude A_{w}, the coupling bound g_*, and the minimum coarse side must satisfy all hypotheses of the results of Sections 13 to 15 and 18 to 22, and these hypotheses refer to one another. Theorem 23.2 lists the choices in an order in

which each choice uses only quantities fixed before it, and Table 23.1 summarizes this order. The main point is that J is chosen using only constants that are uniform in J, and is never enlarged afterward.

Sections 23.1 and 23.2 contain the elementary inequalities and the statements on the choice of parameters, Sections 23.3 to 23.5 the probability estimates, Sections 23.6 and 23.7 the proofs of the parameter theorems, and Section 23.8 the extension to every sufficiently large J, which is needed in Section 29 to pass from the subsequences $n_* B^K$ to the full sequence nM^k.

The main inputs are the moment bounds for coarse actions and the comparison for initial segments of Section 22; the large-field decompositions and their pointwise support bounds for the normalized fluctuation variables in Section 21; the regional estimates of Sections 18 to 20; the recursion for the effective interaction on the torus and the reconstruction maps of Sections 13 to 15; and the chessboard and curvature estimates of Sections 6 and 7. The results of this section are used in Sections 28 and 29 to remove the conditioning and to construct the continuum measure, in Sections 31 and 32 at fixed coupling, and in Sections 34 to 36 at weak coupling.

Throughout, $L > 0$ and an odd integer $M \geq 3$ are fixed. We write $h_n = g_n^2 = \gamma/n$ for the lattice coupling at side n. The letter p with an argument denotes the cutoff radius $p(t) = A_{\mathrm{w}} \log(1/t)$ (written $p_{\mathrm{w}}(t)$ in Definition 4.4); a subscript p on a configuration denotes a plaquette.

23.1 Elementary inequalities

We use the following lemma repeatedly to choose a coupling bound and a minimum side. It states that powers of logarithms are dominated by positive powers, and that sums over geometrically growing sides are dominated by their first term.

Lemma 23.1. *Fix $0 < \gamma_0 \leq 1$, a finite set of ratios $R > 1$, finitely many positive constants a, c, C, ε, and finitely many nonnegative integers k. Then there exists $0 < g_* < e^{-1}$ such that each of the finitely many inequalities $Ct^{\varepsilon}[1 + \log(1/t)]^k \leq c$ holds for all $0 < t \leq g_*$. There exists m_0, independent of $\gamma \in (0, \gamma_0]$, such that each of the finitely many inequalities*

$$C[1 + \log(m/\gamma)]^k \leq \varepsilon m/\gamma$$

holds for all $m \geq m_0$ and $0 < \gamma \leq \gamma_0$. For a fixed $M > 1$ define

$$X_c(m,\gamma) = m^3 e^{-cm/\gamma}, \qquad W_a(m,\gamma) = m^3 e^{-az(m,\gamma)^2}, \qquad z(m,\gamma) = \frac{1}{2}\log(Mm/\gamma).$$

After increasing m_0, each of these functions is decreasing in $m \geq m_0$ and increasing in $\gamma \in (0, \gamma_0]$, and its value at Rm is at most half of its value at m. Consequently

$$\sum_{h \geq 0} X_c(mR^h, \gamma) \leq 2X_c(m,\gamma), \qquad \sum_{h \geq 0} W_a(mR^h, \gamma) \leq 2W_a(m,\gamma),$$

and the right sides tend to zero as $m \to \infty$, uniformly in $\gamma \in (0, \gamma_0]$. Finally, let $\delta > 0$, and let numbers $\epsilon_h \geq 0$, attached to the sides mR^h, be bounded by fixed finite sums of these functions. Then, after increasing m_0, we have $\log \prod_h (1-\epsilon_h)^{-1} \leq \delta$ for all $m \geq m_0$. The thresholds g_* and m_0 depend only on the data fixed in the statement.

Proof. Set $y = \log(1/t)$. For $\varepsilon > 0$ and an integer $l > k$ we have $e^{\varepsilon y/2} \geq (\varepsilon y/2)^l / l!$ for $y > 0$, which implies $e^{-\varepsilon y}(1+y)^k \to 0$ as $y \to \infty$. Then each inequality holds on a half-line $y \geq y_*$, that is, for $0 < t \leq g_*$, and we take the smallest of the finitely many thresholds. The same calculation with $y = \log x$ shows that $(1+\log x)^k / x \to 0$ as $x \to \infty$. Since $x = m/\gamma \geq m_0/\gamma_0$, the supremum of this ratio over the relevant half-line tends to zero as $m_0 \to \infty$, which gives the second assertion.

With $\Delta_R = (1/2)\log R > 0$, the two ratios are

$$\frac{X_c(Rm,\gamma)}{X_c(m,\gamma)} = R^3 e^{-c(R-1)m/\gamma}, \qquad \frac{W_a(Rm,\gamma)}{W_a(m,\gamma)} = R^3 e^{-a(2\Delta_R z + \Delta_R^2)}. \tag{23.2}$$

Their suprema over $m \geq m_0$ and $\gamma \leq \gamma_0$ are attained at $m = m_0$ and $\gamma = \gamma_0$, and tend to zero as $m_0 \to \infty$. The derivatives of $\log X_c$ and $\log W_a$ with respect to $\log m$ are $3 - cm/\gamma$ and $3 - az$, which are negative once m_0 is large; their derivatives with respect to $\log \gamma$ are cm/γ and az, which are positive in the same range. Taking logarithms shows that $m^3 e^{-cm/\gamma_0} \to 0$ and $m^3 e^{-a\log^2(Mm/\gamma_0)/4} \to 0$. The sums are bounded by geometric series with ratio $1/2$. Finally, for $0 \leq \epsilon \leq 1/2$ we have

$$-\log(1-\epsilon) = \int_0^\epsilon \frac{dv}{1-v} \leq 2\epsilon.$$

We increase m_0 so that every ϵ_h is at most $1/2$ and $2\sum_h \epsilon_h \leq \delta$. This proves the last assertion, also for finite sublists of the ϵ_h taken in either order. All thresholds depend only on the fixed data of the lemma. □

23.2 Choice of the parameters

The constants in the next theorem are those of the cited earlier results, evaluated on their larger construction domains before any of the later restrictions. In particular, q_{CA} is the contraction factor for the zero-fluctuation pullback of the effective interaction on the torus in Theorem 13.5, C_G is the constant bounding the part of the effective interaction generated by one RG step, and $Z_\bullet$ are the majorants for the absolute coefficient sums of the background-field map at zero fluctuation from Theorem 13.2. In Step 8 of Section 23.6, we use Theorem 14.6 to identify the recursion controlled by these constants with the recursion defining the small-field event. The number $q_{\mathrm{raw}} > 0$ is a radius reserved for the free logarithmic coordinates. The symbols A_J, R_J denote the coefficient bounds for the reconstruction maps $\widehat{\mathscr{R}}$ in Lemma 15.15; output constants denoted by the same letters

elsewhere can be enlarged to a common bound at fixed J. The normalization constant Λ is kept separate from the bound $\mathcal{L}_V$ for the conditional fluctuation potential. A subscript $\bullet$ stands for either of the two analytic radii, ρ for the effective interaction and ρ_{cl} for the effective classical action, and every condition carrying $\bullet$ is imposed for both.

The radii play different roles. The support radius r defines B_r and D_r; $R_{\mathrm{buf}} = C_{\mathrm{map},J} r$ is the larger radius of coarse fields on which the analytic recursion is defined; ρ and ρ_{cl} are analytic radii of coefficient norms; R_{raw} is the radius of the larger domain of free logarithmic coordinates; r_{eff} is the working radius for the zero-fluctuation reconstruction; $0 < P < Q_{\mathrm{DB}}$ are radii, proportional to r, for the unscaled fluctuation coordinates $\zeta_i = g_i w_i$ in the small-field construction; R_W bounds the unscaled fluctuation coordinates allowed in the regional estimates, and $R_{\mathrm{en}} \le R_W$ is the radius of the enclosing product domain; β_{rec} bounds the frozen coordinates of the large-field decompositions.

In applying Section 15.3, its generic torus interaction exponent a_{sp} is instantiated by $a_{\mathbb{T}}$. Its contraction and the construction and convergence of the torus effective interactions are used at that fixed exponent. The smaller regional exponent $a = a_{\mathrm{sp}}$ chosen below is used for boundary estimates; bounds and convergence of the already constructed torus interactions pass to it by monotonicity of the coefficient norms. No contraction on an entire ball at the weaker exponent is inferred from this monotonicity.

Theorem 23.2. *Fix $L > 0$, an odd integer $M \ge 3$, and $0 < \gamma_0 \le 1$. There exist an integer $J \ge 1$, with $B = M^J$, a tuple Θ of the parameters listed in items* (1)–(10) *below, a number $0 < g_* < e^{-1}$, and an integer $n_0 \in 4\mathbb{N}$, all chosen before the coupling, with the following property. For every*

$$0 < \gamma \le \gamma_0, \qquad u \in 4\mathbb{N},\ u \ge n_0, \qquad K \in \mathbb{N}_0, \qquad N = uB^K,$$

the same J, Θ, and reconstruction maps satisfy the local, moment, and scalar conditions of the results cited below; only the running couplings and the cutoff radii $p(t)$ are evaluated at γ. In particular, the parameters satisfy the hypotheses of Theorem 19.9 on uniform incoming radii, on boundary compatibility, and on conditional displacements, and the bounds of Theorem 20.14 on logarithmic fluctuation radii and on frozen coordinates. In the large-field decompositions only complete renormalization group steps are integrated; remainders modulo J and short scale intervals are treated by the composed insertions and the bounded side-ratio clauses of Theorem 22.1. The coefficient majorants on the torus and the recursion for the effective interaction are those of Theorems 13.2 and 13.5, and Theorem 14.6 identifies this recursion with the effective interactions of the stopped measures used in Theorem 22.1. The geometric hypotheses of Theorem 21.5 hold, including those of Theorem 21.3 for the neighborhoods in which gauge transformations are extended, the closed complex of tested cells at the initial step, and the protection of all older endpoints and tree roots attached to frozen records.

The parameters can be chosen in the order of items (1)–(10). *Each item uses only constants provided by the cited results and quantities fixed in earlier items.*

(1) The number J. *Fix the spatial decay rate $a_{\mathbb{T}}$ of the torus estimates with $0 < a_{\mathbb{T}} < a_{\mathrm{cen}}/8$, where a_{cen} is the J-uniform rate of the bounds of Lemma 11.9 (the contraction of Theorem 11.10 for the aligned representative holds only at such output rates). Fix also all larger spatial, analytic, and differentiation domains and the analytic-radius enlargement factor K_* needed for the connected-network estimates of Theorem 20.9. Enlarge the J-uniform constant C_{CP} of part (3) of Theorem 15.12 to include the reconstruction tolerances. In the notation of that theorem, it bounds the value and the first three coarse-field derivatives of the pair formed by $B\widehat{\Phi}(\theta,0)$ and its first spatial differences $\nabla_{1/B}B\widehat{\Phi}(\theta,0)$, with the row sums, volume-normalized column sums, and polydisc of coarse fields specified there. Bounds for derivatives with respect to the fluctuation inputs are chosen after J is fixed. Let $Z_\bullet(t) \le C_\bullet t/(1-C_\bullet t)$ be the J-uniform majorants for the absolute coefficient sums of the background-field map at zero fluctuation on the torus. Choose J so that*

$$B \ge B_{\mathrm{geom}}, \qquad q_{\mathrm{CA}} < 1/4, \qquad q_{\mathrm{CP}} \le 1/4, \qquad M^{-J} \le \delta_0(a_{\mathbb{T}}),$$

where $q_{\mathrm{CA}} = C_P(a_{\mathbb{T}})/B$ (denoted q_P in Theorem 13.5), $q_{\mathrm{CP}} = C_{\mathrm{CP}}^2/B$, and $C_P(a_{\mathbb{T}})$ and $\delta_0(a_{\mathbb{T}})$ are the constants of Theorem 11.10, and so that the finitely many linear image conditions on the torus hold with strict inequality. These include $C_\bullet K_*/B < 1/32$, which permits the later bound $B^{-1}Z_\bullet(K_*\rho_\bullet) \le \rho_\bullet/16$, and the two conditions (23.25) *on spatial rates. Here B_{geom} is the constant of Theorem 20.9. None of these lower bounds on B uses a constant of the regional estimates or of the effective-interaction estimates computed at fixed J.*

(2) Coordinate domains at fixed J. *Choose the product domains of Lemmas 19.3 and 19.7. In their notation choose $v_{\mathrm{free},J} > 0$ with*

$$Q_J v_{\mathrm{free},J} < \lambda_J/64, \qquad I_J Q_J v_{\mathrm{free},J} < r_{z,J}/64,$$

and choose R_{raw} strictly below the radii in those results for the identities on overlapping gauge charts and for the local constraint coordinates, and strictly below

$$\min\{\min(r_{\Gamma,J}, r_E)/(64G_J),\ \lambda_J/(64Q_J),\ r_{z,J}/(64I_JQ_J),\ v_{\mathrm{free},J}/(64C_{\mathrm{lift},J})\}.$$

For each initial segment of conditional integrations, fix first a neighborhood of its conditional constrained minimizer, then a smaller domain for the parameters of the later integrations, and then a common smaller product domain for the free logarithmic coordinates of the successive substitutions. These domains preserve real values on real arguments, the conditional displacement bound $r_I/4$, and the bound $1/2$ for the error of the preconditioned Hessian. All inverses are inverses of constrained Hessians in the free coordinates.

(3) Analytic radii and coefficient bounds. *Fix $\rho, \rho_{\mathrm{cl}} > 0$, all inner, middle, and outer domains of the reconstruction maps inside the larger construction domains, a bound E^{cl} for the effective classical action on the torus, and a bound*

$$E \ge 2C_G/(1-q_{\mathrm{CA}})$$

for the effective interaction. Set aside the inequality

$$C_{\mathrm{lift},J}[K_* \max(\rho, \rho_{\mathrm{cl}}) + r + \beta_{\mathrm{rec}} + q_{\mathrm{raw}}] < R_{\mathrm{raw}}/8,$$

in which the first summand, fixed now, is required to be below $R_{\mathrm{raw}}/64$; the other summands are made small by the later choices of q_{raw}, of β_{rec} in item (5)*, and of r in item* (6)*. Compute the coefficient constants A_J, R_J of the reconstruction maps on these larger domains, after one fixed enlargement, before the working and support radii are chosen; these constants and the bounds for the limiting maps do not depend on those radii. Then choose the regional rates as in Theorem 20.9: $a = a_{\mathrm{sp}} > 0$, $\alpha = \alpha_{\mathrm{bd}} = a/16$, equal classical rates, $m_{\mathrm{rate}} = C_*^{\mathrm{geom}}(a + \alpha)$, and $b_1 = 8C_*^{\mathrm{geom}}\alpha$, with*

$$m_{\mathrm{rate}} + b_1 < \min(c_{\mathrm{prim},J}, Ba)/C_{\mathrm{alloc}}, \qquad b_1 < B\alpha/C_{\mathrm{alloc}}, \qquad \sqrt{3}\,(a + \alpha) < a_{\mathbb{T}}.$$

Here $c_{\mathrm{prim},J}$ is the reserve for the intrinsic tensors and the unperturbed weighted reconstruction images in the graph metric of Section 20.1, obtained from the Euclidean exponents by dividing by $\sqrt{3}$. It includes the positive exponent obtained once from interpolation of the unperturbed coefficient bounds and is chosen no larger than the intrinsic exponent c_J of Theorem 19.9. Inherited perturbative networks use the separate inequalities against Ba and $B\alpha$. Decreasing a changes neither $a_{\mathbb{T}}$ nor J.

(4) Perturbation bounds and the fluctuation radius. *Choose a preliminary bound $\sigma_0 > 0$ for perturbations that are real on real arguments, on the larger product domains. Compute all local constants of the output, sequential, image, curvature, and mean estimates, and of the estimates of the support of the normalized fluctuation variables, uniformly for $\mathcal{X}^{\mathrm{cl}}(\overline{P}) \le 2\sigma_0$ and $\mathcal{X}(f) \le \sigma_0$. In particular fix*

$$A \ge 1, \quad C_0 \ge 2A^3, \quad C_1, \quad C_{\mathrm{en},J}, \quad \mathcal{L}_V = C_{V,J}(1 + E + \sigma_0) \ge 1,$$

the image constants $C_{T,\bullet}, C_{\Delta,\bullet}, C_{F,\bullet}, C_{P,\bullet}$, and all radii for free logarithmic coordinates that occur in Lemma 20.3. Fix also the geometric constants A_8, C_B, K_B, C_{col}, $C_{\mathrm{conv},J}$, and the mesh and interior-restriction factors of the initial step. None of these constants depends on the widths chosen later (of boundary layers, removed layers, protected neighborhoods, and large cells). Choose R_W below the full minimum in Lemma 20.3, including $1/(16C_0)$, both image bounds, both product domains, and the conversion to the joint solution neighborhood. Then fix

$$0 < \sigma_* \le \sigma_0, \qquad \sigma_*\rho_{\mathrm{cl}} < \lambda_* R_W/(6C_{\mathrm{en},J}), \qquad \lambda_* = M^{-(J-1)/2},$$

all margins for the preconditioned forces and displacements, and $C_{P,\bullet}\sigma_*\rho_{\mathrm{cl}} < \rho_\bullet/64$. This choice precedes item (5)*, and it is not replaced by taking r and β_{rec} small.*

(5) Boundary radii, removed layers, and frozen coordinates. *Fix the outer boundary radius $R_{\partial,\bullet}$, the inner radius $\rho_{\partial,\bullet} = R_{\partial,\bullet}/K_*$, and the width w_{bd} of the boundary layer so that the zero-fluctuation image bound satisfies $A_{0,\bullet} \le \rho_\bullet/4$. Specifically, impose*

$$B^{-1}Z_\bullet(K_*\rho_\bullet) \le \rho_\bullet/16, \qquad C_{\Delta,\bullet}C_{\rho,\bullet}R_{\partial,\bullet} \le \rho_\bullet/16,$$

$$C_{\Delta,\bullet}C_{\rho,\bullet}e^{-a_{W,\bullet}w_{\mathrm{bd}}/2}K_*\rho_\bullet \le \rho_\bullet/16, \qquad C_{T,\bullet}K_*\rho_\bullet \le 1/4,$$

together with the full condition

$$A_{0,\bullet} \le B^{-1}Z_\bullet(K_*\rho_\bullet) + C_{\Delta,\bullet}C_{\rho,\bullet}\big[R_{\partial,\bullet} + e^{-a_{W,\bullet}w_{\mathrm{bd}}/2}K_*\rho_\bullet\big] + C_{F,\bullet}\beta_{\mathrm{rec}} + C_{P,\bullet}\sigma_*\rho_{\mathrm{cl}} \le \rho_\bullet/4.$$

Here $C_{F,\bullet}$ and $C_{P,\bullet}$ are the image constants for frozen coordinates and for perturbed conditional constrained minimizers on the larger domains. Choose the width $s_{\mathrm{er}} \ge w_{\mathrm{bd}}$ of the layer removed after each renormalization group step so that

$$2e^{-\alpha(s_{\mathrm{er}}-1)}[A_J(1+E) + K_J\sigma_* + 1] \le \sigma_*/2, \qquad 2e^{-\alpha(s_{\mathrm{er}}-1)}[A_J^{\mathrm{cl}} + K_J^{\mathrm{cl}}\sigma_*] \le \sigma_*/2.$$

Choose the bound $\beta_{\mathrm{rec}} > 0$ for frozen coordinates below all coordinate-domain, product, and boundary radii, below one quarter of $\min\{\rho_\bullet, \rho_{\partial,\bullet}\}$, and below $\lambda_* R_W/(6C_{\mathrm{en},J})$. Impose the bounds of Lemma 18.9 for the substitution of frozen coordinates and for the boundary-completion differences, in particular

$$C\beta_{\mathrm{rec}}E_\bullet/\rho_\bullet \le \sigma_*/8, \qquad |\xi_j^\sharp| \le \phi_\bullet(j)/4, \qquad z_t, z_t^{\mathrm{cl}} \le \sigma_*/4,$$

including the substitution at the initial step, where C denotes the larger-domain constants of Lemma 18.9. Require also $C_{F,\bullet}\beta_{\mathrm{rec}} < \rho_\bullet/64$.

(6) Working radius and support radius. *Set $\alpha_* = C_{\mathrm{CP}}/B$ and choose*

$$\beta_J \ge \max\{1, R_J^{-1}, A_J/(\alpha_* R_J^2)\}.$$

Choose a working radius $r_{\mathrm{eff}} > 0$ inside the domains of item (3) *with $\beta_J r_{\mathrm{eff}}/(1-\alpha_*) < 1/8$. Then choose the support radius $r > 0$ so that*

$$r < r_{\mathrm{eff}}/4, \quad r < \beta_{\mathrm{rec}}/C_{\mathrm{conv},J}, \quad r < \lambda_* R_W/(6C_{\mathrm{en},J}), \quad (5M-3)(10M)^{J-1}r < \pi,$$

together with the fixed coordinate-domain and chart margins of the earlier constructions, in particular those of Definition 14.4. Set

$$R_{\mathrm{buf}} = C_{\mathrm{map},J}r, \qquad C_{\mathrm{map},J} \ge (10M)^J, \qquad r < R_{\mathrm{buf}} < \rho.$$

There exist radii $0 < P < Q_{\mathrm{DB}}$, proportional to r, such that every reconstruction from a coarse field e^v with $|v| \le r$ and unscaled fluctuation coordinates with $\max_i|\zeta_i| \le Q_{\mathrm{DB}}$ has

all link logarithms smaller than $r/2$. With $\mathscr{L}_{\mathrm{en}}$ the enclosing constant of Definition 14.4 and C the constant of its curvature bound, require $C\mathscr{L}_{\mathrm{en}} r/(1-C\mathscr{L}_{\mathrm{en}} r)^3 < 1/2$; the condition including the coupling is completed in item (8)*. Define*

$$\delta_{\mathrm{en}} = C_{\mathrm{en},J}(r + \beta_{\mathrm{rec}} + \sigma_* \rho_{\mathrm{cl}}), \qquad R_{\mathrm{en}} = 2\delta_{\mathrm{en}}/\lambda_* \le R_W.$$

On the entire enclosing product domain,

$$\frac{C_{T,\bullet} R_{\mathrm{en}}}{1 - C_{T,\bullet}(K_* \rho_\bullet + R_{\mathrm{en}})} + C_{\Delta,\bullet} R_{\mathrm{en}} \le \rho_\bullet/8, \qquad 1 - C_{T,\bullet}(K_* \rho_\bullet + R_{\mathrm{en}}) \ge 1/2.$$

Together with item (5)*, the image under the reconstruction majorant at spatial exponent zero is at most $3\rho_\bullet/8$. The margin of half the radius in the weighted norm is kept, either by the same bounds for weighted sums or by the interpolation of coefficient bounds in Lemma 20.3, whose positive exponent was included before a and α were chosen.*

(7) Geometric widths and the curvature threshold. *Set*

$$R_{\mathrm{cell}} = \lceil A_8/r \rceil, \quad W = 8BR_{\mathrm{cell}}, \quad \varrho = \max(s_{\mathrm{er}}, W), \quad r_F = \lceil \varrho/B \rceil.$$

If desired, r may be taken small enough in item (6) *that $W \ge s_{\mathrm{er}}$. The protected sets contain all lifted endpoints of older frozen links and transports and all tree roots, in the lattices where they were introduced. At the initial renormalization group step, which starts from the Wilson measure, use the block-aligned mesh $S \asymp_J R_{\mathrm{cell}}$, one full layer of large cells (the closed cells of side R_{cell} of Theorem 21.3), and the interior restriction by the full dependence radius of the constraint, tree, and transport paths. These choices fix the constant F_J counting affected plaquettes and the constant $C_{\mathrm{ch},J}$ for the normalization factors attached to threshold failures. Here a threshold failure is a bad plaquette, that is, a plaquette selected by the tests of a large-field decomposition because its energy is at least d_*, together with the neighborhood excluded because of it. Fix $0 < \delta_* \le 1$ for the curvature threshold of Theorem 7.3, as in its proof, and then choose*

$$0 < d_{\mathrm{cut}} \le \min\{d_{\mathrm{SG}}, B_*/(96M^3), \delta_*^2/(2\pi^2)\}, \qquad d_* = d_{\mathrm{cut}}/2, \qquad \pi\sqrt{2d_*}\, S^2 \le 1.$$

The threshold d_{SG}, with its side condition, gives membership in D_r with link bound $r/2$ by Theorem 7.7. Use the constants $K_M, K_1, \kappa_0, c_A^{\mathrm{act}}, \alpha_W$ of Theorem 22.4 for arbitrary fields, $K_W = 48K_1/\alpha_W$, and $\theta = \lambda = 1/2$.

(8) Cutoff amplitude and coupling bound. *Fix $A_{\mathrm{w}} \ge 1$ in the range allowed by Theorem 20.14 (no earlier choice depends on A_{w}, so it may be fixed at any earlier stage), and set $p(t) = A_{\mathrm{w}} \log(1/t)$ and $p^+ = p(t) + A_{\mathrm{w}}(J-1)\log M/2$. Choose $g_* \le t_* < e^{-1}$ such that, for every $0 < t \le g_*$,*

$$C_0 t_*^2 \mathcal{L}_V \le 1/16, \qquad C_1 t_* (\mathcal{L}_V + 2) < 1/(4\sqrt{3}), \qquad tp(t) < P, \qquad tp^+ < R_{\mathrm{en}},$$

$$C_T t^2[p(t)^4 + Ep(t)^2] \le (1 - q_{\mathrm{CA}})/2, \qquad C_J t^2 (E + \sigma_*)[p(t)^4 + (E + \sigma_*)p(t)^2] \le 1,$$

the same two inequalities with p^+ in place of $p(t)$,

$$t \le \frac{c_{z,J}}{2[(p^+)^3 + p^+ + (E + \sigma_*)p^+]}, \qquad \mathfrak{s}(t) \le \epsilon_J, \qquad \frac{C[\mathscr{L}_{\mathrm{en}} r + t^2(1 + E)]}{(1 - C\mathscr{L}_{\mathrm{en}} r)^3} \le \frac{1}{2},$$

and the strict interaction and Jacobian margins of the earlier product theorems with their finitely many bounds for free coordinates and for parameter derivatives of the normalized log density. Here the parameter derivatives are coarse-field derivatives on a fixed fluctuation product: the running couplings, the cutoff radii, and the real frozen data are held fixed. For such a derivative ∂ and $k = Z^{-1}e^{-V}$ on that product, $\partial \log k = -\partial V + \mathbb{E}_k[\partial V]$; the applicable bounds are those of Theorem 13.10 and their regional versions. Each remaining bound is a fixed estimate of the form $Ct^{\varepsilon} \log^k(1/t) \le c$ with $\varepsilon, c > 0$. Require in addition

$$g_*^2 \le \alpha_W, \qquad 2\kappa_*/g_*^2 \ge 1, \qquad a_0 g_* < \min(r/2, 1)$$

for a fixed positive constant a_0 of the tree trial configuration. The total error in the Hessian of the conditional fluctuation potential on the enclosing product domain is then at most $8/27$.

(9) Stopping levels, the insertion interval, and the moment constants. *Fix the finite family of stopping levels, the treatment of each of the J possible remainders modulo J, their side-ratio bound χ_*, and the conversion constant K_{src}. Include both functions whose exponential moments are bounded in Theorem 22.1 and Corollary 22.9, namely the predecessor action $Q_j^{\mathcal{T}}$ of Section 23.3 and the total Wilson action S_W/g^2; we call them the predecessor insertion and the total-action insertion. Enlarge F_J once so that it counts all plaquettes affected by both. Only then choose $s_0 > 0$ in the interval of Theorem 22.1, imposing also*

$$s_0 \le \frac{\kappa_0}{2\max\{K_M, 48K_1\}}.$$

The coefficient of the Wilson action ranges over $[1/4, 1/2]$, and the bounds for the stopping partition-function ratio and its numerator are fixed for that interval. Set

$$s_b = s_0/2, \qquad a_b = 4s_b d_*/c_E, \qquad 0 < \bar{c} \le \min\{d_*/8, a_b/2\}.$$

Compute C_v, C_s, C_b from Theorem 22.1, which places no restriction on the number of averaging steps, keeping $C_s \ge 9\chi_*^2$; these constants may be enlarged for the total-action insertion by Corollary 22.9 and the same proof. Fix the value $C_\delta = 1$ for the bound on the logarithm of the reciprocal products in Lemma 22.12; it is achieved by the minimum side in item (10)*. Set $C_b' = C_b + 1 + \log 2$; a larger fixed choice is allowed.*

(10) The minimum side. *Finally choose $n_0 \in 4\mathbb{N}$ above all fixed geometric, curvature-threshold, mesh, flat, and scalar thresholds, with*

$$n_0 \ge \max\{4, e\gamma_0, \gamma_0/g_{\mathrm{end}}^2, 8R_{\mathrm{cell}}, 8S\}, \qquad 0 < g_{\mathrm{end}} \le \min\{1, g_*, g_{\mathrm{anc}}, \sqrt{\alpha_W}, \sqrt{2\kappa_*}\},$$

where g_{anc} is the coupling bound for the stopping partition-function ratio of Theorem 22.4, uniform for coefficients in $[1/4, 1/2]$. Keep every fixed margin near flat configurations, in particular $2\pi/n_0 < \min\{r/2, r_{\mathrm{flat}}\}$ with strict inequality, where r_{flat} is fixed by Lemma 14.9. Choose n_0 so that the ratios of successive terms in the error sums at the endpoints and in the sums over large-field decompositions are at most $1/2$, the reciprocal products have logarithm at most $C_\delta = 1$, and

$$\mathcal{A}_\gamma(m) = 24C_v M^3 + \frac{4C_s M^2}{m}\log(Mm/\gamma) + \frac{8C_b'}{m^3} \le \frac{a_b m}{2\gamma} \qquad (m \ge n_0,\ 0 < \gamma \le \gamma_0). \tag{23.3}$$

Impose also $M^3 e^{-\bar{c}(M-1)n_0/\gamma_0} \le 1/2$ and the threshold at the initial scale in Lemma 22.12. All these are lower bounds on n_0 in terms of previously fixed constants. No bound on the number of averaging steps is imposed.

The reconstruction maps of Theorem 15.12 are fixed once on the countable family of pairs of finite lattices. Their joint coefficient bound and β_J are obtained before r_{eff} and r; a later refinement of thresholds only increases the finite deterministic thresholds of these maps and does not enlarge that bound. The prescription for the entire indexed family is fixed once and does not depend on γ, on the field, on observations, or on a later comparison index. Its members and their deterministic thresholds are indexed by the pair of finite lattices and the preceding classical depth; no choice is repeated when the coarse side changes. Write $\widehat{C}$ for the group-valued reconstruction and $\widehat{P}(v) = \operatorname{Log}\widehat{C}(e^v, 0)$ for the logarithm of its value at zero fluctuation on the active variables. At every preceding classical depth these maps are majorized by

$$\varphi(z) = \frac{\alpha_* z}{1-\beta_J z}, \qquad \sup_{|v|\le r_{\mathrm{eff}}} \|D\widehat{P}(v)\|_{\mathrm{root}} \le a_{\mathrm{map}} = \frac{\alpha_*}{(1-\beta_J r_{\mathrm{eff}})^2}, \qquad a_{\mathrm{map}}\sqrt{B} \le \frac{32}{49} < 1. \tag{23.4}$$

Here the row sums and volume-normalized column sums follow the conventions of Lemma 15.15. We use its common majorant as a_{map}, which gives $q_{\mathrm{anc}} = B\alpha_*^2 \le B a_{\mathrm{map}}^2 < 1$ as required in the later geometric summations. All constants of the full joint estimates and of the estimates for the gauge transformations of the reconstruction maps are constants at fixed J. The choice of J uses only the J-uniform geometric constants and torus rates, the J-uniform series Z of Lemma 11.9, and the finitely many coarse-field derivative bounds of the reconstruction maps at zero fluctuation.

For every $0 \le a < K$, on the event that the initial condition and the first a renormalization group steps pass the tests of the small-field event, the next J averaging steps, from side uB^{K-a} to side uB^{K-a-1}, avoid the exceptional set of T_M: no based loop holonomy in (4.3) equals $-I$, even if a later test fails. No assertion is made about a further averaging step at $a = K$. Indeed, every closed path of such a holonomy has length at most $5M - 3$, and one averaging step increases a bound on link distances by at most the factor $10M$. Consequently every coarse field produced by the coordinate construction of the small-field event equals the iterate T_M^J of the finer field. The gauge transformations of the reconstruction maps depend only on the coarse field and are

the identity at the tree roots; they preserve this identity and all conditional kernels, cutoffs, and Jacobians.

The local constants have the dependence described in item (3) of Definition 4.14, and do not depend on the widths chosen later. The probability constants and n_0 may depend on L, γ_0, M, J, Θ, and the fixed family of stopping levels, as in item (4) of Definition 4.14; they do not depend on γ, u, N, K, the preceding classical depth, or the regions, frozen coordinates, and numbers of elapsed renormalization group steps of a large-field decomposition. Neither J nor r is changed at a different coarse side. The analytic radii are restored to their full values, after removal of a boundary layer, only at the end of complete renormalization group steps; remainders modulo J are treated by the fixed insertions and side-ratio bounds.

Item	Quantities chosen	Determined by
(1)	J, $B = M^J$	J-uniform constants $a_{\mathbb{T}} < a_{\mathrm{cen}}/8$, $\delta_0(a_{\mathbb{T}})$, K_*, C_{CP}, $C_\bullet$, $C_P(a_{\mathbb{T}})$, B_{geom}, $C^{\mathbb{T}}_{\mathrm{geom}}$, $b_{\mathbb{T}}$, C_{cen}
(2)	$v_{\mathrm{free},J}$, R_{raw}, solution neighborhoods	J; constants of Section 19 at fixed J
(3)	ρ, ρ_{cl}, E^{cl}, E; A_J, R_J; a, α, m_{rate}, b_1	items (1)–(2); C_G, q_{CA}, $c_{\mathrm{prim},J}$, C_{alloc}, C^{geom}_*
(4)	σ_0; local and geometric constants; R_W; σ_*	items (1)–(3); Sections 20 and 21
(5)	$R_{\partial,\bullet}$, $\rho_{\partial,\bullet}$, w_{bd}; s_{er}; β_{rec}	items (1)–(4); Lemma 18.9
(6)	β_J, r_{eff}; r, R_{buf}; P, Q_{DB}; R_{en}	items (1)–(5)
(7)	R_{cell}, W, ϱ, r_F, S; F_J, $C_{\mathrm{ch},J}$; δ_*, d_{cut}, d_*	items (1)–(6); Sections 7, 21, and 22
(8)	A_{w}, t_*, g_*	items (1)–(7); Lemma 23.1
(9)	stopping levels, χ_*, enlarged F_J; s_0; s_b, a_b, $\bar{c}$; C_v, C_s, C_b, C'_b	items (1)–(8); Section 22
(10)	g_{anc}, g_{end}, n_0	items (1)–(9); Lemmas 23.1 and 23.4

Table 23.1. The order of the choices in Theorem 23.2. Each row uses only the quantities of the earlier rows and the constants of the cited results, evaluated on their larger construction domains. The amplitude A_{w} may be fixed at any stage before item (8).

We prove Theorem 23.2 in Section 23.6. The parts of the inequalities in items (3) and (6) reserved for r, β_{rec}, q_{raw}, and the coupling are filled by later upper bounds on these small parameters, so no cycle arises.

Remark 23.3. The parameters of Theorem 23.2 also allow one to fix, before the coupling, the exponents $\alpha_{\mathrm{fl}} = 7/12$ and $\sigma_{\mathrm{sm}} = 5/24$ of Definition 4.8 and

$$\tau_{\mathrm{tail}} = \frac{1}{2}\min\Big\{\frac{5}{24}, \frac{1}{2}, -\frac{\log q_{\mathrm{CP}}}{\log B}\Big\} > 0,$$

together with smaller positive losses in the heat-kernel estimates. These numbers are positive since $q_{\mathrm{CP}} \le 1/4$ and $B > 1$. They satisfy the conditions of Definition 4.8 and the tail condition $0 < \tau_{\mathrm{tail}} < \min\{\sigma_{\mathrm{sm}}, 1/2, -\log q_{\mathrm{anc}}/\log B\}$ of Section 4: indeed $1/2 < 7/12 < 2/3$ and $5/24 < 1 - 7/12$, and the contraction factor of the reconstruction amplitude is $a_{\mathrm{cap}} = C_{\mathrm{CP}}/B$ in the amplitude bound of Lemma 15.10, so that $q_{\mathrm{anc}} = Ba_{\mathrm{cap}}^2 = q_{\mathrm{CP}}$ and the factor $1/2$ makes the inequality strict. This is a numerical choice only; it asserts no stochastic estimate for the flow. The deterministic sequence of matching levels in Theorem 29.19 is chosen only after the convergence at fixed coupling.

Lemma 23.4. *Fix the parameters of items* (1)–(8) *of Theorem 23.2. As in item* (9)*, fix the family of stopping levels with its remainders, the full sets of plaquettes affected by both insertions with the enlarged count F_J, and s_0 in the interval of Theorem 22.1. Fix $0 < \Gamma < \infty$, and set*

$$s_b = s_0/2, \qquad a_b = 4s_b d_*/c_E, \qquad 0 < \bar{c} \le \min\{d_*/8, a_b/2\}.$$

Let C_v, C_s, C_b be the constants of Theorem 22.1 for the ceiling Γ, and let $C_b' \ge C_b$ (for example $C_b' = C_b + 1 + \log 2$). Then there exists $n_\Gamma \in 4\mathbb{N}$, chosen before γ, the coarse side, and the number of renormalization group steps, and larger than every previous geometric, flat, and local threshold, with the following properties. The conclusions of Theorem 22.1 and Lemma 22.13 hold for all coarse sides $u \ge n_\Gamma$ and $0 < \gamma \le \Gamma$, and

$$\mathcal{A}_\gamma(m) \le a_b m/(2\gamma) \qquad (m \ge n_\Gamma,\ 0 < \gamma \le \Gamma),$$

with $\mathcal{A}_\gamma(m)$ as in (23.3)*. For $m \ge n_\Gamma$, the ratios of successive terms in the exponential sums with exponents a_{act}, $\bar{c}$, and $c_* = \min\{a_b, d_*/8\}$ over sides with ratio M or B, and in the sums for the fluctuation cutoffs over sides with ratio B, are at most $1/2$; and every product $\prod(1-\epsilon)^{-1}$ required in Lemma 22.12 has logarithm at most one. No restriction on the number of averaging steps is imposed. The new constants depend only on L, Γ, M, J, Θ, and the family of stopping levels, as described in item* (4) *of Definition 4.14.*

Proof. Theorem 22.1 and Lemma 22.13 provide the thresholds for the endpoints, for the factors attached to threshold failures, and for the initial segments at the fixed parameters. None of their hypotheses is a bound on the probability of a failure at some scale. For $x = m/\gamma \ge e$ and $m \ge 4$ we have

$$\mathcal{A}_\gamma(m) \le D(1 + \log x), \qquad D = 1 + 24C_vM^3 + C_sM^2(1 + \log M) + C_b'/8.$$

Since $(1 + \log x)/x \to 0$, we may choose a half-line $x \ge n_\Gamma/\Gamma$ on which $D(1 + \log x) \le a_b x/2$. The ratio of successive terms with exponent c is $R^3 e^{-c(R-1)m/\gamma}$, with $R = M$ or $R = B$ as appropriate. For the sums of the fluctuation cutoffs we write $z = (1/2)\log(Mm/\gamma)$ and $\Delta = (1/2)\log R$; the ratio is $R^3 e^{-a(2\Delta z + \Delta^2)}$. Both ratios are at most $1/2$ after a further increase of the minimum side, uniformly for $\gamma \le \Gamma$, and the corresponding sums tend

to zero. If $\epsilon \le 1/2$, then $-\log(1-\epsilon) \le 2\epsilon$, and the products of reciprocal errors have logarithm as small as prescribed; this is also the content of Lemma 20.15. We take the maximum of these thresholds, of the threshold at the initial scale, and of all earlier geometric and flat thresholds, rounded up to an element of $4\mathbb{N}$; all of them are monotone conditions on the minimum side.

The structural parameters fixed in the hypotheses involve only the local running couplings and fixed larger products, and none of them is recomputed from C_v, C_s, C_b or from Γ. The same argument works for any prescribed J for which the parameters of items (1)–(8) have been chosen, and it keeps that J. This proves the lemma, with the stated quantifier order and with the margin $a_{\mathrm{map}}\sqrt{B} \le 32/49$ of the reconstruction maps unchanged. □

Theorem 23.5. *Fix $L > 0$, an odd integer $M \ge 3$, and $0 < \Gamma < \infty$. There exist an integer $J \ge 1$, with $B = M^J$, a tuple Θ, reconstruction maps, a number $0 < g_* < e^{-1}$, and an integer $n_\Gamma \in 4\mathbb{N}$, all chosen before γ, the coarse side, and the number of renormalization group steps, such that every structural, local, moment, scalar, flat, and reconstruction conclusion of Theorem 23.2 holds for all*

$$0 < \gamma \le \Gamma, \qquad u \in 4\mathbb{N},\ u \ge n_\Gamma, \qquad K \in \mathbb{N}_0, \qquad N = uB^K,$$

with γ_0 replaced by Γ in its conclusions and side conditions, and with the moment constants of Theorem 22.1 and Lemma 22.13 for the ceiling Γ. In particular $a_{\mathrm{map}}\sqrt{B} \le 32/49$, every coarse field produced by the coordinate construction is the corresponding iterate of T_M, and the reconstruction maps, the support radius, and the local constants are fixed before the coupling. The minimum side satisfies

$$n_\Gamma \ge \max\{4, e\Gamma, \Gamma/g_{\mathrm{end}}^2, 8R_{\mathrm{cell}}, 8S\}$$

and the coupling condition of Lemma 22.13; no restriction on the number of averaging steps is imposed. The parameters satisfy $0 < \delta_* \le 1$, fixed before d_{cut}, $g_*^2 \le \alpha_W$, and

$$0 < s_0 \le \min\Big\{\frac{1}{2},\ \frac{\kappa_*}{2}c_E^{-(J-1)},\ \frac{1}{4K_W},\ \frac{c_A^{\mathrm{act}}d_*}{32F_J},\ \frac{\kappa_0}{2\max\{K_M, 48K_1\}}\Big\}, \qquad K_W = 48K_1/\alpha_W,$$

and the stopping partition-function ratio is controlled uniformly for coefficients of the Wilson action in $[1/4, 1/2]$. The construction can be carried out with any prescribed J for which parameters as in Theorem 23.2 with $\gamma_0 = 1$ have been chosen, without changing J. The local constants have the dependence described in item (3) *of Definition 4.14, and the probability constants the dependence described in item* (4)*, with the fixed ceiling Γ. No uniformity as $\Gamma \to \infty$ is asserted.*

We give the proof in Section 23.7. When $\Gamma = \gamma_0 \le 1$, the parameters of Theorem 23.2 satisfy the conclusions of Theorem 23.5, and in that case we write n_0 for n_Γ.

23.3 Bounds under the Wilson measure

In this subsection, we bound the probability that some averaged configuration has a plaquette of large energy, and we bound exponential moments of coarse actions under the Wilson measure. We recall the notation of Theorem 22.1 and Lemma 22.11. For $N = uB^K$ and $n_j = N/M^j$, fix one of the eight tilings $\mathcal{T}$ of the lattice of side n_j into $r_j = n_j^3/8$ disjoint cells with two sites in each direction (this number is denoted $\mathfrak{m}_j$ in Lemma 22.11). Let $\mathcal{P}_{j-1}^{\mathcal{T}}$ be the union, counted once, of the complete predecessor patches at side n_{j-1} of the internal plaquettes of the cells, and for a configuration V at side n_{j-1} set

$$Q_j^{\mathcal{T}}(V) = \frac{4}{h_{n_{j-1}}} \sum_{p \in \mathcal{P}_{j-1}^{\mathcal{T}}} q(V_p).$$

For a cell C, let $R_{<j}(C; d_{\mathrm{cut}})$ be the local regularity event of Lemma 22.11, which tests at the threshold d_{cut} exactly the plaquettes of the finer scales whose full dependence sets lie in C; let $I_j(C; d_*)$ be the event that some internal plaquette of C at scale j has energy at least d_*; and let $R_{<j}^{\mathcal{T}}(d_{\mathrm{cut}})$ be the intersection of the events $R_{<j}(C; d_{\mathrm{cut}})$ over the cells of $\mathcal{T}$. These local events do not test the plaquettes on the boundaries of the cells. By Lemma 7.4, every plaquette at scale j is internal to a cell of one of the eight tilings.

The probability bounds below rest on the chessboard estimate of Fröhlich, Israel, Lieb, and Simon [92, 93], which we use in the form of Biskup [29, Theorem 5.8]. The Wilson measure is reflection positive [134]. Part (2) of Theorem 6.6 gives the chessboard inequality, for each of the eight shifted tilings, under the image measure $(T_M^j)_* \mu_{N,\gamma}$ for nonnegative observables supported in the coarse cells, and more generally under $\mu_{N,\gamma}$ for nonnegative observables supported in the fine cells formed by the blocks B_{M^j} of the vertices of a coarse cell. The side n_j is divisible by four, as that theorem requires. The event $I_j(C; d_*)$ is a function of $T_M^j U$ on the coarse cell C, and the event $R_{<j}(C; d_{\mathrm{cut}}) \cap I_j(C; d_*)$ is a gauge-invariant function of the fine links in the fine cell of C, since it tests only plaquettes whose full dependence sets lie in C; this is the form in which Lemma 22.11 applies the theorem. All estimates in this subsection are under the Wilson measure $\mu_{N,\gamma}$, normalized by its own partition function; no conditioned measure occurs.

Theorem 23.6. *Use the parameters and the minimum side n_Γ of Lemma 23.4; for $\Gamma \le 1$ these are the parameters of Theorem 23.2 with $\gamma_0 = \Gamma$, and for general finite Γ those of Theorem 23.5. Let $0 < \gamma \le \Gamma$, $u \in 4\mathbb{N}$ with $u \ge n_\Gamma$, and $K \in \mathbb{N}_0$, and let $N = uB^K$, $D = JK$, $n_j = N/M^j$, and $V^j = T_M^j U$. Define*

$$\mathrm{FF}_0 = \{\max_p q(U_p) \ge d_*\}, \qquad \mathrm{FF}_j = \{q(V_p^\ell) < d_* \text{ for all } \ell < j \text{ and all } p,\ \max_p q(V_p^j) \ge d_*\}$$

for $1 \le j \le D$. Then, simultaneously for all $0 \le j \le D$,

$$\mu_{N,\gamma}(\mathrm{FF}_j) \le 3 n_j^3 e^{-\bar{c} n_j/\gamma}. \tag{23.5}$$

For $1 \le j \le D$, each of the eight tilings $\mathcal{T}$, and $0 \le s \le s_0$,

$$\log \mathbb{E}_{\mu_{N,\gamma}}\big[e^{sQ_j^{\mathcal{T}}(V^{j-1})}; R_{<j}^{\mathcal{T}}(d_{\mathrm{cut}})\big] \le 3C_v n_{j-1}^3 + C_s n_{j-1}^2 \log(1/g_{n_{j-1}}) + C_b'.$$

The same bound holds without the indicator of $R_{<j}^{\mathcal{T}}(d_{\mathrm{cut}})$, with C_b in place of C_b'. The constants depend only on L, Γ, M, J, Θ, and the family of stopping levels, as described in item (4) *of Definition 4.14, and are uniform in γ, the side, the number of renormalization group steps, the scale j, and the tiling.*

Proof. At $j = 0$, by the threshold at the initial scale in item (10) of Theorem 23.2 (for general Γ, in Lemma 23.4 and Lemma 22.13), we have

$$\mu_{N,\gamma}(\mathrm{FF}_0) \le 3N^3 e^{-d_* N/(8\gamma)} \le 3N^3 e^{-\bar{c}N/\gamma}, \tag{23.6}$$

where we used $\bar{c} \le d_*/8$. For a scale $j \ge 1$, we apply Theorem 22.1 with the Wilson measure at side N as the starting measure (that is, with $b = 0$) and the same j. This gives the bound without the indicator directly at that scale, whatever its distance from the finest lattice. Since the integrand is nonnegative and $C_b \le C_b'$, the bound with the indicator follows. This proves both moment bounds, without any assumption on earlier failures.

Let $m = n_j$. We divide the logarithm of the moment bound with the indicator by the number $r_j = m^3/8$ of cells. Since $n_{j-1} = Mm$ and $\log(1/g_{Mm}) = (1/2)\log(Mm/\gamma)$, we have

$$\begin{aligned}\frac{3C_v(Mm)^3 + C_s(Mm)^2 \frac{1}{2}\log(Mm/\gamma) + C_b'}{m^3/8} &= 24C_v M^3 + \frac{4C_s M^2}{m}\log(Mm/\gamma) + \frac{8C_b'}{m^3} \\ &= \mathcal{A}_\gamma(m).\end{aligned}$$

This identity explains why a moment bound with a volume term and a surface term carrying a logarithm suffices. After the reciprocal-cell-count exponent in the chessboard estimate is applied, the entropy per cell is of order $1 + \log(m/\gamma)/m$, which is dominated by the action $a_b m/\gamma$ of a cell containing a bad plaquette. Then, by the estimate of Lemma 22.11, which combines Markov's inequality at $s = s_b$ with the chessboard estimate, we have

$$\log \mu_{N,\gamma}\big(R_{<j}(C; d_{\mathrm{cut}}) \cap I_j(C; d_*)\big) \le -a_b m/\gamma + \mathcal{A}_\gamma(m) \le -\bar{c}m/\gamma, \tag{23.7}$$

where in the last inequality we used $\mathcal{A}_\gamma(m) \le a_b m/(2\gamma)$ and $\bar{c} \le a_b/2$.

Since $d_* < d_{\mathrm{cut}}$, regularity at the threshold d_* at all earlier scales implies every local event $R_{<j}(C; d_{\mathrm{cut}})$. Every plaquette of scale j with energy at least d_* is internal to a cell of one of the eight tilings, by Lemma 7.4. Then FF_j is contained in the union of the $8r_j = m^3$ events in (23.7), and by a union bound we have $\mu_{N,\gamma}(\mathrm{FF}_j) \le m^3 e^{-\bar{c}m/\gamma}$. This

implies (23.5), where the constant three is kept only for a common formula with (23.6). The argument applies to each j separately, without induction over scales; if $K = 0$, only the assertion at $j = 0$ remains. □

The next theorem gives exponential moments of coarse actions without any indicator. It is not needed for the bound on S^c, but it is a quantitative consequence of the same estimates.

Theorem 23.7. *Fix $L > 0$, an odd integer $M \geq 3$, and $0 < \Gamma < \infty$. Use parameters as in Theorem 23.5, in which, as in item* (9) *of Theorem 23.2, the count F_J includes the plaquettes affected by both the predecessor insertion and the total-action insertion before s_0 is chosen. There exist $s_* = s_0 > 0$, $n_\Gamma \in 4\mathbb{N}$, and finite nonnegative constants C_v, C_s, C_b, chosen before γ, the side, and the number of renormalization group steps, such that for every $0 < \gamma \leq \Gamma$, $u \in 4\mathbb{N}$ with $u \geq n_\Gamma$, $K \in \mathbb{N}_0$, $N = uB^K$, $n_j = N/M^j$, and $0 \leq s \leq s_*$,*

$$\log \mathbb{E}_{\mu_{N,\gamma}} e^{sQ_j^{\mathcal{T}}(T_M^{j-1}U)} \leq 3C_v n_{j-1}^3 + C_s n_{j-1}^2 \log(1/g_{n_{j-1}}) + C_b, \qquad 1 \leq j \leq JK, \tag{23.8}$$

$$\log \mathbb{E}_{\mu_{N,\gamma}} e^{sS_W(T_M^j U)/g_{n_j}^2} \leq 3C_v n_j^3 + C_s n_j^2 \log(1/g_{n_j}) + C_b, \qquad 0 \leq j \leq JK. \tag{23.9}$$

The first inequality holds for each of the eight tilings $\mathcal{T}$. All expectations are under the Wilson measure, normalized by its partition function, and all iterates of T_M that occur are defined on the given finite sequence of lattices. The constants depend only on L, Γ, M, J, Θ, and the family of stopping levels, as described in item (4) *of Definition 4.14; they are uniform in γ, the side, the scale, and the number of renormalization group steps, and they do not depend on the large-field decompositions used in the proof. Moreover, with $\mathcal{B}_\gamma(n) = 3C_v n^3 + C_s n^2 \log(1/g_n) + C_b$, for every integer $p \geq 1$,*

$$\mathbb{E}_{\mu_{N,\gamma}}\Big[\big(S_W(T_M^j U)/g_{n_j}^2\big)^p\Big] \leq p!\, s_*^{-p} e^{\mathcal{B}_\gamma(n_j)},$$

and the analogous polynomial moment bound holds for $Q_j^{\mathcal{T}}(T_M^{j-1}U)$, with $\mathcal{B}_\gamma(n_{j-1})$.

Proof. Let $F_J' = \max(F_J, F_J^{\mathrm{A}})$ be the larger of the counts for the two insertions, enlarged also over the union of the two finite families of remainders. We take a common interval satisfying the conditions of item (9) of Theorem 23.2 with F_J' and the further restriction

$$0 < s_* = s_0 \leq \frac{\kappa_0}{2\max\{K_M, 48K_1\}}.$$

All entries are positive constants at this stage. The bound (23.8) is Theorem 22.1 with the Wilson measure as the starting measure ($b = 0$). For (23.9), we choose the stopping level $t = J\lfloor j/J \rfloor$, with $v = j - t \in \{0, \dots, J-1\}$, so that $m = n_t = M^v n_j$. All iterates from level t to level j are defined, including for $j = JK$, where $v = 0$ and $t = JK$.

Suppose first that $t > 0$. We integrate exactly t/J complete RG steps, starting from the Wilson measure, and use the bound of Corollary 22.9 for the total-action insertion

inside the invariant density bound without weight of Theorem 22.10. The coefficient of the Wilson action remains $\lambda_s = 1/2 - sK_W \in [1/4, 1/2]$, and the plaquettes affected by the insertion contribute at most $8sF_J' \sum_f n_f/\gamma \le P_0 \sum_f n_f/(4\gamma)$. The factors listed in Table 22.2 are unchanged except for their fixed incidence constants: the normalization terms generated by the integration and the completion terms concern the same large-field decompositions, and the finite dependence set of the insertion was enlarged before the interval was chosen. The quantitative conclusion of Theorem 22.1 on these factors applies, with the scale n_j and enlarged fixed constants. We complete the density bound by Lemma 22.7 and use the single stopping partition-function ratio of Theorem 22.4. Then each large-field decomposition contributes at most

$$e^{3C_T m^3 + 9m^2 \log(1/g_m) + C_\delta} \prod_f e^{-(P_0/2) n_f/\gamma}.$$

The bound of Theorem 22.1 for the sum over decompositions controls the sum of these contributions uniformly at the common minimum side. Converting from $m = \chi n_j$, with $\chi \le M^{J-1}$, leaves exactly a volume term, the surface term $9\chi^2 n_j^2 \log(1/g_{n_j})$, and a fixed volume contribution from $\log \chi$. We take the maximum of the constants for the two insertions.

Suppose now that $t = 0$. Then $0 \le j < J$ and $N/n_j = M^j$ is bounded. By the comparison of Theorem 22.4 for arbitrary fields, valid at all depths, we have $S_W(T_M^j U)/g_{n_j}^2 \le 48K_1 S_W(U)/g_N^2$. Since $48sK_1 \le \kappa_0/2 \le 1/2$, the ratio of the full compact numerator to the periodic trial denominator at depth zero, used for short scale intervals in Theorem 22.1, applies. This ratio has the required surface-order correction in the partition-function comparison at side N, and the bounded ratio $N/n_j \le M^{J-1}$ implies the stated bound at n_j. At $j = 0$ the deterministic inequality holds with the smaller constant one; this case includes $K = 0$. In both cases we bounded the integrals without indicators directly; no indicator of a regularity event was dropped from an upper bound.

Finally, for $x \ge 0$ we have $x^p \le p!\, s_*^{-p} e^{s_* x}$, by the exponential series. Inserting the exponential moment bounds, we obtain the last assertion. □

Corollary 23.8. *Use the parameters and constants of Theorem 23.7, increasing only the minimum side if necessary. There exists $c_{\mathrm{bad}} > 0$ with the following property. Let $0 < \gamma \le \Gamma$, $u \in 4\mathbb{N}$ with $u \ge n_\Gamma$, $K \in \mathbb{N}_0$, $N = uB^K$, and $0 \le j \le JK$, and let $\mathcal{T}$ be one of the eight tilings at scale j. We set*

$$r_j = n_j^3/8, \qquad q_j = e^{-c_{\mathrm{bad}} n_j/\gamma},$$

and for a cell C of $\mathcal{T}$ let I_C be the event that some internal plaquette P of C satisfies $q((T_M^j U)_P) \ge d_*$. Then for every deterministic set A of distinct cells of $\mathcal{T}$,

$$\mu_{N,\gamma}\Big(\bigcap_{C \in A} I_C\Big) \le q_j^{|A|}. \tag{23.10}$$

For $Y_j = \sum_{C\in\mathcal{T}} \mathbf{1}_{I_C}$, every integer $0 \le k \le r_j$, and every $\vartheta \ge 0$,

$$\mathbb{E}_{\mu_{N,\gamma}} \binom{Y_j}{k} \le \binom{r_j}{k} q_j^k, \tag{23.11}$$

$$\mathbb{E}_{\mu_{N,\gamma}} e^{\vartheta Y_j} \le [1 + (e^{\vartheta} - 1)q_j]^{r_j} \le \exp\{r_j q_j (e^{\vartheta} - 1)\}. \tag{23.12}$$

Equivalently, $\mathbb{E}(Y_j)_k \le (r_j)_k q_j^k$ for the falling factorials. The constants depend only on L, Γ, M, J, Θ, and the family of stopping levels (item (4) of Definition 4.14), and are uniform in γ, the side, the number of renormalization group steps, the scale, the tiling, and A.

The bounds (23.11) and (23.12) are those of a sum of independent Bernoulli variables with parameter q_j, but they are proved from the joint bounds (23.10) alone; no independence or stochastic domination is asserted.

Proof. Fix j and $\mathcal{T}$, and let $m = n_j$. The indicator of I_C is a nonnegative, bounded, gauge-invariant function of the configuration $T_M^j U$ on the internal plaquettes of the cell C, that is, an observable supported in the coarse cell C. Part (2) of Theorem 6.6, applied to the image measure $(T_M^j)_* \mu_{N,\gamma}$ and the tiling $\mathcal{T}$, applies to it; equivalently, its pullback is supported in the fine cell formed by the centered blocks of the vertices of C. The reflection positivity in part (1) of that theorem includes the configurations at which the Borel extension of T_M is used. Each I_C is the reflected translate of the corresponding event for the base cell of $\mathcal{T}$, since the energy of a plaquette is invariant under reversal of orientation. For nonempty A, the chessboard inequality with all observables equal to the indicator of this event gives

$$\mu_{N,\gamma}\Big(\bigcap_{C\in A} I_C\Big) \le \mu_{N,\gamma}(I_{\mathrm{all}})^{|A|/r_j}, \qquad I_{\mathrm{all}} = \bigcap_{C\in\mathcal{T}} I_C.$$

On I_{all}, we choose one internal plaquette with energy at least d_* in each cell, in a fixed deterministic order. The chosen plaquettes are distinct, since the cells have disjoint vertex sets and only internal plaquettes are used. This gives, pointwise on I_{all},

$$S_W(T_M^j U)/g_m^2 \ge 4 d_* r_j m/\gamma.$$

By Markov's inequality and (23.9) at $s = s_*$, we have

$$\frac{1}{r_j} \log \mu_{N,\gamma}(I_{\mathrm{all}}) \le -4 s_* d_* m/\gamma + 24 C_v + \frac{4C_s}{m} \log(m/\gamma) + \frac{8C_b}{m^3}.$$

Here the entropy terms are in the units of scale j itself, so no factor M^3 appears. With $x = m/\gamma \ge e$ and $m \ge 4$, their sum is at most $D_{\mathrm{A}}(1 + \log x)$ for a fixed D_{A}. We increase the minimum side so that $D_{\mathrm{A}}(1 + \log x) \le 2 s_* d_* x$ on the half-line $x \ge n_\Gamma/\Gamma$. Then

$c_{\mathrm{bad}} = 2s_* d_* > 0$ works. If $\mu_{N,\gamma}(I_{\mathrm{all}}) = 0$, the chessboard estimate already implies the result; otherwise we exponentiate the bound on its logarithm. For $A = \varnothing$ both sides of (23.10) equal one.

Pointwise we have $\binom{Y_j}{k} = \sum_{|A|=k} \prod_{C \in A} \mathbf{1}_{I_C}$, including for $k = 0$, and taking expectations proves (23.11). For $\vartheta \geq 0$ we expand the finite product

$$e^{\vartheta Y_j} = \prod_{C \in \mathcal{T}} \bigl[1 + (e^{\vartheta} - 1)\mathbf{1}_{I_C}\bigr].$$

Since every coefficient in the expansion is nonnegative, the joint bounds give (23.12); its last inequality uses $1 + y \leq e^y$ for $y \geq 0$. The case $j = 0$, including $K = 0$, is covered by the instance $j = 0$ of (23.9). □

23.4 Probability of the small-field event

We now bound the probability of the complement of the small-field event. Recall from Definitions 4.4 and 14.4 that, for $N = uB^K$ and $V^\ell = T_M^\ell U$,

$$S_{N,u,\gamma} = \{U \in D_r\} \cap \bigcap_{k=0}^{K-1} \Bigl[\mathcal{A}_{k,J}(U) \cap \{\max_{i,e} |w_{k,i,e}(U)| \leq p(t_k)\} \cap \{V^{(k+1)J} \in D_r\}\Bigr],$$

where $t_k^2 = \gamma/(Mn_{(k+1)J})$ and $p(t) = A_{\mathrm{w}} \log(1/t)$. Here $\mathcal{A}_{k,J}(U)$ is the event that, in the inverse coordinates of the k-th RG step at preceding classical depth kJ, each pair (c_{i+1}, z_i) lies in the coordinate domain of Definition 14.4, with its conditional constrained minimizer, its positive constrained Hessian, and a positive constraint Jacobian; and $w_{k,i,e}(U)$ are the normalized fluctuation variables of that step, defined by these inverse coordinates. There is no condition of the form $V^\ell \in D_r$ at levels ℓ that are not multiples of J. For $K = 0$ the event is $\{U \in D_r\}$.

The proof splits S^c according to the event G that every plaquette at every scale has energy below d_*. The probability of G^c is the sum of the probabilities of the first failures FF_j, which Theorem 23.6 bounds under the Wilson measure. On G, Theorem 7.7 implies all conditions $V^{kJ} \in D_r$, and S can fail only through the coordinate-domain conditions or the cutoffs of some RG step. We bound the first such failure using the comparison of Lemma 22.12, which keeps only the passing initial segment and the condition on the next coarse field. In this comparison, the probability of the initial segment is multiplied, never divided, and we never condition on regularity at later scales, which would change the conditional law.

Theorem 23.9. *Use the parameters, the renormalization group steps, and the reconstruction maps of Theorem 23.2. There exist constants $C', C, C_{\mathrm{w}}, a_{\mathrm{w}} > 0$ such that for every $u \in 4\mathbb{N}$ with $u \geq n_0$, every $K \in \mathbb{N}_0$, and every $0 < \gamma \leq \gamma_0$,*

$$\mu_{uB^K,\gamma}\bigl(S^c_{uB^K,u,\gamma}\bigr) \leq C' u^3 e^{-\bar{c}u/\gamma} + C_{\mathrm{w}} u^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mu/\gamma}}$$

and

$$\mu_{uB^K,\gamma}\big(S^c_{uB^K,u,\gamma}\big) \le Cu^3 e^{H_0+H_2\log(1/\gamma)-c_*u/\gamma} + C_{\mathrm{w}}u^3 e^{-a_{\mathrm{w}}\log^2\sqrt{Mu/\gamma}},$$

where

$$H_0 = 24C_vM^3 + \frac{4C_sM^2}{n_0}\log(Mn_0) + \frac{8C_b'}{n_0^3}, \qquad H_2 = \frac{4C_sM^2}{n_0}, \qquad c_* = \min\{a_b, d_*/8\} > 0.$$

One may take a_{w} to be the smallest of the finitely many fixed positive exponents in the fluctuation bounds for the auxiliary measures and the stopped measures. The constants may depend on $L, \gamma_0, M, J, \Theta$, and the family of stopping levels, but not on γ, u, N, K, the preceding classical depth, or the large-field decompositions. The event, and hence these bounds, are the same when the inverse coordinates are computed with the reconstruction maps of Theorem 15.12.

The two theorems have a common proof.

Theorem 23.10. *Use the parameters of Theorem 23.5 for a fixed $0 < \Gamma < \infty$, and the small-field event $S_{N,u,\gamma}$ defined with them, for $0 < \gamma \le \Gamma$, $u \in 4\mathbb{N}$ with $u \ge n_\Gamma$, $K \in \mathbb{N}_0$, and $N = uB^K$. There exist constants $C', C, C_{\mathrm{w}}, a_{\mathrm{w}} > 0$ such that*

$$\mu_{uB^K,\gamma}\big(S^c_{uB^K,u,\gamma}\big) \le C'u^3 e^{-\bar{c}u/\gamma} + C_{\mathrm{w}}u^3 e^{-a_{\mathrm{w}}\log^2\sqrt{Mu/\gamma}}, \tag{23.13}$$

$$\mu_{uB^K,\gamma}\big(S^c_{uB^K,u,\gamma}\big) \le Cu^3 e^{H_0^\Gamma+H_2\log(\Gamma/\gamma)-c_*u/\gamma} + C_{\mathrm{w}}u^3 e^{-a_{\mathrm{w}}\log^2\sqrt{Mu/\gamma}}, \tag{23.14}$$

where

$$H_0^\Gamma = 24C_vM^3 + \frac{4C_sM^2}{n_\Gamma}\log(Mn_\Gamma/\Gamma) + \frac{8C_b'}{n_\Gamma^3} \ge 0,$$

$$H_2 = \frac{4C_sM^2}{n_\Gamma} \ge 0, \qquad c_* = \min\{a_b, d_*/8\} \ge \bar{c} > 0.$$

The constants may depend on the fixed Γ (item (4) of Definition 4.14), and do not depend on γ, the side, the number of renormalization group steps, the preceding classical depth, or the large-field decompositions. Moreover, for every fixed $u \in 4\mathbb{N}$ with $u \ge n_\Gamma$ and every $q > 0$,

$$\sup_{K\ge 0}\mu_{uB^K,\gamma}\big(S^c_{uB^K,u,\gamma}\big) \le C_{u,q,\Gamma}\gamma^q \qquad (0 < \gamma \le \Gamma),$$

with the admissible constant

$$C_{u,q,\Gamma} = Cu^3 e^{H_0^\Gamma}\Gamma^{H_2}\Big(\frac{H_2+q}{c_*ue}\Big)^{H_2+q} + C_{\mathrm{w}}u^3(Mu)^{-q}e^{q^2/a_{\mathrm{w}}}.$$

Finally, for every fixed $n \in 4\mathbb{N}$ with $n \ge n_\Gamma$ and $u_a = nB^a$,

$$\lim_{a\to\infty}\sup_{0<\gamma\le\Gamma}\sup_{K\ge a}\mu_{nB^K,\gamma}\big(S^c_{nB^K,u_a,\gamma}\big) = 0.$$

Proof of Theorems 23.9 and 23.10. For $0 \le a \le K$, let S^a be the event formed by the initial condition $U \in D_r$ and the conditions of the first a RG steps in the definition of $S_{N,u,\gamma}$, and let

$$G = \{q(V_p^j) < d_* \text{ for every } 0 \le j \le JK \text{ and every plaquette } p\}.$$

The disjoint events FF_j, $0 \le j \le JK$, exhaust G^c. By Theorem 23.6 and the condition $M^3 e^{-\bar{c}(M-1)n_\Gamma/\Gamma} \le 1/2$, summing over the sides uM^h in increasing order, we have

$$\mu(G^c) \le 3 \sum_{h \ge 0} (uM^h)^3 e^{-\bar{c}uM^h/\gamma} \le 6u^3 e^{-\bar{c}u/\gamma}. \tag{23.15}$$

The sum over sides starts at the coarse side u, so no factor depending on K appears.

To keep the dependence on γ before absorption, we use (23.7) in the form $\log \mu(R_{<j}(C; d_{\mathrm{cut}}) \cap I_j(C; d_*)) \le -a_b m/\gamma + \mathcal{A}_\gamma(m)$. Since $\log(Mm/\gamma) = \log(Mm/\Gamma) + \log(\Gamma/\gamma)$ and $\log(Mm/\Gamma)/m$ is decreasing for $m \ge n_\Gamma \ge e\Gamma$, we have

$$\begin{gathered} \mathcal{A}_\gamma(m) \le H_0^\Gamma + H_2 \log(\Gamma/\gamma), \\ H_0^\Gamma = 24 C_v M^3 + \frac{4C_s M^2}{n_\Gamma} \log(M n_\Gamma/\Gamma) + \frac{8C_b'}{n_\Gamma^3}, \qquad H_2 = \frac{4C_s M^2}{n_\Gamma}, \end{gathered} \tag{23.16}$$

and this bound is nonnegative. Combining the bound at the initial scale with the bounds at positive scales, and summing the same geometric list of sides, we obtain

$$\mu(G^c) \le 6u^3 e^{H_0^\Gamma + H_2 \log(\Gamma/\gamma) - c_* u/\gamma}, \qquad c_* = \min\{a_b, d_*/8\} \ge \bar{c}. \tag{23.17}$$

For Theorem 23.9 we use instead $H_0 + H_2 \log(1/\gamma)$, which follows from the same calculation with Γ replaced by one in the logarithm; the function $\log(Mm)/m$ is decreasing for $m \ge 4$.

On G, the condition $U \in D_r$ and every condition $V^{(k+1)J} \in D_r$ hold by Theorem 7.7. By the identity of coarse fields in Theorems 23.2 and 23.5, on a passing initial segment each coarse field produced by the coordinate construction is the corresponding iterate of T_M. We conclude that

$$G \cap S^c \subset \bigcup_{0 \le a < K} \big(S^a \cap A_{n_{(a+1)J}} \cap W^c_{n_{(a+1)J}}\big), \tag{23.18}$$

where, for $m = n_{(a+1)J}$, A_m is the event that the coarse field $V^{(a+1)J}$ lies in D_r, and W_m is the event that all coordinate-domain conditions and fluctuation cutoffs of the $(a+1)$-th RG step hold. After this inclusion we discard G before estimating each term. By the comparison with identical unnormalized prefactors in Lemma 22.12, in its form for a fixed upper coupling bound Γ in Lemma 22.13, we have

$$\mu(S^a \cap A_m \cap W_m^c) \le \epsilon_a \mu(S^a) \le C_{\mathrm{rej},J} m^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mm/\gamma}}. \tag{23.19}$$

This is the comparison for coarse fields in D_r at preceding depth aJ; only $a < K$ is used, and the probability $\mu(S^a) \le 1$ of the initial segment is multiplied, never inverted. Summing the bound over the sides $u, uB, uB^2, \dots$ and using the ratio condition for the fluctuation cutoffs, we obtain

$$\mu(G \cap S^c) \le 2C_{\mathrm{rej},J} u^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mu/\gamma}}. \tag{23.20}$$

Adding (23.15) or (23.17) proves both bounds of each theorem, for example with $C = C' = 6$ and $C_{\mathrm{w}} = 2C_{\mathrm{rej},J}$. For $K = 0$ the sum (23.20) is empty, and the initial condition holds on the event that there is no failure at the initial scale. By Theorem 15.12, the reconstruction maps preserve the event, the transitions, the cutoffs, the Jacobians, and the kernels, so the same bounds hold in the coordinates of the reconstruction maps.

For the bound by powers of γ, we divide the curvature term of (23.14) by γ^q. For $\kappa = H_2 + q > 0$ and $A = c_* u > 0$ we have $\sup_{\gamma>0} \gamma^{-\kappa} e^{-A/\gamma} = (\kappa/(Ae))^\kappa$. For the fluctuation term we write $z = (1/2)\log(Mu/\gamma)$, and then

$$\gamma^{-q} e^{-a_{\mathrm{w}} z^2} = (Mu)^{-q} e^{2qz - a_{\mathrm{w}} z^2} \le (Mu)^{-q} e^{q^2/a_{\mathrm{w}}}.$$

These give the constant $C_{u,q,\Gamma}$. For $u_a = nB^a$, both terms of (23.13) decrease in u and increase in γ for sides above the minimum side, by Lemma 23.1. Their values at $\gamma = \Gamma$ tend to zero as $a \to \infty$, uniformly in $K \ge a$, since $nB^K = u_a B^{K-a}$. This proves the last assertion of Theorem 23.10. □

Corollary 23.11. *Use the parameters of Theorem 23.2, and fix $u \in 4\mathbb{N}$ with $u \ge n_0$ before varying the coupling. For every real $q > 0$ there exists a finite $C_{u,q}$ such that*

$$\sup_{K \ge 0} \mu_{uB^K,\gamma}\big(S^c_{uB^K,u,\gamma}\big) \le C_{u,q}\gamma^q \qquad (0 < \gamma \le \gamma_0).$$

With the constants of the second bound of Theorem 23.9, an admissible constant is

$$C_{u,q} = Cu^3 e^{H_0}\Big(\frac{H_2 + q}{c_* ue}\Big)^{H_2+q} + C_{\mathrm{w}} u^3 (Mu)^{-q} e^{q^2/a_{\mathrm{w}}},$$

or any larger finite constant. In particular, if

$$F_u(\gamma) = \limsup_{K \to \infty} \mu_{uB^K,\gamma}\big(S^c_{uB^K,u,\gamma}\big),$$

then $F_u(\gamma) = o(\gamma^\kappa)$ as $\gamma \to 0$ for every fixed $\kappa > 0$. Besides the probability constants, $C_{u,q}$ depends only on u and q; it does not depend on K.

Now fix $n \in 4\mathbb{N}$ with $n \ge n_0$, and set $u_a = nB^a$ and $N_K = nB^K$. For all integers $a \ge 0$ and $K \ge a$,

$$e_{K,a}(\gamma) = \mu_{N_K,\gamma}\big(S^c_{N_K,u_a,\gamma}\big) \le \mathcal{F}(u_a,\gamma), \qquad \mathcal{F}(u,\gamma) = C'u^3 e^{-\bar{c}u/\gamma} + C_{\mathrm{w}} u^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mu/\gamma}},$$

and

$$\lim_{a\to\infty} \sup_{0<\gamma\le\gamma_0} \mathcal{F}(u_a,\gamma) = 0.$$

These bounds use the same small-field events and reconstruction maps for all coarse sides; no radius, cutoff, map, or threshold is chosen again at a larger coarse side.

At each fixed positive coupling, the probability of the complement tends to zero along the sides u_a, while at each fixed side it is smaller than every power of the coupling. The corollary gives no rate, uniform in the coupling, for the convergence of flowed observables, and it does not interchange a limit in the cutoff or in an observable with the limit $a \to \infty$.

Proof. We keep u fixed and let $\tau = \log(1/\gamma)$ and $d_u = \log(Mu)$. Dividing the second bound of Theorem 23.9 by γ^q, its curvature term becomes

$$Cu^3 e^{H_0} \exp\{(H_2+q)\tau - c_* u e^{\tau}\}.$$

For $\kappa = H_2 + q > 0$, the derivative of $v^\kappa e^{-c_* u v}$ on $v > 0$ has the sign of $\kappa - c_* u v$. This function has the global maximum $[\kappa/(c_* u e)]^\kappa$, attained at $v = \kappa/(c_* u)$. Bounding the value at $v = e^\tau = 1/\gamma$ by this maximum, we obtain the first summand of $C_{u,q}$. For the fluctuation term, completing the square gives the identity

$$q\tau - \frac{a_{\mathrm{w}}}{4}(\tau + d_u)^2 = -\frac{a_{\mathrm{w}}}{4}\Big(\tau + d_u - \frac{2q}{a_{\mathrm{w}}}\Big)^2 + \frac{q^2}{a_{\mathrm{w}}} - q d_u,$$

and dropping the negative square gives the second summand. Both constants are finite for fixed u and q, and the bound of Theorem 23.9 is uniform in K. This proves the bound on the supremum. Given $\kappa > 0$, we choose $q > \kappa$; then

$$0 \le \gamma^{-\kappa} F_u(\gamma) \le C_{u,q}\gamma^{q-\kappa} \longrightarrow 0,$$

and no limit in the cutoff has been interchanged with the limit in the coupling.

Now fix n and set $u_a = nB^a$. For $K \ge a$ we have $N_K = u_a B^{K-a}$, and Theorem 23.9 applies directly with coarse side u_a and $K - a$ RG steps. No parameter of the event, of a local reconstruction, or of its finite thresholds is chosen again. We obtain $e_{K,a}(\gamma) \le \mathcal{F}(u_a,\gamma)$.

Since both terms of $\mathcal{F}(u,\gamma)$ increase with γ for $Mu/\gamma \ge Mu/\gamma_0 > 1$, we have

$$\sup_{0<\gamma\le\gamma_0} \mathcal{F}(u_a,\gamma) \le C' u_a^3 e^{-\bar{c}u_a/\gamma_0} + C_{\mathrm{w}} u_a^3 e^{-a_{\mathrm{w}}\log^2(Mu_a/\gamma_0)/4}.$$

Up to fixed constants, the logarithms of these two terms are $3\log u_a - \bar{c}u_a/\gamma_0$ and $3\log u_a - a_{\mathrm{w}}\log^2(Mu_a/\gamma_0)/4$, and both tend to $-\infty$ as $a \to \infty$, since $u_a \to \infty$. □

23.5 Two-sided bounds of logarithm-squared order

The fluctuation term in Theorem 23.9 has a simple heuristic origin. The cutoff radius is $p(t) \asymp \log(1/t)$, and a fluctuation variable with a Gaussian-type tail exceeds it with probability of order $\exp(-c\log^2(1/t))$. At a fixed coarse side u this gives an upper bound of order $\exp(-c\log^2(1/\gamma))$. The next theorem shows that this order is correct for the supremum over the number of RG steps. For the lower bound we fix one RG step, so that the problem is finite dimensional, and we exhibit a set of configurations of controlled Haar measure and controlled action on which one normalized fluctuation variable lies just beyond its cutoff while all other conditions hold.

Theorem 23.12. *Use the small-field event and the parameters of Theorems 23.2 and 23.9. For each fixed $u \in 4\mathbb{N}$ with $u \geq n_0$ set*

$$E_u(\gamma) = \sup_{K \in \mathbb{N}_0} \mu_{uB^K,\gamma}\big(S^c_{uB^K,u,\gamma}\big).$$

There exist $c_u, C_u > 0$ and $0 < \gamma_u \leq \min\{\gamma_0, e^{-1}\}$, depending on u and the probability constants but not on γ or on the number of renormalization group steps, such that

$$e^{-C_u[1+\log(1/\gamma)]^2} \leq \mu_{uB,\gamma}\big(S^c_{uB,u,\gamma}\big) \leq E_u(\gamma) \leq e^{-c_u\log^2(1/\gamma)} \qquad (0 < \gamma \leq \gamma_u). \tag{23.21}$$

In particular, for fixed positive c, ε, and D, the bound $E_u(\gamma) \leq D\exp(-c\gamma^{-\varepsilon})$ does not hold for all sufficiently small $\gamma > 0$. No lower bound on $\limsup_{K\to\infty} \mu_{uB^K,\gamma}(S^c_{uB^K,u,\gamma})$ is asserted.

Proof. Upper bound. Let $x = \log(1/\gamma)$ and $\ell_u = (1/2)\log(Mu) > 0$. The first bound of Theorem 23.9, which is uniform in K, reads

$$E_u(\gamma) \leq C' u^3 e^{-\bar{c}ue^x} + C_{\mathrm{w}} u^3 e^{-a_{\mathrm{w}}(x/2+\ell_u)^2}.$$

For all sufficiently large x, the first term is at most $e^{-(a_{\mathrm{w}}/8)x^2}/2$, since $e^x/x^2 \to \infty$; the second term is also at most this quantity, since its exponent is a negative quadratic in x with leading coefficient $a_{\mathrm{w}}/4$. This proves the upper bound with, for example, $c_u = a_{\mathrm{w}}/8$, after decreasing γ_u.

A box in the coordinates of one RG step. Fix $K = 1$, $N = uB$, and preceding classical depth zero. For the rest of the proof this is a fixed finite-dimensional problem. We set

$$t = \sqrt{\gamma/(Mu)}, \quad p = p(t) = A_{\mathrm{w}}\log(1/t), \quad g_i = t\lambda_i, \quad \lambda_i = M^{(i-J+1)/2} \quad (0 \leq i < J).$$

The recursion of Theorem 12.13 is

$$z_i = z_i^*(c_{i+1}) + g_i S_i(c_{i+1}) w_i, \qquad c_i = b_i(c_{i+1}, z_i), \qquad c_J = c = e^\theta, \qquad S_i = K_i^{-1/2}.$$

We use it as a classical change of coordinates, before any fluctuation cutoff is imposed. This is valid beyond the region $\max|w| \leq p$: Lemma 12.3 gives product domains of fixed

positive radius for the coarse fields and the free coordinates, independent of g and p, and Theorems 12.13 and 13.2 give the composition of the J averaging steps on a common such domain, with the unscaled inputs $q_i = g_i w_i$. The conditional constrained minimizer at the identity is zero by Theorem 10.10, and the gauge transformation of Theorem 13.2 is the identity there. All intermediate Jacobian determinants are positive on a sufficiently small closed product domain.

Fix $0 < \epsilon < 1/4$ and one free link (i_*, e_*) of the step, with its three-dimensional fluctuation variable; such a link exists since $M \geq 3$ and $u \geq 4$. We identify the corresponding copy of $\mathfrak{su}(2)$ with $\mathbb{R}^3$ through the orthonormal basis of Section 4, and let e_1 be its first unit vector. We define the box $\mathcal{B}_\gamma$ of parameters by

$$\begin{gathered} |\theta_e| < \epsilon\sqrt{\gamma} \quad (e \in \mathcal{E}_u), \\ |w_{i,e}| < \epsilon \quad ((i,e) \neq (i_*, e_*)), \qquad |w_{i_*,e_*} - (p+1)e_1| < \epsilon. \end{gathered} \tag{23.22}$$

Each ball for a fluctuation variable has the same positive Lebesgue volume, independent of its center and of γ. The largest unscaled fluctuation input is at most $t(p+1+\epsilon) \to 0$, and $\|\theta\|_\infty \to 0$. Then the closure of the box lies inside the fixed larger coordinate domain, where no cutoff is imposed, for all sufficiently small γ. We do not assign a Gaussian law to fluctuation variables beyond the cutoff. Explicitly, one may take $\widetilde{p} = p + 2$ in Theorem 12.13: the box is contained in $\Omega^{\mathrm{all}}_{\widetilde{p}}$, while $C_J t\widetilde{p} < 1/2$ and $C_J(t\widetilde{p}^3 + t\widetilde{p})/(1 - C_J t\widetilde{p}) \to 0$. All hypotheses of that theorem on the coordinate domains and on the triangular Jacobian hold for this larger domain at small coupling. The radius $\widetilde{p}$ is used only to check the domain; the small-field event still uses exactly $p(t)$.

For the coordinate-domain conditions, we note that at small coupling the unscaled fluctuation inputs lie in the product domain of radius Q_{phys} of Definition 14.4 and Theorem 13.2, and the coarse field is closer to the identity than r. The reconstruction then has all input logarithms smaller than $r/2$, with the intermediate margins for the classical action, the constraint coordinates, and the Jacobians. Then $c_0 \in D_r$, $c \in D_r$, and $\mathcal{A}_{0,J}$ holds, and the averaged field is $T^J_M c_0 = c$. By the uniqueness and the identities on overlapping charts in Theorem 14.3 and Definition 14.4, the constructed w_i are the normalized fluctuation variables defined by the inverse coordinates, up to their norm-preserving triangular orthogonal changes. Let $\mathcal{D}_\gamma \subset \mathcal{U}_N$ be the set of configurations obtained from the configurations with coordinates in $\mathcal{B}_\gamma$ by all gauge transformations of the block axial gauge that equal the identity at the prescribed tree roots, that is, the union over the tree gauge variables of the images of $\mathcal{B}_\gamma$. Every configuration in $\mathcal{D}_\gamma$ fails the small-field event, since

$$|w_{i_*,e_*}| > p + 1 - \epsilon > p,$$

while it satisfies all other conditions of the step. In particular, $\mathcal{D}_\gamma$ is a subset of the complement of the small-field event itself.

Haar measure of the box. By repeated use of Lemma 6.3, followed by the triangular substitution from free coordinates to normalized fluctuation variables, we obtain the exact formula

$$H_N(\mathcal{D}_\gamma) = \int_{\mathcal{B}_\gamma} dH_u(c)\, dw \prod_{i=0}^{J-1} \big[\mathcal{J}_i(c_{i+1}, z_i)\, g_i^{D_i} \det S_i(c_{i+1})\big], \qquad D_i = 6(M^3-1)(uM^{J-i-1})^3. \tag{23.23}$$

The integral is over the Haar box of coarse fields and the balls of fluctuation variables; the tree gauge variables of $\mathcal{D}_\gamma$ are integrated out with Haar probability mass one. The determinant identity is that of Theorem 12.13, and its off-diagonal dependence on the coarser fluctuation variables is kept. The formula is a change of variables on the open coordinate domain, and its restriction to the box needs no indicator of the cutoff product; equivalently, it follows from successive Haar disintegration formulas for single averaging steps and Fubini's theorem for the nonnegative integrand. There is no additional density for the logarithm of the coarse field, no Gram determinant, and no gauge multiplicity. Here D_i is the number of real free coordinates of the i-th averaging step: besides the eliminated edges there are $3(M^3-1)(uM^{J-i-1})^3$ fine links, with three real coordinates each, and the gauge transformations equal to the identity at the tree roots remove $3(M^3-1)(uM^{J-i-1})^3$ of these coordinates.

On the fixed small closed product domain, all $\mathcal{J}_i$ and $\det S_i$ are continuous and strictly positive, by Lemmas 6.3 and 12.3. Their finite product has a positive lower bound depending on u and the fixed chart, but not on γ. Since $g_i = \sqrt{\gamma}\,(Mu)^{-1/2}\lambda_i$, and the box of coarse fields is a product over the $|\mathcal{E}_u| = 3u^3$ links, Lemma 5.1 and (23.23) imply

$$H_N(\mathcal{D}_\gamma) \geq c(u)\gamma^{\kappa_u}, \qquad \kappa_u = \frac{9u^3 + \sum_{i=0}^{J-1} D_i}{2} > 0, \tag{23.24}$$

where $\sum_i D_i = 6[(uB)^3 - u^3]$. This lower bound keeps the Haar densities and all powers of the couplings from the Jacobians.

The Wilson action on the box. By the majorant of Theorem 13.2, or its finite-dimensional derivative bound on the same smaller product, we have, in the gauge representative of that theorem,

$$\max_e |\operatorname{Log} c_{0,e}| \leq C_u\{\epsilon\sqrt{\gamma} + t(p+1+\epsilon)\} \leq C_u'\sqrt{\gamma}\,(1+p).$$

For each plaquette, the triangle inequality for the group distance in Lemma 5.1 bounds its distance from the identity by four times this quantity, and by the same lemma we have $q \leq \rho_G^2/8$. There are $3N^3$ plaquettes, so for a fixed finite A_u,

$$\frac{4N}{\gamma} \sum_P q((c_0)_P) \leq A_u(1+p)^2 \qquad (c_0 \in \mathcal{D}_\gamma).$$

By gauge invariance, the same bound holds on all of $\mathcal{D}_\gamma$. The partition function of the Wilson measure satisfies $Z_{N,\gamma} \le 1$, by Lemma 5.1. Combining these bounds, we obtain

$$\mu_{uB,\gamma}\big(S^c_{uB,u,\gamma}\big) \ge \mu_{uB,\gamma}(\mathcal{D}_\gamma) \ge c(u)\gamma^{\kappa_u}\exp\{-A_u(1+p)^2\}.$$

Finally, $p = (A_{\mathrm{w}}/2)[x + \log(Mu)]$ for $x = \log(1/\gamma) \ge 1$. Then $1 + p \le C''_u(1+x)$ and $\kappa_u x + |\log c(u)| \le C'''_u(1+x)^2$. After increasing C_u and decreasing γ_u to include every threshold of the finite chart and of the upper bound, this is the lower bound in (23.21). Since $e^{\varepsilon x}/(1+x)^2 \to \infty$, comparing logarithms excludes the bound $D\exp(-c\gamma^{-\varepsilon})$. □

Corollary 23.13. *Use the parameters of Theorem 23.5. For each fixed $u \in 4\mathbb{N}$ with $u \ge n_\Gamma$ there exist $c_{u,\Gamma}, C_{u,\Gamma} > 0$ and $0 < \gamma_{u,\Gamma} \le \min\{\Gamma, e^{-1}\}$ such that*

$$\begin{aligned} e^{-C_{u,\Gamma}[1+\log(1/\gamma)]^2} &\le \mu_{uB,\gamma}\big(S^c_{uB,u,\gamma}\big) \le \sup_{K\ge 0}\mu_{uB^K,\gamma}\big(S^c_{uB^K,u,\gamma}\big) \\ &\le e^{-c_{u,\Gamma}\log^2(1/\gamma)} \qquad (0 < \gamma \le \gamma_{u,\Gamma}). \end{aligned}$$

No lower bound is asserted for $\limsup_{K\to\infty}\mu_{uB^K,\gamma}(S^c_{uB^K,u,\gamma})$.

Proof. The upper bound follows from (23.13) exactly as in the proof of Theorem 23.12: with $x = \log(1/\gamma)$, the curvature term decays like e^{-ce^x}, while the fluctuation term has an exponent that is a negative quadratic in x with leading coefficient $a_{\mathrm{w}}/4$. After decreasing $\gamma_{u,\Gamma}$, the sum is at most $e^{-(a_{\mathrm{w}}/8)x^2}$.

For the lower bound we keep u and J fixed and use the coordinates of one RG step as in the proof of Theorem 23.12. Their coordinate domains, the classical change of coordinates, the Jacobians, and the cutoff of the small-field event are the same for the parameters of Theorem 23.5, since that theorem enlarges only the probability constants and the minimum side. On the box $|\theta_e| < \epsilon\sqrt{\gamma}$ of coarse fields, we place all fluctuation variables in balls of radius $\epsilon < 1/4$, except one, whose ball is centered at $(p(t)+1)e_1$, where $t^2 = \gamma/(Mu)$. Since $t(p(t)+2) \to 0$, all unscaled inputs and all Jacobian determinants lie in the same fixed domain without cutoff for sufficiently small γ. Every such point satisfies the other conditions and fails the cutoff. The exact formula (23.23) bounds the Haar measure of the corresponding set of configurations below by $c(u,\Gamma)\gamma^{\kappa_u}$, with $\kappa_u = (9u^3 + \sum_i D_i)/2$ and $D_i = 6(M^3-1)(uM^{J-i-1})^3$. The Wilson exponent on this set is at most $A(u,\Gamma)(1+p(t))^2$, and the partition function is at most one. The probability of the complement is then at least $c\gamma^{\kappa_u}e^{-A(1+p(t))^2}$. Since $p(t) = A_{\mathrm{w}}[x+\log(Mu)]/2$, we obtain the claimed lower bound. All domains and constants are fixed before γ; the restriction $\gamma \le \Gamma$ is obtained by decreasing $\gamma_{u,\Gamma}$ only. □

23.6 Proof of the choice of parameters

In this subsection we prove Theorem 23.2, verifying the choices in the order of the items and using each earlier estimate on its domains and with the quantifiers of its statement.

No probability estimate is used. Steps 1–7 make the choices of items (1)–(8), Steps 8 and 9 verify the hypotheses of the cited results without new choices, Steps 10 and 11 make the choices of items (9) and (10), and Step 12 fixes the reconstruction maps and proves the identity of the coarse fields with the iterates of T_M.

We fix $A_{\mathrm{w}} \geq 1$ in the range allowed by Theorem 20.14 at the start. This precedes every use of the existence of a coupling bound in that theorem. Its constants and the J-uniform conditions do not depend on A_{w}; the coupling bound g_* may depend on it.

Step 1: the choice of J. We apply Theorem 13.2 at the fixed odd M, and denote its J-uniform spatial exponent by b_* and its majorant for the conditional constrained minimizers at zero fluctuation by $Z(v) \leq Cv/(1-Cv)$. First we fix a rate $0 < b_{\mathbb{T}} < b_*$ below the remaining margin of the classical and image estimates. Next we fix a finite scale $\mathscr{L}_{\mathbb{T}}$ for boxes covering supports, and its support-counting factor, as in Theorem 13.5, so that the entropy of supports is compensated by the rate $b_{\mathbb{T}}$. At this stage we enlarge the entropy and support constants to cover the margin for the free degrees of freedom in Theorem 20.9. Only after fixing these boxes do we choose the rate $a_{\mathbb{T}} \in (0, b_{\mathbb{T}})$, with $a_{\mathbb{T}} < a_{\mathrm{cen}}/8$ and small enough for the network bound below. Here a_{cen} is the J-uniform rate of the bounds of Lemma 11.9; for the aligned representative, Theorem 11.10 gives the contraction at every output rate below $a_{\mathrm{cen}}/8$ and at no larger rate, so this restriction is necessary. It also gives $a_{\mathbb{T}} < a_*/8$ for the rate a_* of Theorem 10.11, as observed in Theorem 13.5. These choices precede J, and decreasing $a_{\mathbb{T}}$ does not change the boxes.

We check the support condition of the conversion from supported coefficient bounds to coefficient norms at the same analytic radius in Theorem 13.5. A connected set Y of boxes joins the coefficient locations of the background in its boxes by a network of length at most $C_{\mathscr{L}_{\mathbb{T}}}|Y|$, with $C_{\mathscr{L}_{\mathbb{T}}}$ independent of J. Indeed, we connect the centers of adjacent boxes along a spanning tree of Y, and connect the finitely many locations in each box by the coordinate grid inside that box. The same construction covers a connected union of intersecting boxes, and shortest periodic connections give the same bound in directions that wrap around the torus. The bound also covers the supports of the logarithms in the cluster expansion and the larger output radius. Repeated locations add no length. There are only nine types of orientation and color at a site, and the density of free variables does not change this count. With this $C_{\mathscr{L}_{\mathbb{T}}}$ we take $a_{\mathbb{T}} C_{\mathscr{L}_{\mathbb{T}}} \leq 2$, so that $a_{\mathbb{T}} \mathrm{t} \leq 2|Y|$ for every support used in the conversion. The effective interaction and its output as a whole, rather than the individual polymer activities, have the translation symmetry required by the conversion, and their color and inversion identities are those kept by Theorem 13.5.

Let $C^{\mathbb{T}}_{\mathrm{geom}}$ be the network comparison constant of that theorem. We include the conditions

$$C^{\mathbb{T}}_{\mathrm{geom}} b_{\mathbb{T}}/B \leq a_{\mathbb{T}}, \qquad C_{\mathrm{cen}}/B < 1/8 \tag{23.25}$$

in the choice of J. The first compensates the conversion from the trees on the finer lattice to the trees on the coarse lattice, while keeping the rate $a_{\mathbb{T}}$ on the torus; it is separate from the smaller regional rates of item (3). By part (3) of Theorem 15.12, one enlarged constant $C_{\mathrm{CP}} \geq 1$ bounds the value, the first spatial differences, and the first three coarse-field derivatives of the zero-fluctuation reconstruction, with all row sums and all volume-normalized column sums, uniformly before J is chosen; the enlargement includes the prescribed reconstruction tolerances. Derivatives with respect to the fluctuation inputs use the fixed-J joint bounds of Lemma 15.15, not this uniformity. The same results provide the signed conservation identities for the volume-normalized derivative kernels and the full bound at fixed J. The series Z of Lemma 11.9 and its spatial rate are J-uniform, as are these finite derivative bounds and the geometric constants. Neither the full joint norm nor the full norm of the gauge transformations of the reconstruction maps is J-uniform. We enlarge the J-uniform constant C_{alloc} of Theorem 20.9, which controls the distribution of the spatial decay rates, so that it also covers the corresponding geometric constant in Theorem 19.9, choose $C_*^{\mathrm{geom}} \geq \max(1, C_g)$, and keep $B_{\mathrm{geom}} = 256 C_{\mathrm{alloc}}(C_*^{\mathrm{geom}} + 1)$ from Theorem 20.9. All lower bounds on M^J in item (1) now have fixed finite right sides, and they hold simultaneously for large J, since $M^J \to \infty$.

It remains to separate the linear conditions that choose J from the later choice of radii. For existence we may take $\rho_{\mathrm{cl}} = \rho$, but we keep the subscript $\bullet$ to check both functions. The same classical map evaluates both the effective interaction and the effective classical action, and the series Z provides both Z_{q} and Z_{cl}; fixed different ratios of radii would only require the two restrictions of the same series. We choose a J-uniform bound ρ_0 with $4K_* C\rho_0 \leq 1/2$. With $Z_\bullet(v) \leq C_\bullet v/(1 - C_\bullet v)$, the conditions

$$C_\bullet K_*/B < 1/32, \qquad C_\bullet K_* \rho_\bullet \leq 1/2$$

give $B^{-1} Z_\bullet(K_* \rho_\bullet) < \rho_\bullet/16$, and at the enlarged radii, uniformly for $0 < \rho_\bullet \leq \rho_0$,

$$B^{-1} Z_\bullet(4K_* \rho_\bullet) \leq (8 C_\bullet K_*/B)\rho_\bullet < \rho_\bullet/4. \tag{23.26}$$

Only the first condition chooses J; the second is an upper bound on a later radius. Together with $q_{\mathrm{CA}} < 1/4$, the threshold $M^{-J} \leq \delta_0(a_{\mathbb{T}})$ of Theorem 11.10, and (23.25), these are the J-uniform conditions of Theorem 13.5, whose contraction constant $C_P(a_{\mathbb{T}})$ is uniform over the later radii $0 < \rho \leq \rho_0$. Since $a_{\mathbb{T}}$ is fixed before J and depends only on J-uniform data, these conditions are lower bounds on B with fixed right sides. The finitely many additional conditions on classical first derivatives use the same J-uniform series and C_{CP}, and we impose them with strict inequality in the same choice. No constant at fixed J, no radius for free coordinates, and no constant of the effective-interaction estimates has entered; no later step changes J.

Step 2: larger domains, solution neighborhoods, and rates. At this J, all entries in the minima defining $v_{\mathrm{free},J}$ and R_{raw} in Lemma 19.7 are positive and depend only on

the larger construction data, and we choose each radius strictly below its minimum. For each of the finitely many initial segments of conditional integrations, we choose by Lemma 19.3 a neighborhood of the conditional constrained minimizer and then a smaller domain for the later parameters. At zero perturbation we choose, with a positive margin, a smaller product domain for the free coordinates whose successive substitutions stay inside all the previously chosen domains; the condition with a perturbation is checked at every value of the later parameters in Step 3. Taking the minimum of the finitely many margins at zero perturbation preserves them. In particular, the conditional displacement bound and the bound on the preconditioned Hessian hold on these products, and a slice of a larger joint solution domain is never used in their place. The real lower bound for the constrained Hessian and the complex domain of its inverse in the two cited lemmas apply on the resulting product domains.

We choose the inner, middle, and outer domains of the reconstruction maps strictly inside these construction domains; Theorem 15.12 provides its bounds on these domains independently of the later support and working radii. We choose $\rho, \rho_{\mathrm{cl}} > 0$ inside them, small enough that the first summand in the inequality of item (3) is below $R_{\mathrm{raw}}/64$ and that both denominators of the torus images are positive. All coefficient sums used here can be bounded on the larger domains before the radii are restricted, since a restriction can only decrease a sum of absolute coefficients; this is the convention of Lemma 19.7. We also impose the hypotheses of Theorems 13.2 and 13.5 on the larger product. With r_J and C_J fixed on that product, we choose

$$\begin{aligned} 0 < \rho \le \min\{\rho_0, r_J/(16K_*)\}, \qquad & 4K_*C_J\rho < 1/4, \\ 0 < s_J < \min\{r_J/(16K_*), 1/(16K_*C_J), \rho/(64K_*C_J)\}. & \end{aligned} \tag{23.27}$$

These restrictions are compatible with the bounds on the coordinate and reconstruction domains just chosen. We have $4K_*(\rho + s_J) < r_J$ and $1 - 4K_*C_J(\rho + s_J) > 1/2$. Then the majorant of the free part is at most $8K_*C_J s_J < \rho/8$. Together with (23.26), the enlarged image is strictly below $3\rho/8 < \rho/2$. All intermediate margins for the classical action and for the constraint Jacobians are the strict margins of Theorem 13.2, since we work on a restriction of its product. We keep this larger product after r is fixed.

The two majorants for the input functions used here concern the torus map of Theorem 13.2. We do not assert a J-uniform bound of all orders for the gauge transformations of the reconstruction maps. The full bound at fixed J and the strict image margins of Theorem 15.12 apply on nested subproducts of the same domains, and their limiting maps and later refinements of thresholds preserve these margins. The only constants of the reconstruction maps used before J were the finitely many coarse-field derivative bounds at zero fluctuation.

Theorem 13.5 now provides finite constants $C_G, C_T > 0$, and the constant $c_* > 0$ for its auxiliary discs (not to be confused with the exponent $c_* = \min\{a_b, d_*/8\}$ of the

probability bounds), on the fixed data $(M, J, \rho, a_{\mathbb{T}}, b_{\mathbb{T}}, K_*, s_J)$. They do not depend on the side, the preceding depth, or the later support radius. We fix E^{cl} and take a finite $E \geq 2C_G/(1 - q_{\mathrm{CA}})$; the denominator is positive by item (1). We verify the invariance of this bound under the recursion in Step 8, after the coupling bound has been chosen; it is not assumed as a hypothesis of a regional estimate. For example, the radius $q_{\mathrm{raw}} > 0$ and the later r and β_{rec} can each be taken at most $R_{\mathrm{raw}}/(64C_{\mathrm{lift},J})$; then the sum in item (3) is strictly below $R_{\mathrm{raw}}/8$.

The interpolation of Lemma 19.7 provides a positive bound on the spatial rate of the unperturbed coefficients on these larger products, and we include it in $c_{\mathrm{prim},J}$ after the conversion of Section 20.1 to the graph metric. Its finite bound for sums with the remaining exponent can be written as $C_J\rho_\bullet$: we divide a common bound on the larger product by the smaller of the two positive radii and enlarge C_J to at least one. The bound is uniform over the later restrictions, which stay inside the larger product. For its remaining exponent $c > 0$ we choose $0 < \vartheta < 1$ with

$$\vartheta \max\{1, \log(8C_J/3)\} < \frac{1}{2}\log(4/3), \tag{23.28}$$

and take the minimum of the resulting positive exponents over the two radii and the finitely many initial segments. By Lemma 19.7, the bounds on the larger product are uniform in the later smaller radii and widths, so this choice precedes the choice of r.

We now set $\alpha = a/16$, $m_{\mathrm{rate}} = C_*^{\mathrm{geom}}(a + \alpha)$, and $b_1 = 8C_*^{\mathrm{geom}}\alpha$. Then $m_{\mathrm{rate}} + b_1 = (25/16)C_*^{\mathrm{geom}}a$, and the inequalities of item (3) containing Ba and $B\alpha$ reduce to

$$\frac{25}{16}C_*^{\mathrm{geom}} < B/C_{\mathrm{alloc}}, \qquad 8C_*^{\mathrm{geom}} < B/C_{\mathrm{alloc}},$$

which follow from $B \geq B_{\mathrm{geom}}$. We decrease $a > 0$ further so that $\sqrt{3}\,(a + \alpha) < a_{\mathbb{T}}$ and the conditions involving $c_{\mathrm{prim},J}$ and the unperturbed image exponent hold, including $m_{\mathrm{rate}} < \vartheta c$ for every radius and initial segment. The cluster expansion with exact supports imposes no further restriction on lengths. The rate $a_{\mathbb{T}}$ and J are unchanged.

Step 3: perturbation bounds, the fluctuation radius, and the final perturbation bound. We choose a positive preliminary bound σ_0 for perturbations that are real on real arguments, inside the margins for the force, for the lower bound of the constrained Hessian, and for the domain of its complex inverse in Lemma 19.3 and Theorem 19.9. Here and in every later application, the incoming classical norm is taken on the incoming list D_{in} of active labels, with the lattices where its coefficient locations were introduced and the volumes of its variables, at the uniform radius ρ_{cl}. The spatially varying radii are output radii. In Step 9 we verify, using the coverage by large-field decompositions and the substitution of frozen coordinates, that these are the incoming radii and compatible complements after any number of RG steps.

The perturbation must be controlled at every value of the later parameters, not only at the joint constrained minimizer. Let $\varepsilon_{\mathrm{tube}} > 0$ be the minimum of the margins of the unperturbed solution and parameter domains, and let I_0 and $C^{\mathrm{force}}_{P,J}$ be the constants on the larger product for the inverse and for the conditional force in Theorem 19.9; here V_I is the z_I-derivative, in the original free coordinates, of the function V in (21.12). The estimate of that theorem, uniform over all $y \in \mathcal{T}_I$, gives

$$\begin{gathered}\delta_V = \max_I \sup_{y\in\mathcal{T}_I} \|A_I^{-1} V_I(c, a_I(c,y;\xi), y)\|_{\mathrm{coeff}} \le I_0 C^{\mathrm{force}}_{P,J} \sigma_0 \rho_{\mathrm{cl}}, \\ C_{\mathrm{seq},J}(2\delta_V + r_{q,P}) < \varepsilon_{\mathrm{tube}}/2.\end{gathered} \tag{23.29}$$

To obtain the last strict inequality, we first decrease σ_0 so that $2C_{\mathrm{seq},J} I_0 C^{\mathrm{force}}_{P,J} \sigma_0 \rho_{\mathrm{cl}} < \varepsilon_{\mathrm{tube}}/8$ and $I_0 C^{\mathrm{force}}_{P,J} \sigma_0 \rho_{\mathrm{cl}} < \min_I r_I/4$. Then we choose $0 < r_{q,P} < \varepsilon_{\mathrm{tube}}/(8C_{\mathrm{seq},J})$ inside the fixed margin of the joint solution domain; the sum is then even less than $\varepsilon_{\mathrm{tube}}/4$. We decrease σ_0 also for the bound $1/2$ on the error of the preconditioned Hessian, for half of the real lower bound of the constrained Hessian, and for the domain of its complex inverse; these are the coefficient bounds of Theorem 19.9 on the same larger product. Its contraction at fixed parameters bounds every conditional displacement by $2\delta_V$, and the sequential conclusion of Lemma 19.3 applies at all such y with a margin of a factor two. In particular, the chain of conditional constrained minimizers at zero fluctuation satisfies the coordinate-domain conditions before the fluctuation radius is chosen. A smaller final σ_* preserves all these conditions.

All derivatives here are taken in the active background variables and the free coordinates, at fixed real frozen data $b = (\xi, b_{\mathrm{rec}})$. The incoming coefficients and charts are Borel functions of b. At the initial step, the input consists of finite products of link variables and the analytic charts of the classical action; at a step starting from a stopped measure, it is the effective interaction, which is invariant on overlapping charts; and each later input is obtained by substitution, finite products, and convergent operations on coefficients. Integration over a fixed compact product of fluctuation balls preserves Borel dependence on b. Indeed, after rescaling the balls to unit balls the measure is a fixed finite measure, and the integral of a nonnegative jointly Borel function against a fixed finite measure is a Borel function of the parameters; this is the monotone class argument given in the proof of Theorem 21.9. Then the uniformly convergent Picard iterations in Theorem 19.9 preserve Borel dependence on b. No derivative in a frozen real parameter is needed.

On these larger fixed products, Lemma 20.3 and Theorems 20.14 and 21.8 provide finite constants for the output, sequential, image, potential, and mean estimates, and for the estimates of the support of the normalized fluctuation variables, uniformly for the doubled classical bound $2\sigma_0$. Their dependence, described in item (3) of Definition 4.14, excludes all later widths and all values of frozen coordinates. We use these bounds, rather than bounds computed on the eventual small cutoff domain. The threshold $\epsilon_{\mathrm{en},J}$ and

the constant $C_{\mathrm{en},J}$ of Theorem 21.8 are fixed at this stage as well; the threshold already contains the smallness $C_J(r+\beta_{\mathrm{rec}}) \le \epsilon_{M,J}$ that its proof needs for the Hessian bound (18.45) of Lemma 18.14, at the small representative, before the orthogonal transport to the representatives used in the descent. The radius of the auxiliary box in that proof is chosen there. The constant $C_{\mathrm{en},J}$ is a bound for every covered large-field decomposition; its conclusion for every point is applied only after the coverage is established in Step 9.

We fix all geometric constants at this stage. Let C, C', R_0, c be the constants of Theorem 21.3. We take $A_8 \ge R_0 + 1$ so large that $C'/A_8 < 1/4$, and enlarge it for the fixed mesh at the initial step and the fixed margins for path lengths. This is a lower bound independent of r and β_{rec}. Let $C_B \ge (10M)^J$ cover the lengths of all tree and transport paths within one RG step, and set

$$K_B = 2 + C_B(A_8 + 1), \qquad C_{\mathrm{col}} = CK_B^{10}/A_8. \tag{23.30}$$

Every small frozen coordinate created at the first step after a stopped measure is a product of a fixed number of current small links and of their at most J iterates under T_M. By repeated use of the triangle inequality for the group distance and the factor $10M$ per averaging step, it is bounded by $C_{\mathrm{ad},J} r$, where $C_{\mathrm{ad},J}$ depends only on these fixed products. The frozen coordinates at the protected initial step satisfy the same bound. Older long transports are frozen group variables, not new small analytic coordinates. Let $C_{\mathrm{an},J} \ge 1$ bound all fixed conversions from group or transported coordinates to the analytic coordinates at the lattice where a frozen coordinate was introduced. For a link variable in the identity chart this constant is one, since $|\mathrm{Log}\, U| = \rho_G(U)$; a fixed longer product is bounded by its fixed length and its analytic derivative bound. We fix $C_{\mathrm{conv},J}$ large enough for these conversions, including

$$C_{\mathrm{conv},J} \ge C_{\mathrm{ad},J}, \qquad C_{\mathrm{conv},J} > 2C_{\mathrm{an},J}C_{\mathrm{col}}, \qquad C_{\mathrm{conv},J} > C_{\mathrm{an},J}C_{\mathrm{ad},J},$$

and enlarge it for the fixed transport paths and the protected frozen coordinates of Theorem 21.5. We fix the mesh multiplier $C_{\mathrm{mesh},J}$ of the initial step and the interior restriction by the full dependence radius at the same stage. None of these constants depends on a later width.

Every entry in the minimum defining R_W in Lemma 20.3 is positive at this J. We choose R_W strictly below this minimum, including the conversion to the joint solution neighborhood and both product domains. Include in $C_{P,\bullet}$ the larger-product absolute coefficient row constant for the difference of the perturbed and unperturbed reconstructions at output rates (m_{rate}, b_1) in Theorem 19.9. These rates satisfy its conditions by item (3), since C_{alloc} includes its geometric constant. Then we fix $\sigma_* > 0$ below σ_0, below all preconditioned displacement margins, and below

$$\frac{\lambda_* R_W}{6C_{\mathrm{en},J}\rho_{\mathrm{cl}}}, \qquad \min_{\bullet} \frac{\rho_\bullet}{64C_{P,\bullet}\rho_{\mathrm{cl}}}.$$

If a constant vanishes, the corresponding upper bound is not needed. Only fixed positive upper bounds occur. In particular, the perturbation term in the radius R_{en} of the enclosing product domain is accounted for before the removed layer is chosen.

Step 4: boundary radii, removed layers, and frozen coordinates. We choose each outer boundary radius so that its contribution is at most $\rho_\bullet/16$, and set $\rho_{\partial,\bullet} = R_{\partial,\bullet}/K_*$. Since $a_{W,\bullet} > 0$, a finite common width w_{bd} makes each contribution from distant parts of the boundary at most $\rho_\bullet/16$. The torus contribution was made smaller than this in Step 1. Once β_{rec} is chosen below with $C_{F,\bullet}\beta_{\mathrm{rec}} < \rho_\bullet/64$, and since $C_{P,\bullet}\sigma_*\rho_{\mathrm{cl}} < \rho_\bullet/64$ by Step 3, the sum at zero fluctuation satisfies

$$A_{0,\bullet} < \Big(\frac{1}{16} + \frac{1}{16} + \frac{1}{16} + \frac{1}{64} + \frac{1}{64}\Big)\rho_\bullet = \frac{7}{32}\rho_\bullet < \rho_\bullet/4. \tag{23.31}$$

The individual bounds give the full sum condition of item (5), with every summand counted.

The brackets in the two inequalities for s_{er} are fixed finite numbers. For example, if $Y = A_J(1+E) + K_J\sigma_* + 1$, then $s_{\mathrm{er}} \geq 1 + \alpha^{-1}\log(4Y/\sigma_*)$ suffices for the first inequality, and the same calculation with $Y^{\mathrm{cl}} = A_J^{\mathrm{cl}} + K_J^{\mathrm{cl}}\sigma_*$ yields the second. We take an integer above these bounds and above $\max(2, w_{\mathrm{bd}})$. If a bracket vanishes, its inequality holds already.

We now choose $\beta_{\mathrm{rec}} > 0$ below the minimum of the coordinate-domain, product, and boundary radii and of the bound $\lambda_* R_W/(6C_{\mathrm{en},J})$ used for the radius of the enclosing product domain. On every label with reduced radius, β_{rec} below one quarter of the corresponding inner boundary radius makes the frozen fraction at most $1/4$. The bound for the boundary-completion difference in Lemma 18.9 is $8\beta_{\mathrm{rec}}E_\bullet/\rho_\bullet$ at uniform radius; the fixed conversion to the spatially varying radius changes only its constant on the larger domain. This is part (2) of that lemma. Its hypothesis on the torus rate holds for both functions, since their torus norms have the rate $a_{\mathbb{T}}$ and $\sqrt{3}\,(a+\alpha) < a_{\mathbb{T}}$ by item (3). We fix a constant $C_{\mathrm{bc},\bullet} \geq 8$ for the simultaneous substitution of all frozen coordinates and every required conversion, including the boundary layer, the neighborhoods where gauge transformations are extended at the lattices of introduction, the based transports of frozen links across the boundary, and the initial step. If these substitutions are made in several fixed stages, we take the sum of their converted bounds in this constant. The number of frozen labels, of components, and of earlier RG steps does not enter, since the estimate of Lemma 18.9 already bounds the union. We require

$$C_{\mathrm{bc},\bullet}E_\bullet\beta_{\mathrm{rec}}/\rho_\bullet \leq \sigma_*/8, \qquad \beta_{\mathrm{rec}} < \frac{1}{4}\min\{\rho_\bullet, \rho_{\partial,\bullet}\} \quad (\bullet \in \{\mathrm{q}, \mathrm{cl}\}). \tag{23.32}$$

Then the sum of these differences is below the bound $\sigma_*/4$ required in item (5). We also require $\beta_{\mathrm{rec}} < \min(\pi/4, \epsilon_{\mathrm{en},J}/4)$, where $\epsilon_{\mathrm{en},J}$ is the fixed margin of Theorem 21.8. The geometric argument of Step 6 provides these bounds in the analytic coordinates at the

lattice of introduction. We include the bound for frozen coordinates used in (23.31). All these choices are compatible, since each is an upper bound with a fixed positive right side.

For a large-field decomposition with the hypotheses on incoming radii and boundaries verified in Step 9, these conditions preserve the initial norm bound. If the input norm is at most σ_*, the last nonlinear term in Theorem 20.14 is at most one after the coupling bound is chosen in Step 7. Then its output is bounded by Y, and its output after removal of the layer of width s_{er} is bounded by $\sigma_*/2$. Adding the boundary-completion difference, we obtain at most $3\sigma_*/4$. The classical calculation uses Y^{cl} and gives the same bound $3\sigma_*/4$. The initial norm is at most σ_* once the initial substitution has been checked. Step 9 provides this initialization and the input hypotheses at every step, so no errors are summed over earlier RG steps.

Step 5: the majorant of the reconstruction maps, the working radius, and the support radius. The coefficient constants of Lemma 15.15 were computed on the fixed larger domains. Recall that $\alpha_* = C_{\mathrm{CP}}/B$. Since $B \geq 3$ and $C_{\mathrm{CP}}^2/B \leq 1/4$, we have $0 < \alpha_* \leq 1/(2\sqrt{B}) < 1$. For the coefficients in that lemma, the choice of β_J gives, for every $m \geq 2$,

$$\alpha_* \beta_J^{m-1} \geq \alpha_* \frac{A_J}{\alpha_* R_J^2} R_J^{-(m-2)} = A_J R_J^{-m},$$

where we used $\beta_J \geq A_J/(\alpha_* R_J^2)$ and $\beta_J \geq R_J^{-1}$. The linear term is also bounded by α_*. This proves the majorant φ in (23.4) and its derivative bound at every fixed input, in the volume normalization of that lemma. We choose $r_{\mathrm{eff}} > 0$ inside the domains of item (3) and below $(1-\alpha_*)/(8\beta_J)$. Then $\beta_J r_{\mathrm{eff}} < 1/8$, and we have

$$\sup_{|v| \leq r_{\mathrm{eff}}} \|D\widehat{P}(v)\|_{\mathrm{root}} \leq \varphi'(r_{\mathrm{eff}}) = \frac{\alpha_*}{(1-\beta_J r_{\mathrm{eff}})^2} \leq \frac{64}{49}\alpha_*, \qquad a_{\mathrm{map}}\sqrt{B} \leq \frac{32}{49}. \tag{23.33}$$

We choose r below all positive bounds displayed in item (6), including the bound from path lengths, the bound from frozen coordinates, and $r_{\mathrm{eff}}/4$. Further upper bounds used for the protected neighborhoods below are imposed in the same choice. We include $r < \min(1, \epsilon_{\mathrm{en},J}/4)$ and

$$K_B^2 r/A_8 < c, \qquad C_{\mathrm{an},J} C_{\mathrm{col}} r < \beta_{\mathrm{rec}}/2, \qquad C_{\mathrm{ad},J} r < \beta_{\mathrm{rec}}, \tag{23.34}$$

which hold after decreasing r, since all constants in (23.30) are fixed. In particular, $\beta_{\mathrm{rec}} > C_{\mathrm{conv},J} r$. With $R_{\mathrm{buf}} = C_{\mathrm{map},J} r$ and a fixed $C_{\mathrm{map},J} \geq (10M)^J$, the requirement $R_{\mathrm{buf}} < \rho$ and the margins of the larger charts are again upper bounds on r. No lower bound on r occurs.

We also choose the radii P and Q_{DB} explicitly. On a fixed smaller joint product, the bound of Lemma 15.15 provides a finite $C_{\mathrm{free},J} \geq 1$ such that the free increment of the reconstruction is at most $C_{\mathrm{free},J} \max_i |\zeta_i|$. For $|v| \leq r$ we have

$$|\widehat{P}(v)| \leq \frac{\alpha_* r}{1 - \beta_J r} \leq \frac{32}{31} \cdot \frac{r}{2\sqrt{B}} < \frac{r}{3},$$

where we used $\beta_J r < 1/32$ and, in the last inequality, $B \geq 3$. For the torus map of Theorem 13.2 we also take $Cr < 1/2$ and $r < \min(r_J/4, 1/(4C_J))$; by the J-uniform condition we have $B^{-1}Z(r) \leq 2Cr/B < r/3$. We choose

$$0 < Q_{\mathrm{DB}} = q_{\mathrm{DB},J} r, \qquad q_{\mathrm{DB},J} \leq \min\{1/2, 1/(12C_{\mathrm{free},J}), 1/(24C_J)\}. \tag{23.35}$$

Then $r + Q_{\mathrm{DB}} < r_J$ and $1 - C_J(r + Q_{\mathrm{DB}}) > 1/2$. The majorant of the free part of the torus map is then below $2C_J Q_{\mathrm{DB}} \leq r/12$, and the hypotheses of Theorem 13.2 for coarse fields in B_r hold, including the domain before the pole of its majorant and $\mathfrak{M}_J(r, Q_{\mathrm{DB}}) < r/2$. The same Q_{DB} works for the free part of the reconstruction maps, since $C_{\mathrm{free},J} Q_{\mathrm{DB}} \leq r/12$. We take $P = Q_{\mathrm{DB}}/2$, decreasing the fixed proportionality factor if necessary so that every intermediate coordinate-domain condition holds. Then every input logarithm is smaller than $r/3 + r/12 < r/2$. At zero coarse field and zero fluctuation all these intermediate maps vanish, and their finite coefficient bounds at fixed J and the positive margins of the coordinate and product domains justify this simultaneous decrease. It is made when r is chosen, before the coupling. The enclosing constant $\mathscr{L}_{\mathrm{en}}$ of Definition 14.4 can be bounded on the larger fixed domains, and taking r smaller first makes the part of its curvature bound without the coupling strictly less than $1/2$, as required in item (6). The remaining term $t^2(1 + E)$ is controlled in Step 7.

The three contributions to the radius of the enclosing product domain give

$$r + \beta_{\mathrm{rec}} + \sigma_* \rho_{\mathrm{cl}} \leq \frac{\lambda_* R_W}{2C_{\mathrm{en},J}}, \qquad R_{\mathrm{en}} = \frac{2C_{\mathrm{en},J}}{\lambda_*}(r + \beta_{\mathrm{rec}} + \sigma_* \rho_{\mathrm{cl}}) \leq R_W. \tag{23.36}$$

For either radius, each of the two terms subtracted in the denominator of item (6) is at most $1/4$, since $C_{T,\bullet} K_* \rho_\bullet \leq 1/4$ and, by the choice of R_W, $C_{T,\bullet} R_W \leq 1/4$. The denominator is then at least $1/2$, and the increment from the fluctuations is at most

$$(2C_{T,\bullet} + C_{\Delta,\bullet}) R_{\mathrm{en}} \leq (2C_{T,\bullet} + C_{\Delta,\bullet}) R_W \leq \rho_\bullet/8.$$

Together with (23.31), this gives the bound $3\rho_\bullet/8$ at spatial exponent zero. Write S^0_b for the absolute image row of the unperturbed reconstruction at exponent b, and ΔS_b for the absolute coefficient row of the difference of the perturbed and unperturbed reconstructions on the same products. The interpolation of Lemma 19.7 and (23.28), applied to the unperturbed coefficients, gives

$$S^0_{m_{\mathrm{rate}}} \leq S^0_{\vartheta c} < (\sqrt{3}/4)\rho_\bullet,$$

where the choice in Step 2 includes $m_{\mathrm{rate}} < \vartheta c$. Applying Theorem 19.9 at output rates (m_{rate}, b_1) and the bound on σ_* in Step 3 now gives

$$\Delta S_{m_{\mathrm{rate}}} \le C_{P,\bullet}\sigma_*\rho_{\mathrm{cl}} \le \rho_\bullet/64, \qquad S_{m_{\mathrm{rate}}} \le S^0_{m_{\mathrm{rate}}} + \Delta S_{m_{\mathrm{rate}}} < \left(\frac{\sqrt{3}}{4} + \frac{1}{64}\right)\rho_\bullet < \rho_\bullet/2.$$

This is the required absolute weighted image bound for both input functions on the entire enclosing product. The higher exponent included in $c_{\mathrm{prim},J}$ belongs to the unperturbed construction; inherited perturbative networks use the separate inequalities against Ba and $B\alpha$.

Step 6: widths, the curvature threshold, and the large-field decompositions. Let R_{cell}, W, ϱ, and r_F be as in item (7). We may also require $8BA_8/r \ge s_{\mathrm{er}}$ at the initial choice of r; replacing the width of the removed layer by ϱ only decreases the left sides of its exponential inequalities. We now verify the geometric hypotheses of Theorem 21.5, using Theorem 21.3 for the neighborhoods in which gauge transformations are extended. Here $R_{\mathrm{cell}} \ge R_0$, and the output side after each RG step must be at least $8R_{\mathrm{cell}}$; both follow from the choice of A_8 and from the minimum side in Step 11. Whenever $\delta R^2_{\mathrm{cell}} \le 1$ and $\eta \le C_B r$, the constants of the estimate on large cells satisfy

$$\begin{aligned} K_R &= 1 + \eta R_{\mathrm{cell}} + \delta R^2_{\mathrm{cell}} \le K_B, \\ K_R^2/R_{\mathrm{cell}} \le K_B^2 r/A_8 < c, &\qquad CK_R^{10}/R_{\mathrm{cell}} \le C_{\mathrm{col}} r < \beta_{\mathrm{rec}}/(2C_{\mathrm{an},J}), \end{aligned} \tag{23.37}$$

where we used $rR_{\mathrm{cell}} \le A_8 + r \le A_8 + 1$. Away from the two prescribed boundary layers of cells, the bound is $C'/R_{\mathrm{cell}} < r/4$. Then the fixed conversion for products of links and (23.34) give the margin $r/2$ in the bulk and the bound for frozen analytic coordinates required by Theorem 21.5. These small representatives are used only for their existence, not for a change of variables in a probability.

To protect older data, we mark, in each lattice where data were introduced, both endpoints of every older frozen link, both endpoints of every transported frozen coordinate, and all prescribed tree roots and coefficient locations attached to frozen records. We exclude every current block of the coarse lattice whose centered lift to any of these lattices meets a mark. A gauge transformation supported in the remaining active blocks has a lift that is constant on blocks and equals the identity at every mark, by the corresponding clause of Theorem 21.3; hence every older frozen link and transport is preserved exactly. The newly chosen roots of the current constraint coordinates are fixed separately by the current based gauge, as in that theorem; they are not added to the persistent exclusion marks unless attached to a frozen record. The endpoints of the current links across the boundary are fixed by the target-dependent gauge of Lemma 19.5, and their records are protected at subsequent steps if those links are frozen. The union of the persistent exclusions protects the data of all earlier RG steps at once, without a product of losses over these steps.

We fix the block-aligned input mesh $S = B\lceil C_{\mathrm{mesh},J} R_{\mathrm{cell}}/B\rceil$, where $C_{\mathrm{mesh},J} \geq 1$ was fixed in Step 3, large enough for the layer of large cells around the active blocks and for the full dependence radius of the constraint, tree, and transport paths. Then $R_{\mathrm{cell}} \leq S \leq (C_{\mathrm{mesh},J} + B)R_{\mathrm{cell}}$, so $S \asymp_J R_{\mathrm{cell}}$. At an initial RG step from the Wilson measure, the input side n_{input} is divisible by B. When $n_{\mathrm{input}} \geq 8S$, this mesh partitions each coordinate circle into block-aligned intervals with lengths in $[S/2, 2S]$: we distribute the n_{input}/B blocks among $\lfloor n_{\mathrm{input}}/S \rfloor$ intervals as evenly as possible.

At the initial step, the procedure of Theorem 21.5 tests the input plaquettes before a representative is chosen, and keeps only those closed large cells whose full dependence sets avoid the excluded dependencies. Every plaquette of the resulting complex, including each boundary plaquette, is tested good. We restrict the active blocks to the interior by one full layer of large cells and by the fixed dependence radius. This places every plaquette that depends on an active variable, and every relevant constraint, tree, and transport path, inside this closed complex. There are no older protected data at the initial step. The curvature condition below implies the estimate on large cells there, and the remaining complement consists of arbitrary compact data. This is the initial covering construction of Theorem 21.5; it is not a restriction of the Wilson measure to D_r.

The three upper bounds d_{SG}, $B_*/(96M^3)$, and $\delta_*^2/(2\pi^2)$ for d_{cut} are fixed and positive; the first is given explicitly below. Since $d_* = d_{\mathrm{cut}}/2$, the mesh condition $\pi\sqrt{2d_*}S^2 \leq 1$ is the additional bound $d_{\mathrm{cut}} \leq 1/(\pi^2 S^4)$. Since $S \geq R_{\mathrm{cell}}$, it also implies $\pi\sqrt{2d_*}R_{\mathrm{cell}}^2 \leq 1$ for the estimate on large cells. For the link bound $r/2$ we use Theorem 7.7 with support radius $r/2$; one may take

$$d_{\mathrm{SG}} = \min\{\delta_{\mathrm{SG}}^2/(2\pi^2),\ r^4/(8192\pi^2 C_{\mathrm{SG}}^4)\}, \qquad m \geq 8C_{\mathrm{SG}}/r,$$

where the second condition is a condition on the side m. Strict inequalities in the threshold and in the side give the link bound $r/2$. The constants $K_M, K_1, \kappa_0, c_A^{\mathrm{act}}, \alpha_W, K_W$ are those of Theorem 22.4 for arbitrary fields. Its hypotheses require the Borel extension of T_M and complete predecessor patches, both of which we use. We use no improvement of K_M based on tests at an untested stopping level; such an improvement would require an energy hypothesis at the base and tests at the top plaquettes.

With these conditions, Theorem 21.5 gives, for each finite sequence of RG steps starting from a stopped measure or from the protected initial step, a finite Borel partition of the support of the starting measure into large-field decompositions. Its tests use the iterates of T_M, including its Borel extension, and every test is kept. Its geometric constants $C_{\mathrm{cov},J}$ do not depend on the widths, and the counts keep the widths explicitly:

$$\begin{gathered} R_{t+1}(f) \leq B^{-1}R_t(f) + C_{\mathrm{cov},J}(W + R_{\mathrm{cell}} + 1), \qquad R_{\mathrm{first}}(f) \leq C_{\mathrm{cov},J}(W + R_{\mathrm{cell}} + 1), \\ N_{\mathrm{first}}(f) \leq C_{\mathrm{cov},J}(BW + R_{\mathrm{cell}} + 1)^3, \qquad N_{\mathrm{later}}(f) \leq C_{\mathrm{cov},J}(W + R_{\mathrm{cell}} + 1)^3, \\ F_J = C_{\mathrm{cov},J}(W + R_{\mathrm{cell}} + 1)^3. \end{gathered} \tag{23.38}$$

Here, for a threshold failure f, $R_t(f)$ is the radius of the neighborhood attributed to f at the output of the t-th following RG step, and $R_{\mathrm{first}}(f)$ is its radius at creation. The counts $N_{\mathrm{first}}(f)$ and $N_{\mathrm{later}}(f)$ bound the numbers of labels of normalization factors attributed to f at its creation and at each later step, and F_J bounds the number of plaquettes of the insertion at the stopping level affected by f. The affected sets include the full excluded neighborhoods: the protected neighborhoods, the touching cells, the boundary layers of frozen coordinates, the links across the boundary, the cores enlarged by the fixed layer, and the attachments at the lattices of introduction, together with the closed excluded sets at the initial step. They are not just the smaller predecessor sets used in the energy estimate. For the fixed finite family of stopping levels in Step 10, we enlarge $C_{\mathrm{cov},J}$ to count the discarded plaquettes of the insertion whose full dependence sets meet these excluded sets. The family of remainders is bounded independently of the number of averaging steps. This enlargement keeps the local dependence at fixed J, and all dependence on widths remains in the polynomials of (23.38). These counts are subadditive under unions of fixed complements, and they, rather than local norm constants that do not depend on widths, determine F_J and $C_{\mathrm{ch},J}$. The only side conditions used for this cover are $8R_{\mathrm{cell}}$ for outputs and $8S$ for the input at the initial step; both are imposed in Step 11. If the active region is empty, the construction stops, and all its frozen data are kept.

Step 7: the coupling bound. With A_{w} fixed, we set $c_J^{\log} = A_{\mathrm{w}}(J-1)\log M/2$, so that $p^+ = A_{\mathrm{w}}\log(1/t) + c_J^{\log}$. All fluctuation products used with Theorem 20.14 have radii $p(t) \le p_i \le p^+$. In the choice of the coupling bound we impose the two remainder conditions also with p^+:

$$\begin{aligned} C_T t^2[(p^+)^4 + E(p^+)^2] &\le (1-q_{\mathrm{CA}})/2, \\ C_J t^2(E+\sigma_*)[(p^+)^4 + (E+\sigma_*)(p^+)^2] &\le 1, \qquad tp^+ < R_{\mathrm{en}}. \end{aligned} \tag{23.39}$$

These imply the conditions of item (8) with the common radius $p(t)$ and the conditions for every product in the family of logarithmic radii. No radius of size R_{en}/t enters a cluster expansion: the enclosing product domain is used only for the Hessian, for the mean, and for the comparison with the auxiliary measure. Every inequality of item (8) involving t, after multiplication by a fixed positive denominator if necessary, is bounded by finitely many terms $Ct^{\varepsilon}[1+\log(1/t)]^k$. For the interaction radius, for example, we first impose $C_J t p^+ \le 1/2$; then its denominator is at least $1/2$, and

$$\mathfrak{s}(t) \le 2C_J t[(p^+)^3 + p^+ + (E+\sigma_*)p^+] \longrightarrow 0.$$

The other bound for discs has the same limit. We apply Lemma 23.1 to all these inequalities, to $tp(t) < P$ and $tp^+ < R_{\mathrm{en}}$, and to every fixed bound for free coordinates, for these coarse-field derivatives of the normalized log density on the fixed fluctuation product, and for Jacobians. We choose t_* for the two conditions on the potential and the mean,

and then $g_* \le t_*$ for the remaining inequalities. These include the curvature condition of item (8) involving $t^2(1+E)$, the conditions $g_*^2 \le \alpha_W$, $g_*^2 \le 2\kappa_*$, and $a_0 g_* < \min(r/2, 1)$, and the bound $t[p(t)^3 + Ep(t)] \le c_*/2$ for the auxiliary discs, with the constant c_* of Theorem 13.5. For the bound on the reconstruction amplitude in Lemma 15.15 we require in addition

$$C_{\mathrm{free},J}\, t p(t) < (1 - a_{\mathrm{map}}) r_{\mathrm{eff}}/2 \qquad (0 < t \le g_*), \tag{23.40}$$

which is possible by the same argument. Together with $b_0 \le r < r_{\mathrm{eff}}/4$ and $a_{\mathrm{map}} < 1$, this keeps the recursion for the amplitude bound inside the working ball, since $a_{\mathrm{map}} r_{\mathrm{eff}}$ plus this forcing term is strictly below r_{eff}. All these conditions hold on the interval $0 < t \le g_*$.

Step 8: the effective interaction on the torus. We now attach the constants to the recursion that defines the small-field event. We start with $R_0 = 0$ and use the common fluctuation product $p_i = p(t)$ and the full formula for the auxiliary integral in Theorem 13.5. At every step the input effective interaction is invariant on overlapping charts, has vanishing first derivatives at the identity, and has the total color, translation, and inversion symmetries; these hold at $R_0 = 0$ and are preserved by that theorem. Its hypothesis on the enlarged image is (23.27), and the unscaled fluctuation inputs lie in the product domain by the coupling conditions of Step 7. The conversion of coefficients at the same radius is valid by the checks of supports and symmetries in Step 1. If $\mathcal{B}_{\rho,a_{\mathbb{T}}}(R_k) \le E$, then we have

$$\begin{aligned} \mathcal{B}_{\rho,a_{\mathbb{T}}}(R_{k+1}) &\le C_G + q_{\mathrm{CA}} E + C_T t^2 E[p(t)^4 + Ep(t)^2] \\ &\le \frac{1}{2}(1 - q_{\mathrm{CA}})E + q_{\mathrm{CA}} E + \frac{1}{2}(1 - q_{\mathrm{CA}})E = E, \end{aligned} \tag{23.41}$$

where we used $C_G \le (1 - q_{\mathrm{CA}})E/2$ and item (8). The norm does not change when a constant is subtracted. This proves the bound, at the fixed radius and with the torus rate, at every finite depth of the form kJ. The constants C_G and C_T were chosen after J and the outer radii, and neither was used to choose J.

We apply Theorem 14.6 to the same parameters. The condition on the product for coarse fields in B_r was checked in (23.35), and $tp(t) < P$ and the intermediate margins for coordinates, the classical action, and the Jacobians hold. The support of the starting measure is D_r, the fluctuation cutoff is the same common radius, the constrained Hessians are the same positive Hessians of the classical action, and the triangular determinant and the constant A_{coord} are unchanged. At every coarse field in D_r, the integral of the Wilson density over the fiber of the block averaging map, restricted by the conditions of the small-field event, equals the auxiliary integral just used. At preceding classical depth aJ we write $r_{aJ} = R_a - R_a(I)$. The stopped measure used as a starting measure in Theorem 22.1 is then

$$\widehat{Z}^{-1} \mathbf{1}_{D_r} e^{-E_{aJ,\mathrm{sat}}/g^2 - r_{aJ,\mathrm{sat}}}\, dH, \qquad \mathcal{B}_{\rho,a_{\mathbb{T}}}(r_{aJ}) \le E, \tag{23.42}$$

where the subscript sat denotes the gauge-invariant extension to D_r. All removed values $R_a(I)$ and all constants from coordinates and Gaussian integrals stay in the normalization constant. With the convention that unnormalized densities are written $\exp(\Lambda - E/g^2 - R)$, the update is $\Lambda_{a+1} = \Lambda_a + \log A_{\mathrm{coord}} - R_+(I)$. The same holds at every allowed starting side and preceding depth, since the two cited theorems are uniform in these parameters. In particular, this is the recursion on the torus used in Theorem 22.1; no new analytic class is assumed.

The reconstruction maps give the same effective interaction. At coarse fields in B_r, invariance on overlapping charts and the gauge transformations depending only on the coarse field preserve the full fiber integral, including its constant, by Theorem 15.12. On the common outer domain both auxiliary formulas are holomorphic. Equality on a real open ball of coarse fields implies equality of all real Taylor derivatives there, and hence of the holomorphic series. Their nonconstant parts, and the bound (23.41), coincide; no J-uniform bound of all orders for the reconstruction maps is used in this identification.

Step 9: the hypotheses of the regional estimates. We take the large-field decompositions of Theorem 21.5, with the geometric conditions verified above. The controlled analytic functions are evaluated in the simultaneous gauge representatives, provided by the cover, in which all frozen coordinates are small. The protection of Step 6 preserves all older frozen data and their attachments exactly. The new analytic coordinates in the neighborhoods where gauge transformations are extended have the bound checked in Step 6, and $C_{\mathrm{conv},J} \geq C_{\mathrm{ad},J}$ covers the initial representative of size r (not $r/2$) after a stopped measure. Frozen logarithms of single links have Euclidean norm equal to their group distance, and the larger constant $C_{\mathrm{an},J}$ covers the other fixed products. We conclude that every substitution of analytic frozen coordinates, including the initial one, satisfies

$$|c_j^\sharp| \leq \min\{\beta_{\mathrm{rec}}, \phi_\bullet(j)/4\} \qquad \text{for both spatially varying radii.} \tag{23.43}$$

Plaquettes with energy of order one and arbitrary distant data are frozen group variables, and they are never substituted into an analytic coordinate. We do not claim that an arbitrary independent gauge transformation at the endpoints preserves the norm of a frozen logarithm. The bounds for small frozen coordinates are used in the simultaneous representatives provided by the cover, with older marks fixed; the later comparison of measures is the conclusion of Theorem 22.1 for representatives satisfying the reconstruction identities. Color rotations at the roots, without perturbation, preserve the relevant free norms, since they act by isometries of the adjoint representation.

At a step starting from a stopped measure, the incoming action on the torus and (23.42) have no boundary perturbation before the substitution. At a step starting from the Wilson measure, $R_0 = 0$ and the active Wilson action is the exact restriction; the action of the fixed complement stays with its compact variables and its normalizing constant. The first substitution of analytic coordinates creates only the stated boundary-completion

differences. The initial boundary norms are at most σ_*, by (23.32), with their constants kept in the full action and in the normalization constant. This proves the initialization $x_0, x_0^{\mathrm{cl}} \le \sigma_*$ for both kinds of starting measure.

After each substitution at the output, the zone of reduced radius is removed, and all remaining labels have distance at least $s_{\mathrm{er}} \ge w_{\mathrm{bd}}$ from the fixed complement. Lemma 18.9 then gives the uniform incoming radii ρ and ρ_{cl} on the next list D_{in} of active labels, with the lattices of introduction of its coefficient locations and the volumes of its variables. This is the uniform input norm required in Theorem 19.9; no derivative is estimated with a reduced radius at the boundary of the output. Its adjustment for the completion adds only the boundary-completion difference already accounted for, and we have $\mathcal{X}^{\mathrm{cl}}(\overline{P}) \le 2\sigma_*$. The input for the effective interaction has $\mathcal{X}(f) \le \sigma_*$, and its part on the torus is the effective interaction in (23.41).

Theorem 21.5 also places every older incoming complement and its older coefficient locations in the next current fixed complement, up to its fixed buffer for the dependence of paths. In input units this gives, with $B_s = B$ for each integrated step,

$$d_{D_{\mathrm{in}}}(i) \ge B d_{\mathrm{current}}(e) - B \operatorname{dist}(e, i/B) - C_{\mathrm{buf},J}. \tag{23.44}$$

Indeed, a point of the older complement nearest to i, divided by B, lies in the current fixed complement up to $C_{\mathrm{buf},J}/B$, so $d_{\mathrm{current}}(i/B) \le (d_{D_{\mathrm{in}}}(i) + C_{\mathrm{buf},J})/B$; the triangle inequality from e to i/B and a rearrangement yield (23.44). Additional fixed complements only enlarge the current complement and preserve this implication. At an initialization without boundary, the input marked by the boundary vanishes. The input norm and the norm of differences use this same list and uniform radius, and every input image and connecting segment lies strictly inside it, by the weighted image bound of half the radius and the product domains of Step 2.

We conclude that the hypotheses of Theorem 19.9 on conditional displacements, frozen real data, uniform radii, and boundary compatibility hold after any number of RG steps. The inequalities for the rates required there are included in the choice of rates in Step 2 and in $m_{\mathrm{rate}} + b_1 < c_{\mathrm{prim},J}/C_{\mathrm{alloc}}$. For each complete RG step we use the common fluctuation product, or one of the products with logarithmic radii in an auxiliary comparison. By the bounds (23.29), (23.32), (23.39), and (23.43), all hypotheses of Theorem 20.14 hold. Combining its output estimate, the removal of the boundary layer, and the new boundary-completion difference, we obtain the recursion with bound $3\sigma_*/4$ of Step 4. By induction, these hypotheses hold again at the next complete RG step.

We now apply Theorem 21.8 to each covered large-field decomposition. Its construction hypotheses and its hypotheses on the two images have been checked, and $r + \beta_{\mathrm{rec}} < \epsilon_{\mathrm{en},J}$ by our choices. For every point of every fiber in the support, over compatible fixed data, we have $g_i|w_i| \le \delta_{\mathrm{en}}$ by that theorem. Since $g_i \ge \lambda_* t$, this implies

$$|w_i| \le \delta_{\mathrm{en}}/(\lambda_* t) = R_{\mathrm{en}}/(2t). \tag{23.45}$$

Conversely, every point of the enclosing product domain satisfies $|g_i w_i| \le R_{\mathrm{en}}$. The full coordinate, sequential, and image margins apply on the enclosing product domain, while the points of the support keep a margin of half the radius.

By Lemma 20.3, on the enclosing product domain we have

$$\|D_w^2(V - |w|^2/2)\|_{\mathrm{row,col}} \le \frac{C_0(R_{\mathrm{en}} + t^2\mathcal{L}_V)}{(1 - AR_{\mathrm{en}})^3} \le \frac{1/16 + 1/16}{(1 - 1/4)^3} = \frac{8}{27} < \frac{1}{2}, \tag{23.46}$$

where we used $R_{\mathrm{en}} \le R_W \le 1/(16C_0)$, $C_0 t_*^2 \mathcal{L}_V \le 1/16$, and $AR_{\mathrm{en}} \le A/(16C_0) \le 1/4$, the last since $C_0 \ge 2A^3$ and $A \ge 1$. The separate condition for the mean also holds. Convexity is asserted only in the fluctuation variables; all inverses above are inverses of constrained Hessians in the free coordinates.

We also check the hypotheses of the comparison on the enclosing product domain in Lemma 21.11, which compares the outgoing density with the integral over the fluctuation cutoff domain. Its hypotheses are those of Theorem 21.8, verified above, the conditions on the enclosing product domain verified in Steps 5 and 7, and an incoming density bound (21.32). At the first RG step after either kind of starting measure, this bound holds with equality. At a later step, it is the incoming bound at the representatives satisfying the reconstruction identities provided by the induction from fine to coarse scales in Theorem 21.12, whose hypotheses are the conditions verified in this step. We next check the measurability required by the comparison. For fixed finite geometry and fixed real frozen data, the enclosing product domain $\mathcal{K} = \prod_i \overline{B}_{\mathbb{R}^3}(0, R_{\mathrm{en}}/t)$ is compact and has finite positive Lebesgue measure when an active fluctuation coordinate is present. The support and the fluctuation product are Borel sets: the tests of the decomposition use finitely many Borel iterates of T_M and finitely many inequalities, and the inverse coordinates and their dependence on frozen data are Borel by Step 3. Every indicator of a support or of an event of the decomposition is a Borel function χ with values in $[0, 1]$. The conditional fluctuation potential V is real and smooth on a neighborhood of $\mathcal{K}$, by the margins on the full product and the positive real constrained Hessians. In particular, for fixed data there exist finite numbers $V_{\min}$ and $V_{\max}$ bounding V on $\mathcal{K}$, and

$$0 < e^{-V_{\max}}|\mathcal{K}| \le Z_{\mathcal{K}} = \int_{\mathcal{K}} e^{-V(w)}\, dw \le e^{-V_{\min}}|\mathcal{K}| < \infty. \tag{23.47}$$

No uniform bound on these extrema is needed for the normalization. The integrand is jointly Borel, and integration over each fixed compact product, after rescaling its balls to unit balls, preserves Borel dependence on the parameters, by the fact on parameter integrals recalled in Step 3. The comparison then applies to a measurable finite normalizing constant. For an empty active region the product has mass one, the nonconstant norm vanishes, the determinant is one, and the fluctuation integral is one. All factors independent of the field keep their places in the normalization constant.

Step 10: stopping levels and the insertion interval. We fix the finite family of stopping levels and remainders of Theorem 22.1, with finite constants for side ratios and conversions. Explicitly, for a scale j and a starting level b divisible by J, let $t_{\mathrm{align}} = J\lfloor (j-1)/J \rfloor$ and $u_{\mathrm{ph}} = j - 1 - t_{\mathrm{align}} \in \{0, \dots, J-1\}$. For each fixed offset $r_{\mathrm{stop}} \in \mathbb{N}_0$ of the family, the integrated sequence of RG steps ends at $t_{\mathrm{stop}} = t_{\mathrm{align}} - r_{\mathrm{stop}} J \geq b$. Every integrated step consists of J averaging steps, and the remaining insertion at the stopping level is

$$C \longmapsto Q_j^{\mathcal{T}}\big(T_M^{r_{\mathrm{stop}}J+u_{\mathrm{ph}}} C\big), \qquad n_{t_{\mathrm{stop}}} = M^{r_{\mathrm{stop}}J+u_{\mathrm{ph}}} n_{j-1}, \qquad n_{j-1} \in 4\mathbb{N}. \tag{23.48}$$

Indeed $j - 1 - t_{\mathrm{stop}} = r_{\mathrm{stop}} J + u_{\mathrm{ph}}$, and every level between t_{stop} and $j-1$ belongs to the given finite sequence of lattices, whose last side is $n_{j-1} \geq u \geq 4$. These iterates of T_M are defined, with the required pairs of integer lattices; a large side alone would not justify this. We use the conversion of predecessor sets for arbitrary fields, with its fixed constant K_{src}, without adding a regularity test at the stopping level. The side ratio to n_{j-1} is $M^{r_{\mathrm{stop}}J+u_{\mathrm{ph}}} \leq \chi_*$, after taking the maximum over the fixed finite family. If no complete RG step fits, we apply the clause of the same theorem for a bounded side ratio at the starting measure, with the exponent $j-1-b$ and the side identity $n_b = M^{j-1-b} n_{j-1}$; in this case the exponent is bounded by the same fixed bound. Every remainder is kept as part of the insertion, and none requires an integrated step of fewer than J averaging steps, a short recursion for the normalization constant, or a new output radius.

We fix a covered large-field decomposition of length $\ell = t_{\mathrm{stop}} - b$, with the set F of coarse links kept at the stopping level. We use the list $\mathcal{P}_{\mathrm{orig}} = \mathcal{P}_{j-1}^{\mathcal{T}}$ at scale $j-1$ and $Q_{\mathrm{orig}}(V) = Q_j^{\mathcal{T}}(T_M^{j-1-b} V)$, with the coefficient $4/h_{n_{j-1}}$. The exponent and the side identity in (23.48) are the hypotheses of Lemma 22.8. Using the full excluded sets and the enlarged count in (23.38), we obtain, at every value (c, b_{rec}) of the coarse field and the frozen coordinates,

$$Q_{\mathrm{orig}}(V) \leq K_W \mathcal{V}_{m;F}(c)/g_m^2 + 8F_J \sum_{f \in \mathcal{X}} n_{\ell_f}/\gamma, \qquad m = n_{t_{\mathrm{stop}}}, \quad K_W = 48K_1/\alpha_W, \tag{23.49}$$

where $\mathcal{X}$ is the set of threshold failures of the decomposition, n_{ℓ_f} is the side at which f was created, and $\mathcal{V}_{m;F}$ is the compact minimal action of Lemma 22.8. We include both the predecessor insertion and the total-action insertion of Theorem 22.1 and Corollary 22.9, and enlarge F_J to count all their affected plaquettes. Only then do we choose $s_0 > 0$ in the full interval of Theorem 22.1, in particular with $s_0 K_W \leq 1/4$ and $s_0 \leq \theta c_A^{\mathrm{act}} d_*/(16F_J)$, where $\theta = 1/2$, and we impose $s_0 \leq \kappa_0/(2\max\{K_M, 48K_1\})$ for the total-action insertion. Each bound is fixed and positive before the coupling. We write $\Psi_F = \mathcal{V}_{m;F}$, $\lambda_s = 1/2 - sK_W \in [1/4, 1/2]$, $P_0 = 4\theta c_A^{\mathrm{act}} d_*$, and $H_{\mathcal{X}} = \sum_f n_{\ell_f}/\gamma$. At every value of the coarse field and the frozen coordinates, the action bound and the gauge-invariant threshold tests imply

$$sQ_{\mathrm{orig}}(V) - \frac{\Psi_F(c)}{2g_m^2} - \theta A_{\mathcal{X}}(b_{\mathrm{rec}}) \leq -\lambda_s \frac{\Psi_F(c)}{g_m^2} - \frac{3P_0}{4} H_{\mathcal{X}}. \tag{23.50}$$

Indeed $\theta A_{\mathcal{X}} \geq P_0 H_{\mathcal{X}}$ by the threshold tests, and $8sF_J \leq P_0/8 \leq P_0/4$. We use this inequality in the sense of image measures, as in (22.16); no factorization of the full insertion through the coarse variables is asserted. The invariant density bound without weight has been extended to the whole configuration space before this multiplication. We complete its Wilson factor once, at the coefficient λ_s, using (22.17). The scalar and completion factors attributable to the threshold failures are at most $P_0 H_{\mathcal{X}}/4$ after the same choice of minimum side, which leaves $a_{\mathrm{act}} H_{\mathcal{X}}$ with $a_{\mathrm{act}} = P_0/2$. The constants for the stopping partition-function ratio are chosen uniformly for $\lambda_s \in [1/4, 1/2]$, with $g_m^2 \leq \alpha_W$ and the fixed coupling bound g_{anc}. The denominator is the same centered trial integral on the torus, and the partition function Z_ν of the starting measure is unchanged. This argument uses only the positive action bound, and it adds no constant and no further surface logarithm. It includes the decompositions of Lemma 22.8 that become empty early.

We define s_b, a_b, and $\bar{c}$ as in item (9). The full affected sets were fixed before this sequence of choices: an enlargement for the finite family affects only these later choices and C_v, C_s, C_b, n_0, never J or an earlier analytic constant. We apply Lemma 23.4 with $\Gamma = \gamma_0$ to obtain the moment constants and their common minimum side; its hypotheses on the local product domains, the protection of older data, the norm bounds, and the insertions for the remainders have been checked above. Its surface coefficient is kept with $C_s \geq 9\chi_*^2$.

Step 11: the minimum side. All geometric thresholds, including $8R_{\mathrm{cell}}$, $8S$, $8C_{\mathrm{SG}}/r$, and every fixed margin near flat configurations, are finite lower bounds on the side. We also fix a coupling bound $0 < g_{\mathrm{anc}} < 1$ for the stopping partition-function ratios of Theorem 22.4, on the fixed intervals of coefficients of the Wilson action used in Theorem 22.1, whose lower endpoint is $1/4$. It depends on the fixed torus domains, r, the norm bounds, and that interval, and it is uniform in the depth, the side, and γ. We take $g_{\mathrm{end}} = \min\{1, g_*, g_{\mathrm{anc}}, \sqrt{\alpha_W}\} > 0$ and impose

$$n_0 \geq \gamma_0/g_{\mathrm{end}}^2, \qquad g_m = \sqrt{\gamma/m} \leq g_{\mathrm{end}} \qquad (m \geq n_0,\ 0 < \gamma \leq \gamma_0). \tag{23.51}$$

This verifies the completion at the stopping level, the uniform bound on the stopping partition-function ratio, and every coupling bound of an integrated averaging step. At the output of a complete RG step we have $g_m = \sqrt{M}\, t_{\max}$, and the coupling restriction at the stopping level is checked directly from the bound on the side; it is not inferred from $t_{\max} \leq g_*$ alone. The two side conditions of the cover hold separately: an output after an RG step has side at least $u \geq n_0 \geq 8R_{\mathrm{cell}}$, and an input at the initial step has side at least $u \geq n_0 \geq 8S$. They need no congruence condition on u beyond $u \in 4\mathbb{N}$; an integrated step has input side Bm with $m \in 4\mathbb{N}$, and every intermediate side is at least four.

We fix $r_{\mathrm{flat}} > 0$ from Lemma 14.9, below r and below all fixed margins of one RG step for the real classical action, the constraint, and the gauge transformations; these are

uniform in the preceding depth and are fixed before γ. We impose, with strict inequality,

$$2\pi/n_0 < \min\{r/2, r_{\mathrm{flat}}\}. \tag{23.52}$$

Lemma 14.9 then applies at every $u \geq n_0$ and every finite K for the same parameters: constant commuting links have distance at most $2\pi/u$ from the identity, the averaging steps preserve their holonomies, all free normalized fluctuation variables vanish, and all coordinate-domain conditions hold. This uses the uniform margin of that lemma near all flat configurations, not an open neighborhood of the flat set that depends on the cutoff.

The factors attached to threshold failures and the ratios of the sums over decompositions are controlled by Lemma 23.1, with $x = m/\gamma$ and $k \leq 2$. The errors at the endpoints in Lemma 22.12 have the forms $C_J X_c$ and $C_J W_a$ with fixed positive exponents; the finite family of remainders adds only finitely many constants and ratios of scales. Explicitly, for every transition $0 \leq a < K$, we take the minimum side so large that the exterior error z_a and the cutoff error δ_a of that lemma are at most $1/4$; the exterior error is the positivity condition on d_t in the comparison of Theorem 14.7. Then $z_a < 1$ and $\epsilon_a = \delta_a/(1 - z_a) \leq 1/3 < 1$, and every rejection estimate and every domination by reciprocals applies. The error ϵ_t of the regional comparison on the enclosing product domain in Lemma 21.11 is likewise made at most $1/4$; in particular, every reduction through the auxiliary measure and its annular region has error strictly below one. We make the ratios of successive envelopes at most $1/2$, and the sum of the ϵ_a so small that every reciprocal product has logarithm at most one; this achieves $C_\delta = 1$ before the final enlargement of n_0. The measures for the initial segments are defined up to $a = K$, but no quantity of a next transition is used at $a = K$; when $K = 0$ these products and lists are empty.

For the entropy, at $m \geq 4$ and $x = m/\gamma \geq e$, the quantity $\mathcal{A}_\gamma(m)$ of (23.3) satisfies

$$\mathcal{A}_\gamma(m) \leq D_0(1 + \log x), \qquad D_0 = 1 + 24C_v M^3 + C_s M^2(1 + \log M) + C_b'/8,$$

since $4/m \leq 1$, $8/m^3 \leq 1/8$, and $\log(Mm/\gamma) = \log M + \log x$. Increasing n_0 makes this at most $a_b x/2$, uniformly in γ. The ratio with exponent $\bar{c}$ is made at most $1/2$ by (23.2). These conditions become stronger as the minimum side increases.

Finally we keep the exact correction at the initial scale from Lemma 22.12. With $\beta = 4N/\gamma \geq 4N/\gamma_0 \geq e$, its positive term divided by β is at most

$$\frac{C_{\mathrm{LT}}\gamma_0}{4N} + \frac{9\gamma_0 \log(4N/\gamma_0)}{N^2} \longrightarrow 0,$$

where we used that $1/\beta$ and $\log\beta/\beta$ are decreasing for $\beta \geq e$. We require this to be at most $d_*/4$. The exponent at the initial scale is then at most $-\beta d_*/32 = -d_* N/(8\gamma)$, at all larger sides and all couplings in the interval. We choose $n_0 \in 4\mathbb{N}$ above this threshold and all preceding ones. The logarithmic correction at the initial scale is not replaced by a bound along a fixed sequence of sides.

Step 12: the reconstruction maps and the identity of coarse fields. The nested domains and the tolerances for coefficients and derivatives used in Theorem 15.12 are fixed. Its thresholds at fixed lattices can now be increased for the smaller inner image margins, by Lemma 15.15: below the threshold the earlier bound holds, and above it the bound for the limit plus the same fixed tolerance holds. This increase therefore cannot enlarge C_{CP}, A_J, R_J, or β_J. There are countably many pairs of finite lattices and preceding depths, and we fix the maps on all of them at once, rather than choosing a new limit or threshold at some coarse side. Each choice concerns classical maps on domains of free coordinates and has no argument depending on the coupling, the field, or an observation. The coarse fields, kernels, cutoffs, and Jacobians are preserved, by Theorem 15.12.

The bound on the reconstruction amplitude in Lemma 15.15 applies to these maps. To check its parameters, we fix $u \geq n_0$ and let $H = L/u$, $a_j = HB^{-j}$, and $g_3^2 = \gamma/L$. Then

$$t_j = M^{(J-1)/2} g_3 \sqrt{a_j}, \qquad t_1^2 = \gamma/(Mu) \leq g_*^2, \qquad t_{j+1} = t_j/\sqrt{B},$$

where $t_1^2 \leq \gamma_0/n_0 \leq g_{\mathrm{end}}^2 \leq g_*^2$ by (23.51). Here $p(t_j) \geq 1$. The free input is at most $t_j p(t_j)$, all products remain in the common working ball by (23.40), and $b_0 \leq r$. Then the amplitude bound and its sum give

$$\begin{aligned} b_j &\leq C_{\mathrm{cap},J}\big[r\alpha_*^j + g_3\sqrt{a_j}\, p(t_j)\big], \\ \sum_{j=1}^{k} b_{j-1} &\leq C_{\mathrm{cap},J}\big[r/(1-\alpha_*) + g_3\sqrt{H}\,(p(t_1)+1)\big]. \end{aligned} \tag{23.53}$$

The constant does not depend on H, u, γ, or the length of the finite chain. We used the deterministic bound of Lemma 15.15, not a stochastic bound at fixed H, and made no new choice at a coarse side.

Finally, the path-length condition gives the identity of coarse fields, even before a test that may fail. In a representative whose link distances are at most s, a product of l links has distance at most ls, by repeated use of the triangle inequality for the bi-invariant distance. The two tree paths have total length at most $3(M-1)$; adjoining the straight segment of M links and the inverse of the reference path of M links gives the closed paths of the based loop holonomies, of length at most $5M-3$. If $(5M-3)s < \pi$, all these based loop holonomies have principal logarithms. In (4.3), the exponential of the average logarithm then has distance at most $(5M-3)s$, and multiplication by the reference transport gives the bound $(6M-3)s \leq 10Ms$. Starting from $s = r$, induction gives the link bound $(10M)^i r$ before averaging step $i < J$, so the condition $(5M-3)(10M)^{J-1}r < \pi$ covers each of the next J averaging steps. For a next RG step with $0 \leq a < K$, the input side is $uB^{K-a} = M^J m$ with $m = uB^{K-a-1} \geq n_0 \geq 4$, so each of these J averaging steps has a valid pair of input and output lattices. There is no next step at $a = K$.

For an arbitrary input in D_r, we apply this argument to a small periodic representative. Under a gauge transformation, the based loop holonomies are conjugated at their

basepoint, and their distances and their membership in the exceptional set are unchanged. Conjugation commutes with the principal logarithm and with the exponential, and the reference transport transforms in the usual way at its endpoints. The same covariance holds for the Borel extension, since $-I$ is central. Then T_M and all its iterates are gauge covariant, and the conclusion transfers back without taking a logarithm of the gauge transformation. On an initial segment that passes the tests, the current coarse field lies in D_r, and the same argument applies to the next coarse field. The inverse coordinates in Definition 14.4 satisfy the identity for one averaging step on this coordinate domain; composing the J identities shows that the coarse field produced by the construction equals T_M^J of the finer field, even when a later cutoff fails. A gauge transformation depending only on the coarse field and equal to the identity at the tree roots preserves this identity, as well as the kernels and Jacobians, by Theorem 15.12.

All local estimates were evaluated before the later widths, and all side conditions used fixed constants and the bound γ_0. This proves the stated dependences, and the absence of any dependence on the number of elapsed RG steps, on shapes, or on depths. The single choice of J used only the J-uniform geometric constants and torus rates, the J-uniform series Z, and the finitely many coarse-field derivative bounds of the reconstruction maps at zero fluctuation; the full joint norms and the norms of the gauge transformations of the reconstruction maps were fixed after J. The full radii were restored only after complete RG steps, and the remainders were included in the fixed family of insertions. This completes the proof of Theorem 23.2.

23.7 Parameters below an arbitrary coupling ceiling

In this subsection we prove Theorem 23.5.

Proof of Theorem 23.5. We start with parameters given by Theorem 23.2 with $\gamma_0 = 1$. The argument works for every J obtained from that construction; it does not select a new J. We keep its J, the analytic domains and rates on the torus and on block regions, the margins of the product domains for free coordinates, the cutoff amplitude, the widths of boundary layers, removed layers, and protected neighborhoods, the margins near flat configurations, g_*, the interval for s, the family of remainders, and the numbers s_0, d_*, a_b, and $\bar{c}$. Before the curvature threshold is chosen, δ_* is normalized to $(0, 1]$, which keeps the range of Theorem 7.3. The parameters include K_W and $g_*^2 \le \alpha_W$, and the stopping partition-function ratio is controlled for coefficients in $[1/4, 1/2]$ before the side is enlarged. The deterministic column bounds come from Lemma 15.15; no stochastic estimate is used in this choice. All these quantities are constructed from the local results cited in Theorem 23.2, whose hypotheses concern g_i, t, and fixed products and contain no upper bound on γ. In particular, the classical constants, the coefficient constants of the reconstruction maps, and the J-uniform constants are not chosen again using a later

probability constant. The reconstruction maps of Lemma 15.15 and Theorem 15.12 are fixed on the same countable family of pairs of finite lattices; they depend on deterministic domains, not on the coupling. Their exact identities and the margin $32/49$ are unchanged.

At these parameters we apply Theorem 22.1 and Lemma 22.13 for the ceiling Γ, without a restriction on the number of averaging steps. We obtain C_v, C_s, C_b, and we set $C_b' = C_b + 1 + \log 2$. Only the later probability constants and thresholds use these constants, so their possible dependence on Γ creates no cycle with an earlier choice. We choose the final side at least $\Gamma/g_{\mathrm{end}}^2$ and above every earlier geometric and flat threshold. For every side $m \geq n_\Gamma$ of a stopping lattice we have $g_m^2 = \gamma/m \leq \Gamma/n_\Gamma \leq g_{\mathrm{end}}^2$, and also $t_k^2 = \gamma/(Mn_{(k+1)J}) \leq \Gamma/(Mn_\Gamma) \leq g_{\mathrm{end}}^2 \leq g_*^2$. These inequalities verify the coupling bounds at the stopping level and for the integrated steps, respectively. The separately imposed flat thresholds give $2\pi/n_\Gamma < \min(r/2, r_{\mathrm{flat}})$. All inequalities involving local small parameters hold on $0 < t \leq g_*$, including every fixed power of t multiplied by a logarithmic cutoff, and they hold at these sides on the new coupling interval.

We apply Lemma 23.4. At $x = m/\gamma \geq e$ we have

$$\mathcal{A}_\gamma(m) = 24C_vM^3 + \frac{4C_sM^2}{m}\log(Mm/\gamma) + \frac{8C_b'}{m^3} \leq D_0(1+\log x),$$

with the same $D_0 = 1 + 24C_vM^3 + C_sM^2(1+\log M) + C_b'/8$ as in Step 11 of Section 23.6, since $m \geq 4$. Lemma 20.15 makes this at most $a_b x/2$ uniformly on $x \geq n_\Gamma/\Gamma$. The same lemma makes all ratios at the endpoints at most $1/2$ and the exterior errors at most $1/4$, and it makes the cutoff errors and the logarithms of the reciprocal products as small as prescribed; in particular $C_\delta \leq 1$. The ratio over scales satisfies $M^3 e^{-\bar{c}(M-1)n_\Gamma/\Gamma} \leq 1/2$. The exact positive term at the initial scale, divided by β, is bounded by the vanishing expression in Lemma 22.13. Finally, the constant $C_{\mathrm{ch},J}^\Gamma$ for the factors attached to threshold failures at the ceiling Γ is absorbed there, before the moment constants and the final side are used. All these requirements become stronger as the minimum side increases, and we take their maximum, rounded up to an element of $4\mathbb{N}$.

The amplitude bounds of Lemma 15.15 require only $t_1^2 = \gamma/(Mu) \leq g_*^2$ and the common working ball. The coupling condition just verified provides this, and under this hypothesis the bound is uniform in $H = L/u$ and g_3. The conditions from path lengths and the coordinate-domain conditions are deterministic in r, M, and J, and they are unchanged. The conditions listed in this proof are the only places where the proof of Theorem 23.2 uses the bound $\gamma \leq \gamma_0$. Hence every conclusion of that theorem holds, with the same local dependences and with the fixed Γ entering only the probability constants. No support radius or reconstruction map changes at a larger coarse side. □

23.8 Every sufficiently large number of averaging steps

Section 29 compares the limits obtained along the sequences $n_* M^{JK}$ for two consecutive values of J, so it needs the construction of Theorem 23.2 for every sufficiently large J. No uniformity of the constants in J is asserted.

Lemma 23.14. *Fix $L > 0$, an odd integer $M \geq 3$, a ceiling $0 < \Gamma \leq 1$, and the J-uniform constants in item* (1) *of Theorem 23.2. There exists a finite J_0 such that, for every integer $J \geq J_0$, there exist a tuple Θ_J, a positive local coupling bound $g_{*,J}$, and $n_{\mathrm{sf},J} \in 4\mathbb{N}$, chosen before the coupling and the side, for which all conclusions of Theorems 23.2 and 23.9 hold with $B = M^J$, simultaneously for*

$$0 < \gamma \leq \Gamma, \qquad u \in 4\mathbb{N},\ u \geq n_{\mathrm{sf},J}, \qquad N = uB^K, \quad K \geq 0.$$

In particular, two consecutive values of J can be fixed before γ is varied. Neither the tuples nor any later constants or thresholds are asserted to be uniform in J.

Proof. We verify the additional quantifier "for all $J \geq J_0$" in the proof of Theorem 23.2; it is not inferred from the existence statement. We fix the outer rate on the torus, the boxes, and the analytic-radius enlargement factor K_*. The series for the conditional constrained minimizers at zero fluctuation of Lemma 11.9 and Theorem 13.2 has a J-uniform majorant $Z(v) \leq Cv/(1 - Cv)$ and a J-uniform spatial rate. The finitely many coarse-field derivative bounds of the reconstruction maps at zero fluctuation, as opposed to the full analytic norm of their gauge transformations, are also J-uniform, by Theorem 15.12 and Lemma 15.15. The additional identity at fixed J for hierarchical trees in Lemma 11.9 does not change its J-uniform series, and only that series is used here. Thus all constants in the following list are fixed before J:

$$\begin{gathered} B \geq B_{\mathrm{geom}}, \quad C_P(a_{\mathbb{T}})/B < 1/4, \quad C_{\mathrm{CP}}^2/B \leq 1/4, \\ C_\bullet K_*/B < 1/32, \quad C_{\mathrm{geom}}^{\mathbb{T}} b_{\mathbb{T}}/B \leq a_{\mathbb{T}}, \quad C_{\mathrm{cen}}/B < 1/8, \quad B^{-1} \leq \delta_0(a_{\mathbb{T}}). \end{gathered} \tag{23.54}$$

These are the conditions of item (1) of Theorem 23.2 and (23.25); the rate $a_{\mathbb{T}} < a_{\mathrm{cen}}/8$ and the threshold $\delta_0(a_{\mathbb{T}})$ are fixed before J. The finitely many additional image conditions on first derivatives use the same series and derivative bounds; they are also strict lower bounds on B with fixed finite right sides. The maximum of their thresholds is exceeded by M^J for every $J \geq J_0$. This uses the exception for J-uniform constants in item (2) of Definition 4.14, not a bound on a joint free map.

The constants C_{alloc} and C_g in Theorem 20.9 do not depend on J. We choose $C_*^{\mathrm{geom}} \geq \max(1, C_g)$ and keep $B_{\mathrm{geom}} = 256 C_{\mathrm{alloc}}(C_*^{\mathrm{geom}} + 1)$. For each fixed J above the threshold we set $\alpha = a/16$, $m_{\mathrm{rate}} = C_*^{\mathrm{geom}}(a + \alpha)$, and $b_1 = 8C_*^{\mathrm{geom}}\alpha$. The inequalities against Ba and $B\alpha$ reduce to

$$\frac{25}{16} C_*^{\mathrm{geom}} < B/C_{\mathrm{alloc}}, \qquad 8C_*^{\mathrm{geom}} < B/C_{\mathrm{alloc}}.$$

We decrease $a > 0$ below the positive bounds at fixed J from the initial spatial decay rate and the image exponent, and so that $\sqrt{3}\,(a + \alpha) < a_{\mathbb{T}}$. No further inequality on supports or connecting lengths remains.

We also check the later choices. At each fixed J there are finitely many product domains for initial segments. The positive lower bounds for the constrained Hessians and the radii of the inverses in Lemmas 19.3 and 19.7 have a positive finite minimum, and the coordinate, analytic, and reconstruction domains are chosen within them. The contraction on the torus satisfies $q_{\mathrm{CA}} < 1/4$, and the bound $E \geq 2C_G/(1 - q_{\mathrm{CA}})$ is finite by Theorem 13.5. The preliminary perturbation bound, the radius of the enclosing product domain, and the image bounds of Lemma 20.3 and Theorem 20.14 can be chosen positive on the fixed domains at this J. The widths of boundary layers and removed layers can be increased after their output constants are computed, and the bound for frozen coordinates, the working radius, and the support radius can then be decreased. In particular, $(5M - 3)(10M)^{J-1} r < \pi$ is an upper bound on r, not on J.

The bound on derivatives follows the same order of choices. Its linear coefficient is $\alpha_* = C_{\mathrm{CP}}/B$, and by (23.54) we have $\alpha_* \sqrt{B} \leq 1/2$. At this fixed J, β_J is finite by Lemma 15.15. The restriction $\beta_J r_{\mathrm{eff}}/(1 - \alpha_*) < 1/8$ implies $\beta_J r_{\mathrm{eff}} < 1/8$, and hence

$$a_{\mathrm{map}} \sqrt{B} \leq \frac{1/2}{(1 - \beta_J r_{\mathrm{eff}})^2} \leq \frac{32}{49}.$$

This requires no new choice of J. The remaining conditions for the fluctuations and the interaction are finitely many inequalities $C_J t^{\varepsilon} \log^b(1/t) \leq c_J$ with $\varepsilon, c_J > 0$, including the fixed additive term $A_{\mathrm{w}}(J - 1) \log M/2$ in a logarithmic radius. They hold after decreasing $g_{*,J} > 0$, by Lemma 23.1.

We next check items (7)–(10). We normalize $0 < \delta_* \leq 1$ before fixing d_{cut}. The product domains, the block-aligned initial mesh S, the classical lower bound $\alpha_W > 0$, the count F_J, and the constant for the normalization factors are all fixed at this J. By Lemma 22.8, $K_W = 48K_1/\alpha_W < \infty$ and the insertion satisfies

$$Q_{\mathrm{orig}} \leq K_W \mathcal{V}_{m;F}/g_m^2 + 8F_J \sum_f n_{\ell_f}/\gamma.$$

We enlarge F_J for the finitely many remainders. The interval of Theorem 22.1 allows

$$0 < s_0 \leq \min\Big\{\frac{1}{2},\ \frac{\kappa_*}{2} c_E^{-(J-1)},\ \frac{1}{4K_W},\ \frac{\theta c_A^{\mathrm{act}} d_*}{16F_J},\ \frac{\kappa_0}{2\max\{K_M, 48K_1\}},\ s_{\mathrm{short},J}\Big\},$$

where $s_{\mathrm{short},J} > 0$ is the minimum of its finitely many conditions for short scale intervals and $\theta = 1/2$. Every entry is positive once J is fixed, and $\lambda_s = 1/2 - sK_W \in [1/4, 1/2]$. The action bound keeps at least $3P_0/4$ of the coefficient of the threshold failures, with $P_0 = 4\theta c_A^{\mathrm{act}} d_*$, and the later scalar threshold uses at most $P_0/4$, so that $P_0/2$ remains.

The compact minimum in the action bound uses the partition function of the starting measure once; no factorization of the insertion through the coarse variables is needed. We decrease $g_{*,J} > 0$ to impose $g_{*,J}^2 \le \alpha_W$ and every local condition already listed. We choose the bounds for the stopping partition-function ratio and its numerator on the fixed interval $[1/4, 1/2]$, and let $g_{\mathrm{end},J} > 0$ be their minimum with 1 and $g_{*,J}$. Finally, we increase the minimum side to include $n_{\mathrm{sf},J} \ge \Gamma / g_{\mathrm{end},J}^2$ and all fixed geometric and scalar thresholds and the thresholds for initial segments. The latter are conditions on the minimum side, by Lemma 22.12; for $\Gamma \le 1$ their uniform scalar thresholds also follow from Lemma 23.1.

These are exactly the later choices in Theorem 23.2, and none of them requires enlarging J using a constant already computed at that J. By Theorems 23.6 and 23.9, we then obtain the bound on the small-field failure probability on $0 < \gamma \le \Gamma$. The positive exponent $\min(5/24, 1/2, -\log q_{\mathrm{CP}} / \log B)/2$ of Remark 23.3 is also available at each fixed J. □

Corollary 23.15. *Fix $L > 0$, an odd integer $M \ge 3$, and $0 < \Gamma < \infty$. There exists a finite J_0 such that, for every $J \ge J_0$, there are a tuple Θ_J, $g_{*,J} > 0$, and $n_{\Gamma,J} \in 4\mathbb{N}$, fixed before γ, the side, and the number of renormalization group steps, for which every conclusion of Theorems 23.5 and 23.10 holds on $0 < \gamma \le \Gamma$ with this prescribed J. In particular, consecutive values of J can be fixed before the coupling. No constant or threshold is asserted to be uniform in J.*

Proof. We apply Lemma 23.14 with the ceiling one. Its check of the J-uniform conditions provides J_0 and parameters for $\gamma \le 1$ for every $J \ge J_0$. The constant $K_W = 48K_1/\alpha_W$ is fixed after the classical lower bound α_W and before s_0, and the normalization $\delta_* \le 1$ is fixed before the curvature threshold; neither changes a J-uniform lower bound on $B = M^J$ or imposes an upper bound on J. The interval for s is a finite minimum of positive numbers at fixed J, and the coupling bound at the endpoints is positive. For each prescribed $J \ge J_0$, we apply the construction in the proof of Theorem 23.5 to these parameters. That construction changes only the later probability constants and the final minimum side, and it keeps this J and the deterministic bounds of Lemma 15.15. By Theorem 23.10, we then obtain the bounds for all finite numbers of RG steps on the interval $0 < \gamma \le \Gamma$. For two values J and $J+1$ one may take the larger of the two minimum sides, with no uniformity as J varies. □

PART VII

Wilson flow and continuum comparison

SECTION 24

Local Wilson flow and continuum solutions

This section proves the deterministic Wilson-flow estimates used to pass from the renormalization group variables to flowed Wilson loops. We also record an elementary comparison for exponential transforms of bounded random observables. The section has three parts.

The first part concerns the lattice. Let $a = L/n$ be the mesh and write a configuration close to the identity as $U_e = e^{aA_e}$. After a time-dependent gauge transformation, which adds a damping term, the Wilson flow $\Psi_t^{(n)} = \Phi^{\mathrm{W}}_{4t/a^2}$ becomes the parabolic equation

$$\partial_t A = \Delta_a A + \mathcal{N}_a(A, A) + F_a(A), \tag{24.1}$$

where Δ_a is the lattice Laplacian, $\mathcal{N}_a$ is an explicit bilinear map containing one lattice difference, and F_a collects the terms of degree at least three (Lemma 24.2). We write

$$A(t) = x_a(t) + y_a(t) + r_a(t), \qquad x_a(t) = P_t^a A(0), \qquad y_a(t) = \int_0^t P_{t-s}^a \mathcal{N}_a\big(x_a(s), x_a(s)\big)\, ds, \tag{24.2}$$

where $P_t^a = e^{t\Delta_a}$. As in Section 3.5, x_a is the linear heat evolution and y_a the quadratic Picard term, and (x_a, y_a) is the flow data of $A(0)$. Theorem 24.5 constructs a local solution on a time interval independent of the mesh, with remainder of order $(t + a^2)^{1-3\alpha/2}$, and proves Lipschitz dependence on these data. The probabilistic bounds on the flow data are proved in Sections 26 to 28, using the bilinear estimate of Lemma 24.6.

The second part, Section 24.6, concerns the Yang–Mills heat flow on $\mathbb{T}_L^3$ and is independent of the lattice. For smooth initial data near a compact family, it represents the flow on a finite time interval by finitely many local solutions of the DeTurck equation, joined by fixed gauge transformations.

The third part (Section 24.7) treats the flows of the actions $\sum_p (q(U_p) + c\, q(U_p)^2)$ with $0 \le c \le C_0$, which appear in Theorem 2.6. The additional force begins in degree three and is $O(a^3)$ on every fixed bounded C_a^1 ball. We show that these flows have the same flow data as the Wilson flow, and that for the same flow data their solutions differ from the Wilson-flow solution by $O(a^\varepsilon)$ on the local time interval.

The inputs are the conventions of Section 4, in particular the weighted norms of Definition 4.8 and the continuum conventions of Definition 4.10; the finite-word analyticity and the plaquette bounds of Lemma 5.1; and the heat kernel bounds, convolution estimates, and cardinal interpolation of Lemmas 16.1, 16.3, and 16.8. The lattice results are used in

Section 25 (continuation to fixed time intervals and stability), in Sections 26 to 28 (estimates for the flow data and convergence of flowed loops), in Sections 29 and 30 (lattice energy, trajectories, and alternative flows), and in Sections 32 and 34. The continuum theorem is used in Sections 25, 28 to 30, and 34.

The lattice flow is the Wilson flow of Lüscher [128, 129]; the factor $4/a^2$ in its time variable comes from our normalization of q, of the plaquette sum, and of the metric on $\mathrm{SU}(2)$. Zwanziger [157], DeTurck [66] (for the Ricci flow), and Donaldson [76] made gauge-invariant flows parabolic by adding a gauge velocity. The decomposition (24.2) into a rough linear part and smoother corrections is the lattice analogue of the decomposition used by Cao and Chatterjee [42, §§1.1 and 2.1] for the Yang–Mills heat flow with random initial data, an idea that goes back to Bourgain [32] and to Da Prato and Debussche [63]. Here the subtracted term is the quadratic Duhamel term of the lattice equation, with the bilinear map fixed in Lemma 24.2. The global smooth theory of the continuum flow is due to Råde [139] and Charalambous and Gross [47]; we use it in the form stated by Cao and Chatterjee [42, 43]. The explicit lattice coefficient, the weighted remainder estimates, and the finite continuation construction are proved in this section.

24.1 The local equation for the Wilson flow

Notation. Throughout this section $L > 0$ is fixed, $n \geq 4$ is an integer, and $a = L/n$. A field A on Λ_n assigns to each positive link $(x, x + ae_i)$ an element $A_i(x) \in \mathfrak{su}(2)$; we use the norm $|X| = (-2 \operatorname{tr} X^2)^{1/2}$ on $\mathfrak{su}(2)$, for which $|[X, Y]| \leq |X||Y|$, since the bracket corresponds to the cross product in $\mathbb{R}^3$. Let T_i be the translation $(T_i f)(x) = f(x + ae_i)$, and let

$$D^+_{a,i} = \frac{T_i - I}{a}, \qquad D^-_{a,i} = \frac{I - T_i^{-1}}{a}, \qquad \Delta_a = \sum_{i=1}^{3} D^-_{a,i} D^+_{a,i}$$

act on each link component separately, a link being identified with its starting vertex. The heat semigroup $P^a_t = e^{t\Delta_a}$ acts componentwise and includes the constant mode. We write $\|A\|_\infty = \max_e |A_e|$, and $\|D_a A\|_\infty$ for the maximum of $\|D^\pm_{a,j} A\|_\infty$ over $j \in \{1, 2, 3\}$, both signs, and all link components. We set

$$\|A\|_{C^1_a} = \|A\|_\infty + \max_{j \in \{1,2,3\},\, \epsilon \in \{+,-\}} \|D^\epsilon_{a,j} A\|_\infty. \tag{24.3}$$

Since translations permute the sites of the periodic lattice, they are isometries for these norms and commute with P^a_t and with all differences. More generally, D^m_a denotes the maximum over all ordered products of m differences $D^\pm_{a,k}$.

We identify tangent vectors at $U \in \mathrm{SU}(2)$ with $\mathfrak{su}(2)$ through $X \mapsto (d/d\varepsilon)\, e^{\varepsilon X} U|_{\varepsilon=0}$. A curve $U(s)$ then has velocity $\dot U U^{-1}$, and the gradient $\nabla f(U) \in \mathfrak{su}(2)$ of a function f on $\mathrm{SU}(2)$ is defined by $\langle \nabla f(U), X \rangle = (d/d\varepsilon)\, f(e^{\varepsilon X} U)|_{\varepsilon=0}$; since the metric is bi-invariant,

this is the Riemannian gradient. On $\mathcal{U}_n$ we use the product metric. As in Section 2.1, Φ^{W}_s is the flow of $-\nabla \sum_{p\in\mathcal{P}_n} q(U_p)$ and $\Psi^{(n)}_t = \Phi^{\mathrm{W}}_{4t/a^2}$; no coupling enters this time change.

All constants in Section 24.1 depend only on the fixed finite stencils, the orders of the derivatives involved, and the margins of the logarithm charts, and not on L, n, the coupling, or any probability law. These are the dependences of item (1) of Definition 4.14. Later constants may depend in addition on the quantities displayed in each statement.

Local analytic maps of a finite stencil. The terms of degree at least three in the flow equations of this section are functions of the link variables in a fixed finite neighborhood, with the same functional form at every link. We first record the estimates that such functions satisfy after the rescaling $\theta = aA$. Let S_0 be a finite set of pairs (η, j) with $\eta \in \mathbb{Z}^3$ and $j \in \{1,2,3\}$. For a field θ and a site x, we write $Z_x(\theta) = (\theta_j(x + a\eta))_{(\eta,j)\in S_0}$ for the stencil array of θ at x. A map G from fields to fields is a local analytic map with stencil S_0 if there exist functions g_1, g_2, g_3, real analytic in a neighborhood of 0 in $\mathfrak{su}(2)^{S_0}$, such that $G(\theta)_i(x) = g_i(Z_x(\theta))$ whenever θ is small. For a homogeneous polynomial P of degree m on $\mathfrak{su}(2)^{S_0}$ with values in $\mathfrak{su}(2)$, let $\|P\|_{\mathrm{coeff}}$ denote the sum of the norms of its coefficients in the monomial basis of the real coordinates. If g_i extends to a bounded analytic function on a complex polydisc around 0, then by the Cauchy estimates there exist constants K_0, K_1 such that the homogeneous parts $P_{m,i}$ of g_i satisfy $\|P_{m,i}\|_{\mathrm{coeff}} \le K_0 K_1^m$.

Lemma 24.1. *Let G be a local analytic map with stencil S_0 whose Taylor coefficients at zero vanish through degree two, and suppose that the homogeneous parts of the g_i satisfy $\|P_{m,i}\|_{\mathrm{coeff}} \le K_0 K_1^m$ for $m \ge 3$; on $\{Z : K_1\|Z\| < 1\}$, where $\|Z\|$ is the maximum of the norms of the entries, we use the convergent Taylor series $g_i = \sum_{m\ge3} P_{m,i}$ to define g_i and hence G. Fix $0 < \eta < 1$. For $0 < a \le 1$ and a field A with $K_1 a\|A\|_\infty \le \eta$, set $G_a(A) = a^{-3}G(aA)$ and $M_A = \|A\|_\infty$, and let*

$$b_j(M,a) = \begin{cases} M^{3-j}, & 0 \le j \le 3, \\ a^{j-3}, & j > 3. \end{cases}$$

Then the following statements hold, with constants depending only on S_0, K_0, K_1, η, and the indicated orders.

1. *The series $G_a(A)_i(x) = \sum_{m\ge3} a^{m-3} P_{m,i}(Z_x(A))$ converges absolutely.*
2. *For every $j \ge 0$ and all fields $V_1, \dots, V_j$,*

$$\|D^j G_a(A)[V_1,\dots,V_j]\|_\infty \le K_j\, b_j(M_A,a) \prod_{r=1}^{j} \|V_r\|_\infty.$$

3. *If B is another field with $K_1 a\|B\|_\infty \le \eta$, then $\|G_a(A) - G_a(B)\|_\infty \le K(\|A\|_\infty^2 + \|B\|_\infty^2)\|A - B\|_\infty$.*

4. For every $m \geq 1$,

$$\|D_a^m G_a(A)\|_\infty \leq K_m \sum_{j=1}^{m} b_j(M_A, a) \sum_{\substack{\nu_1+\cdots+\nu_j=m \\ \nu_r \geq 1}} \prod_{r=1}^{j} \|D_a^{\nu_r} A\|_\infty.$$

5. If B is as in (3) and $M = \max(\|A\|_\infty, \|B\|_\infty)$, then

$$\|D_a(G_a(A) - G_a(B))\|_\infty \leq K\big\{M^2 \|D_a(A-B)\|_\infty + M(\|D_a A\|_\infty + \|D_a B\|_\infty)\|A-B\|_\infty\big\}.$$

Proof. We write $g_i^a(Z) = a^{-3} g_i(aZ) = \sum_{m\geq 3} a^{m-3} P_{m,i}(Z)$, so that $G_a(A)_i(x) = g_i^a(Z_x(A))$; every entry of $Z_x(A)$ has norm at most M_A. For a homogeneous polynomial P of degree m, differentiating each monomial, we find

$$|D^j P(Z)[W_1, \ldots, W_j]| \leq m(m-1)\cdots(m-j+1)\, \|P\|_{\text{coeff}}\, \|Z\|^{m-j} \prod_{r=1}^{j} \|W_r\|,$$

where $\|Z\|$ is as in the statement; the right side is zero when $j > m$. For $j \leq 3$ we have $a^{m-3} K_1^m M_A^{m-j} = K_1^3 M_A^{3-j} (K_1 a M_A)^{m-3}$, and for $j > 3$ and $m \geq j$ we have $a^{m-3} K_1^m M_A^{m-j} = a^{j-3} K_1^j (K_1 a M_A)^{m-j}$. Since $K_1 a M_A \leq \eta < 1$, summing over m, we obtain (1) and (2), with

$$K_j = K_0 K_1^{\max(3,j)} \sum_{m \geq \max(3,j)} m(m-1)\cdots(m-j+1)\, \eta^{m-\max(3,j)} < \infty.$$

For (3), we write $G_a(A) - G_a(B) = \int_0^1 DG_a(B + u(A-B))[A-B]\, du$. Since the field $B + u(A-B)$ has norm at most $\max(\|A\|_\infty, \|B\|_\infty)$, (2) with $j = 1$ implies the claim.

For (4), we use that G_a has the same form at every site. Since $Z_{x+ae_k}(A) = Z_x(T_k A)$, by the fundamental theorem of calculus we have

$$D_{a,k}^+\big(G_a(A)\big) = \int_0^1 DG_a\big((1-u)A + uT_kA\big)\big[D_{a,k}^+ A\big]\, du,$$

and similarly $D_{a,k}^-(G_a(A)) = \int_0^1 DG_a((1-u)T_k^{-1}A + uA)[D_{a,k}^- A]\, du$. The fields $(1-u)A + uT_kA$ are convex combinations of translates of A, so they satisfy the same bound $K_1 a\|\cdot\|_\infty \leq \eta$. The map $(W, V) \mapsto DG_a(W)[V]$ is again of the same form at every site, so the same identity applies to it; differences of the two arguments are differences of W and of V, and differences of products obey $D_{a,k}^+(fg) = (D_{a,k}^+ f)\, T_k g + f\, D_{a,k}^+ g$ and $D_{a,k}^-(fg) = (D_{a,k}^- f)\, T_k^{-1} g + f\, D_{a,k}^- g$. By induction on m, $D_a^m G_a(A)$ is a finite sum, with a number of terms depending only on m, of integrals over $[0,1]^m$ of expressions $D^j G_a(W)[\widetilde{V}_1, \ldots, \widetilde{V}_j]$, where $1 \leq j \leq m$, W is a convex combination of translates of A, and each $\widetilde{V}_r$ is a convex combination of translates of a difference $D_a^{\nu_r} A$ with $\nu_r \geq 1$ and $\nu_1 + \cdots + \nu_j = m$. No

factor a^{-1} appears outside a difference of A. Since translations preserve the supremum norm, (2) implies (4).

For (5), we apply one difference to $\int_0^1 DG_a(B + u(A - B))[A - B]\,du$ in the same way. The terms in which the difference falls on the second argument are bounded by $K\,b_1(M,a)\|D_a(A - B)\|_\infty = KM^2\|D_a(A - B)\|_\infty$. The other terms contain D^2G_a, evaluated at convex combinations of translates of A and B, applied to a difference of $B + u(A - B)$ and to a translate of $A - B$; by (2) with $j = 2$ they are bounded by $KM(\|D_aA\|_\infty + \|D_aB\|_\infty)\|A - B\|_\infty$. □

The equation. We derive (24.1) and fix the bilinear map $\mathcal{N}_a$. In the lemma and its proof we use dimensionless differences; the symbols d_0, C_0, and H_0 have the meaning given there only in this lemma and its proof.

Lemma 24.2. *Let $L > 0$, $n \geq 4$, and $a = L/n$. Write $\nabla_i = T_i - I$, $d_0 = -\nabla$, $(C_0\theta)_{ij} = \nabla_i\theta_j - \nabla_j\theta_i$ for $i < j$, and $H_0 = \sum_i \nabla_i^*\nabla_i$, where adjoints are taken with respect to counting measure on sites, links, and positive plaquettes.*

1. *We have*
$$C_0^*C_0 + d_0d_0^* = H_0I, \qquad d_2C_0 = 0, \qquad \Delta_a = -a^{-2}H_0,$$
where d_2 is the next forward exterior difference.

2. *For θ in a sufficiently small fixed ball of link logarithms and the plaquette $p = p_{ij}(x)$, $i < j$, put*
$$(v_{p,1}, v_{p,2}, v_{p,3}, v_{p,4}) = \big(\theta_i(x), \theta_j(x + ae_i), -\theta_i(x + ae_j), -\theta_j(x)\big),$$
$$\mathfrak{q}_p(\theta) = \frac{1}{2}\sum_{k<l}[v_{p,k}, v_{p,l}],$$
so that $U_p = e^{v_{p,1}}e^{v_{p,2}}e^{v_{p,3}}e^{v_{p,4}}$ for $U = e^\theta$. Let $\|\theta\|_{\infty,p}$ be the maximum of $|\theta_e|$ over the four links e of p. Then, with positive plaquettes counted once,
$$\operatorname{Log} U_p = (C_0\theta)_p + \mathfrak{q}_p(\theta) + O(\|\theta\|_{\infty,p}^3),$$
$$\sum_p q(U_p) = \frac{1}{8}\|C_0\theta\|_2^2 + \frac{1}{4}\langle C_0\theta, \mathfrak{q}(\theta)\rangle + R_E(\theta), \qquad |R_E(\theta)| \leq C\sum_p \|\theta\|_{\infty,p}^4.$$
Each local remainder and each of its derivatives of fixed order is bounded on a smaller fixed ball, independently of n.

3. *Let $s = t/a^2$, so that $\Psi_t^{(n)} = \Phi_{4s}^{\mathrm{W}}$ and the Wilson flow has velocity $-4\nabla\sum_p q(U_p)$ in the variable s. Add to this velocity the infinitesimal gauge transformation*
$$(G_U\phi)_i(x) = \phi(x) - \operatorname{Ad}(U_i(x))\phi(x + ae_i), \qquad \phi = -d_0^*\theta.$$

With $\mathcal{J}(\theta) = (e^{\operatorname{ad}\theta} - I)/\operatorname{ad}\theta$, *the resulting velocity in logarithmic coordinates is* $\mathcal{J}(\theta)^{-1}(-4\nabla \sum_p q + G_U\phi)$, *and it has the expansion*

$$\partial_s\theta = -H_0\theta + N_2(\theta) + R_3(\theta), \qquad N_2 = -C_0^*\mathfrak{q} - D\mathfrak{q}(\theta)^* C_0\theta + G_2(\theta),$$
$$(G_2)_i(x) = \frac{1}{2}\big[\theta_i(x), (d_0^*\theta)(x) + (d_0^*\theta)(x + ae_i)\big].$$

The adjoint is given by

$$z_{p,k} = \frac{1}{2}\Big[\sum_{l>k} v_{p,l} - \sum_{l<k} v_{p,l},\, y_p\Big], \qquad D\mathfrak{q}(\theta)^* y = \sum_{p,k} \epsilon_{p,k} T_{p,k}^* z_{p,k},$$

where $v_{p,k} = \epsilon_{p,k} T_{p,k}\theta_{\mathrm{dir}(p,k)}$ *with* $\epsilon_{p,k} \in \{\pm 1\}$ *and a translation* $T_{p,k}$, *and* $T_{p,k}^*$ *also inserts the result in the direction* $\mathrm{dir}(p,k)$.

4. *Expand* N_2 *by the rules (i)–(iii) in Step 5 of the proof below. This gives a fixed finite list of terms, each a numerical multiple of* $[T_\eta\theta_i, T_\zeta\nabla_k\theta_j]$ *or* $[T_\eta\theta_i, T_\zeta\nabla_k^*\theta_j]$ *for translations* T_η, T_ζ. *Replacing the first entry of each bracket by* au, *the second by* av, *and dividing by* a^3, *defines a bilinear map* $\mathcal{N}_a$, *which satisfies*

$$a^{-3}N_2(aA) = \mathcal{N}_a(A,A), \qquad \mathcal{N}_a(u,v) = \sum_{\lambda=1}^{m_0} c_\lambda\big[T_{\lambda,1}u_{i_\lambda}, T_{\lambda,2}D_{a,k_\lambda}^{\pm} v_{j_\lambda}\big], \tag{24.4}$$
$$\|\mathcal{N}_a(u,v)\|_\infty \le C\|u\|_\infty\|D_a v\|_\infty,$$

where each term also carries the insertion in the output direction prescribed by its rule. The number m_0, *the coefficients* c_λ, *the directions, and the translations do not depend on* a, n, *or* L. *Further differences of* $\mathcal{N}_a(u,v)$ *are distributed by the exact rules* $D_{a,k}^+[u,v] = [D_{a,k}^+u, T_k v] + [u, D_{a,k}^+ v]$ *and* $D_{a,k}^-[u,v] = [D_{a,k}^-u, T_k^{-1}v] + [u, D_{a,k}^- v]$. *Every later occurrence of* $\mathcal{N}_a$ *refers to this map; it is not symmetric in its two arguments.*

5. *There exist numerical constants* $r_* > 0$ *and* $C < \infty$ *such that, if* $\|\theta\|_\infty, \|\theta'\|_\infty \le r_*$, *then*

$$\|R_3(\theta)\|_\infty \le C\|\theta\|_\infty^3, \qquad \|R_3(\theta) - R_3(\theta')\|_\infty \le C\big(\|\theta\|_\infty^2 + \|\theta'\|_\infty^2\big)\|\theta - \theta'\|_\infty.$$

Moreover, R_3 *is a local analytic map whose Taylor coefficients vanish through degree two and satisfy the hypotheses of Lemma 24.1. In particular, for* $0 < a \le 1$ *the physical remainder* $a^{-3}R_3(aA)$ *is the sum of a convergent series whose term of degree* m *carries the factor* a^{m-3}, $m \ge 3$, *and on a fixed smaller ball it satisfies the bounds of Lemma 24.1, uniformly in the mesh.*

6. *Let* A *be a solution of*

$$\partial_t A = \Delta_a A + \mathcal{N}_a(A,A) + a^{-3}R_3(aA)$$

on an interval $[0,T]$ *with* $a\|A(t)\|_\infty < r_*$ *throughout. Let* $k(t) \in \mathrm{SU}(2)^{\Lambda_n}$ *solve*

$$\partial_t k_x\, k_x^{-1} = a^{-2}\phi_x\big(aA(t)\big), \qquad k_x(0) = I,$$

for every site x. Then k is a periodic lattice gauge transformation and, for every positive link (x, y),

$$e^{aA_{xy}(t)} = k_x(t)\,\Psi_t^{(n)}\big(e^{aA(0)}\big)_{xy}\,k_y(t)^{-1}, \qquad 0 \le t \le T.$$

Proof. We first compute the linear algebra, then expand the plaquette logarithms and the energy, convert the group gradient into logarithmic coordinates, add the gauge velocity, fix the bilinear map, bound the remainder, and finally identify the flow.

Step 1: Hodge identities. With counting measure, $\nabla_i^* = T_i^{-1} - I$, and differences in different directions commute. We extend a function on positive plaquettes antisymmetrically by $z_{ji} = -z_{ij}$ and $z_{ii} = 0$. By summation by parts, we have

$$(C_0^* z)_i = -\sum_j \nabla_j^* z_{ij}, \qquad d_0^*\theta = -\sum_j \nabla_j^* \theta_j. \tag{24.5}$$

We obtain

$$(C_0^* C_0\theta)_i = H_0\theta_i - \nabla_i \sum_j \nabla_j^*\theta_j, \qquad (d_0 d_0^*\theta)_i = \nabla_i \sum_j \nabla_j^*\theta_j,$$

which proves the first identity. The component of $d_2 C_0\theta$ in the directions $i < j < k$ is

$$\nabla_i(\nabla_j\theta_k - \nabla_k\theta_j) - \nabla_j(\nabla_i\theta_k - \nabla_k\theta_i) + \nabla_k(\nabla_i\theta_j - \nabla_j\theta_i) = 0.$$

Finally $D_{a,i}^+ = a^{-1}\nabla_i$ and $D_{a,i}^- = -a^{-1}\nabla_i^*$, so $D_{a,i}^- D_{a,i}^+ = -a^{-2}\nabla_i^*\nabla_i$. This checks the signs of all three identities.

Step 2: plaquette logarithms and the energy. All matrix norms below are equivalent to the norm on $\mathfrak{su}(2)$, with numerical constants. We fix a complex neighborhood of zero in four copies of $\mathfrak{su}(2)_{\mathbb{C}}$ on which the product of the four exponentials lies in the domain of the identity logarithm chart. Expanding the exponentials through degree two, and then $\log(I + Z) = Z - Z^2/2 + \cdots$, we obtain

$$\operatorname{Log}\big(e^{v_1}e^{v_2}e^{v_3}e^{v_4}\big) = \sum_k v_k + \frac{1}{2}\sum_{k<l}(v_k v_l - v_l v_k) + \text{terms of degree at least three.}$$

The linear term is $\sum_k v_{p,k} = \theta_i(x) + \theta_j(x + ae_i) - \theta_i(x + ae_j) - \theta_j(x) = (C_0\theta)_p$. The finite-word analyticity of Lemma 5.1 applies, since the word has four letters and all its arguments lie in the same fixed identity chart. Alternatively, the two convergent series give the coefficient bounds directly on a smaller polydisc. In either description the radius and the constants are numerical. If $w_p = \|\theta\|_{\infty,p}$, the remainder has size at most Cw_p^3, and its derivatives of order $j \le 3$ are at most $C_j w_p^{3-j}$; derivatives of higher fixed order are bounded on each smaller chart.

By Lemma 5.1, $q(e^X) = |X|^2/8 + O(|X|^4)$. Substituting the expansion of the logarithm, we obtain on each plaquette

$$q(U_p) = \frac{1}{8}|(C_0\theta)_p|^2 + \frac{1}{4}\langle (C_0\theta)_p, \mathfrak{q}_p(\theta)\rangle + O(w_p^4).$$

Summing over positive plaquettes, each counted once, we obtain the expansion of the energy. These estimates are local: a link lies in four positive plaquettes, so differentiating the energy with respect to one link introduces at most four of these plaquette remainders, and no volume factor.

Step 3: the group gradient in logarithmic coordinates. For a differentiable curve $\theta(s)$,

$$\Big(\frac{d}{ds}e^{\theta}\Big)e^{-\theta} = \int_0^1 e^{u\theta}\dot\theta e^{-u\theta}\,du = \mathcal{J}(\theta)\dot\theta;$$

the integral formula follows by differentiating the exponential series term by term. The pullback of the bi-invariant metric to logarithmic coordinates is $g_\theta = \mathcal{J}(\theta)^*\mathcal{J}(\theta)$. Since the inner product is invariant, $\operatorname{ad}(\theta)^* = -\operatorname{ad}(\theta)$ for real θ, and hence

$$\mathcal{J}(\theta) = I + \tfrac{1}{2}\operatorname{ad}(\theta) + O(|\theta|^2), \qquad g_\theta = I + O(|\theta|^2).$$

We write $E_W = \sum_p q(U_p)$ and let ∇_θ denote its gradient in the Euclidean coordinates θ (only in the next formula). The velocity of $-4\nabla E_W$ in logarithmic coordinates is $-4g_\theta^{-1}\nabla_\theta E_W$. The metric correction first contributes in degree three, and by the energy expansion of Step 2 we have

$$\dot\theta_W = -C_0^*C_0\theta - C_0^*\mathfrak{q}(\theta) - D\mathfrak{q}(\theta)^*C_0\theta + O_{\mathrm{loc}}(\theta^3), \tag{24.6}$$

where $O_{\mathrm{loc}}(\theta^3)$ denotes a local analytic map vanishing to third order. The linear term $-\operatorname{ad}(\theta)/2$ of $\mathcal{J}^{-1}$ cannot be dropped unless the group gradient is also converted: the two corrections cancel only in the combination $g_\theta^{-1} = (\mathcal{J}^*\mathcal{J})^{-1}$.

We now verify the formula for $D\mathfrak{q}(\theta)^*$. Varying the kth entry of a plaquette by δv_k changes $\mathfrak{q}_p$ by

$$\frac{1}{2}\sum_{l>k}[\delta v_k, v_l] + \frac{1}{2}\sum_{l<k}[v_l, \delta v_k].$$

The invariant inner product satisfies $\langle y,[h,v]\rangle = \langle h,[v,y]\rangle$ and $\langle y,[v,h]\rangle = \langle h,[y,v]\rangle$. Pairing with y_p, we obtain exactly $\langle \delta v_k, z_{p,k}\rangle$. Since $\delta v_k = \epsilon_{p,k}T_{p,k}\delta\theta_{\mathrm{dir}(p,k)}$, transposing gives $\epsilon_{p,k}T_{p,k}^*z_{p,k}$, including the insertion in the direction $\mathrm{dir}(p,k)$. Adding the four entries and all plaquettes containing a given link proves the formula.

Step 4: the gauge velocity. If a lattice gauge transformation has velocity $\dot{k}_x k_x^{-1} = \phi_x$, then differentiating $k_x U_{xy} k_y^{-1}$ and multiplying on the right by its inverse gives the link velocity $\phi_x - \mathrm{Ad}(U_{xy})\phi_y$. For fixed ϕ, the corresponding logarithmic velocity on the link $(x, x + ae_i)$ is

$$\begin{aligned}&\big(I - \tfrac{1}{2}\,\mathrm{ad}(\theta_i) + O(|\theta_i|^2)\big)\big(\phi_x - \phi_{x+ae_i} - [\theta_i, \phi_{x+ae_i}] + O(|\theta_i|^2|\phi|)\big)\\ &\quad = (d_0\phi)_i - \tfrac{1}{2}[\theta_i, \phi_x + \phi_{x+ae_i}] + O_{\mathrm{loc}}(|\theta|^2|\phi|).\end{aligned}$$

We now set $\phi = -d_0^*\theta$. The linear part is $-d_0 d_0^*\theta$ and the quadratic part is G_2. Combining this with (24.6) and the identity $C_0^* C_0 + d_0 d_0^* = H_0$ proves the linear part $-H_0\theta$ and the formula for N_2. We define R_3 as the logarithmic velocity of part (3) minus $-H_0\theta + N_2(\theta)$.

Step 5: the bilinear map. We specify the expansion of N_2 by explicit rules, so that no choice of polarization is left to later applications. We write $T_\eta = \prod_{j=1}^3 T_j^{\eta_j}$ for $\eta \in \mathbb{Z}^3$, and apply the rules in the following order.

(i) Expand $-C_0^*\mathfrak{q}$ using (24.5), the antisymmetric extension, and the six terms $[v_k, v_l]/2$, $k < l$. For each resulting outer ∇_j^* use, in the order displayed, the two terms

$$\nabla_j^*[u, v] = [\nabla_j^* u, T_j^{-1} v] + [u, \nabla_j^* v].$$

In the first of these terms, move the difference into the second entry of the bracket by antisymmetry, keeping the minus sign.

(ii) Expand $-D\mathfrak{q}(\theta)^* C_0\theta$ using the formula for the adjoint in part (3), writing each $v_{p,l}$ as its signed translated link variable and each component of $C_0\theta$ as $\nabla_i\theta_j - \nabla_j\theta_i$. Distribute the translations over the brackets.

(iii) Expand G_2 using $d_0^*\theta = -\sum_j \nabla_j^*\theta_j$, and distribute its two translations.

Within each rule, order the directions and the entries increasingly, and keep repeated terms. This produces one fixed finite list. Every entry is a numerical multiple of $[T_\eta\theta_i, T_\zeta\nabla_k\theta_j]$ or $[T_\eta\theta_i, T_\zeta\nabla_k^*\theta_j]$; these rules, and not a symmetrization, define the two entries. The product identity in rule (i) is exact, since both sides equal $[T_j^{-1}u, T_j^{-1}v] - [u, v]$. The number of entries and their integer translations do not depend on n or L. The finite sum is read componentwise, and each term carries the insertion in the output direction prescribed by its rule.

In this list, we replace the first entry of each bracket by au and the second by av, and divide by a^3. Since $\nabla_k = aD_{a,k}^+$ and $\nabla_k^* = -aD_{a,k}^-$, the result has the form (24.4), and $a^{-3}N_2(aA) = \mathcal{N}_a(A, A)$ because the list is an exact expansion of the quadratic map N_2. The inequality $|[X, Y]| \le |X||Y|$ and the fact that translations are isometries give the bound in (24.4). A further forward difference of a bracket is distributed by

$$D_{a,k}^+[u, v] = \frac{[T_k u, T_k v] - [u, v]}{a} = [D_{a,k}^+ u, T_k v] + [u, D_{a,k}^+ v],$$

and a backward difference by $D^-_{a,k}[u,v] = [D^-_{a,k}u, T_k^{-1}v] + [u, D^-_{a,k}v]$. Iterating, we obtain the exact rules at each fixed order.

Step 6: the remainder. The logarithmic velocity $\mathcal{J}(\theta)^{-1}(-4\nabla E_W + G_U\phi)$ at a link is an analytic function of the link variables in a fixed finite neighborhood of that link, with the same form at every link. Indeed, the gradient of E_W at a link involves the four plaquettes containing it, and ϕ involves the links at the two endpoints. By Step 2, by the analyticity of $\mathcal{J}^{-1}$ and of Ad near the identity, and by the Cauchy estimates on a fixed complex polydisc, R_3 is a local analytic map whose homogeneous parts satisfy $\|P_{m,e}\|_{\text{coeff}} \le K_0 K_1^m$. Its Taylor coefficients vanish through degree two by Steps 3 and 4. For $0 < a \le 1$ we have

$$a^{-3}R_{3,e}(aA) = \sum_{m\ge 3} a^{m-3}P_{m,e}(A), \qquad \|P_{m,e}\|_{\text{coeff}} \le K_0 K_1^m, \tag{24.7}$$

where $P_{m,e}$ is homogeneous of degree m in the stencil of e. We choose r_* so that $K_1 r_* \le \eta < 1$ for a fixed η. Lemma 24.1 with $a = 1$ implies the two bounds on R_3 in part (5). Explicitly, by Taylor's formula with integral remainder, we have

$$|R_{3,e}(\theta)| \le C \max_f |\theta_f|^3, \qquad \|DR_{3,e}(\theta)\| \le C \max_f |\theta_f|^2,$$

where the maxima are over the stencil of e. Integrating the second bound along the segment from θ' to θ, which stays in the chart, and using $((1-u)b + uc)^2 \le b^2 + c^2$ for $b, c \ge 0$, we obtain the difference bound. Bounded incidence makes the constants independent of the number of links. Lemma 24.1 with $0 < a \le 1$ implies the bounds on the physical remainder. On $K_1 a\|A\|_\infty \le \eta$, its jth field derivative is at most $C_{j,\eta}\|A\|_\infty^{3-j}$ for $j \le 3$ and $C_{j,\eta}a^{j-3}$ for $j > 3$, and its spatial differences are finite sums of products of differences of A with these field derivatives, with no inverse power of a left over. The factors a^{m-3} in (24.7) are nonnegative powers of a for $m \ge 3$ and $a \le 1$.

Step 7: identification with the Wilson flow. On a finite lattice the Wilson vector field is smooth and gauge equivariant: the energy is gauge invariant, and the product metric is invariant under the action of each fixed gauge transformation. Let A be as in part (6). We solve $\dot{k}_x k_x^{-1} = \lambda_x$ with $\lambda = a^{-2}\phi(aA)$ and $k_x(0) = I$. The matrix integral equation has a convergent Picard series on every bounded time interval, since its mth iterated integral is at most $(\int\|\lambda\|)^m/m!$. Since λ_x is skew-Hermitian and traceless, $k_x^* k_x = I$ and $\det k_x = 1$ are preserved, and periodic coefficients give a periodic gauge transformation. In the variable $s = t/a^2$, the substitution $\theta = aA$ turns the equation of part (6) into $\partial_s\theta = -H_0\theta + N_2(\theta) + R_3(\theta)$, which by part (3) says that the links $U(t) = e^{aA(t)}$ move with velocity equal to the Wilson velocity (with factor $4/a^2$ in the variable t) plus the gauge velocity generated by λ. Differentiating $k_x^{-1}U_{xy}k_y$ cancels the gauge velocity, and the remaining velocity is the Wilson vector field with factor $4/a^2$,

by gauge equivariance; the initial links are $e^{aA(0)}$. By uniqueness for this smooth finite-dimensional ordinary differential equation (for example by the local Lipschitz integral inequality), $k^{-1}Uk = \Psi_t^{(n)}(e^{aA(0)})$, which is the claimed formula. The chart is needed only to define the damping generator, and no coupling enters. □

Substituting $\theta = aA$ and $s = t/a^2$ into part (3) shows that the equation of part (6) is (24.1) with $F_a(A) = a^{-3}R_3(aA)$, without approximation. We call the solution A in part (6) the *damped representative* of the Wilson flow started from $e^{aA(0)}$, and k its *damping gauge transformation*. The gauge velocity added in part (3) is the lattice analogue of the gauge damping of Zwanziger [157] and DeTurck [66]. By (24.5), $\phi = -d_0^*\theta = \sum_j \nabla_j^*\theta_j$, so the generator of the damping gauge transformation, which we call the *physical damping generator*, is

$$\lambda_a = a^{-2}\phi(aA) = -\sum_j D^-_{a,j}A_j, \tag{24.8}$$

a linear function of A.

24.2 Linear and quadratic flow data

We recall the weighted norms of Definition 4.8. Throughout the rest of this section $1/2 < \alpha < 2/3$, and

$$\beta = \alpha - \tfrac{1}{2}, \qquad \kappa = 1 - \tfrac{3}{2}\alpha;$$

in the applications $\alpha = \alpha_{\mathrm{fl}}$. Fix a horizon $T > 0$ and write $v_a(t) = t + a^2$. For paths x, y on $[0,T]$ with values in fields on Λ_n, and for a field f, set

$$\begin{aligned}
\mathsf{X}^a_\alpha(x) &= \sup_{0\le t\le T}\big\{v_a(t)^{\alpha/2}\|x(t)\|_\infty + v_a(t)^{(\alpha+1)/2}\|D_a x(t)\|_\infty\big\},\\
\mathsf{Y}^a_\alpha(y) &= \sup_{0\le t\le T}\big\{v_a(t)^{\beta}\|y(t)\|_\infty + v_a(t)^{\alpha}\|D_a y(t)\|_\infty\big\},\\
\mathsf{H}^a_\sigma(f) &= \sup_{0\le t\le T}\big\{v_a(t)^{\sigma/2}\|P^a_t f\|_\infty + v_a(t)^{(\sigma+1)/2}\|D_a P^a_t f\|_\infty\big\}, \qquad 0<\sigma<1-\alpha.
\end{aligned} \tag{24.9}$$

The horizon is part of the norms; when it matters we say that a bound holds on $[0,T]$. Each norm controls a value and every first difference, and translations do not change it. For paths u, v we write

$$\mathcal{Q}_a(u,v)(t) = \int_0^t P^a_{t-s}\mathcal{N}_a\big(u(s),v(s)\big)\,ds, \qquad \mathcal{B}_a(u,v) = \mathcal{Q}_a(u,v) + \mathcal{Q}_a(v,u),$$

with the bilinear map $\mathcal{N}_a$ of Lemma 24.2; in general $\mathcal{Q}_a(u,v) \neq \mathcal{Q}_a(v,u)$.

Definition 24.3. Fix $L, T > 0$ and α as above. Let $a = L/n$ and let A_0 be a field on Λ_n. The *flow data* of A_0 on $[0,T]$ are the linear heat evolution and the quadratic Picard term

$$x_a(t) = P^a_t A_0, \qquad y_a(t) = \mathcal{Q}_a(x_a,x_a)(t), \qquad 0 \le t \le T,$$

and we write $\|(x_a, y_a)\|_{\mathrm{fl},a} = \mathsf{X}^a_\alpha(x_a) + \mathsf{Y}^a_\alpha(y_a)$. The equation associated with A_0 is

$$\partial_t A = \Delta_a A + \mathcal{N}_a(A, A) + a^{-3} R_3(aA), \qquad A(0) = A_0, \tag{24.10}$$

considered as long as $a\|A(t)\|_\infty < r_*$. Differences of flow data on the same lattice are measured by the same two norms applied to the differences of the paths.

For comparisons between different lattices, let I_a be the continuous cardinal interpolation of Lemma 16.3 on Λ_n, applied to each component of a field on positive links, each link being anchored at its starting vertex. It is applied to the value array of a path and, separately, to each of its difference arrays $D^\pm_{a,j}$. For flow data (x, y) on the mesh a and $(\widetilde{x}, \widetilde{y})$ on the mesh $\widetilde{a}$, set

$$\begin{aligned} d_T\big((x,y),(\widetilde{x},\widetilde{y})\big) = \sup_{0<t\le T} \Big\{ & t^{\alpha/2}\|I_a x(t) - I_{\widetilde{a}}\widetilde{x}(t)\|_\infty \\ & + t^{(\alpha+1)/2} \max_{j,\pm} \|I_a(D^\pm_{a,j}x(t)) - I_{\widetilde{a}}(D^\pm_{\widetilde{a},j}\widetilde{x}(t))\|_\infty \\ & + t^{\beta}\|I_a y(t) - I_{\widetilde{a}}\widetilde{y}(t)\|_\infty \\ & + t^{\alpha} \max_{j,\pm} \|I_a(D^\pm_{a,j}y(t)) - I_{\widetilde{a}}(D^\pm_{\widetilde{a},j}\widetilde{y}(t))\|_\infty \Big\}. \end{aligned} \tag{24.11}$$

The interpolated difference array $I_a(D^\pm_{a,j}x)$ is a separate component of this comparison; it is not the derivative of $I_a x$. The definition involves neither a choice of gauge nor a comparison of the maps $\mathcal{N}_a$ on different lattices.

We record four elementary properties.

Interpolation. The one-dimensional cardinal weight ζ of Lemma 16.3 is nonnegative and satisfies $\sum_{m\in\mathbb{Z}} \zeta(u-m) = 1$. Multiplying three such identities and periodizing shows that the weights in each row of I_a are nonnegative and sum to one, so $\|I_a f\|_\infty \le \|f\|_\infty$. This applies separately to each difference component, and it uses no derivative estimate for an interpolant. The maps I_a do not depend on time.

Behavior at time zero. On a fixed lattice all arrays are finite dimensional and the heat matrices are continuous in t, so $x(t)$, $D^\pm_{a,j}x(t)$, $y(t)$, and $D^\pm_{a,j}y(t)$ are continuous and bounded on $[0, T]$. Since the four weights in (24.11) have positive exponents, each weighted component of d_T extends continuously by zero to $t = 0$.

Comparison of weights. Since $t^c \le (t + a^2)^c$ for $c > 0$, the interpolation bound implies

$$\begin{aligned} \sup_{0<t\le T} \Big\{ & t^{\alpha/2}\|I_a x(t)\|_\infty + t^{(\alpha+1)/2} \max_{j,\pm} \|I_a(D^\pm_{a,j}x(t))\|_\infty \\ & + t^{\beta}\|I_a y(t)\|_\infty + t^{\alpha} \max_{j,\pm} \|I_a(D^\pm_{a,j}y(t))\|_\infty \Big\} \le \|(x,y)\|_{\mathrm{fl},a}. \end{aligned}$$

In particular, bounds in the norms with weights $t + a^2$ imply bounds in the weights of d_T; the reverse does not hold uniformly near $t = 0$. The local existence arguments below use the norms with weights $t + a^2$.

Exactness. On a fixed lattice, the substitution $\theta = aA$, $s = t/a^2$ in Lemma 24.2(3) gives (24.10) without approximation, and the quadratic Duhamel term generated by A_0 in this equation is y_a, with the map $\mathcal{N}_a$ fixed there.

24.3 Local existence for the Wilson flow

We first explain the choice of exponents. Suppose that a field satisfies $\|A(t)\|_\infty \lesssim t^{-\alpha/2}$ and $\|D_a A(t)\|_\infty \lesssim t^{-(\alpha+1)/2}$, as the linear heat evolution of initial data of regularity $-\alpha$ does. Then the sources in (24.10) have the following sizes:

source	size	integrable at $t = 0$
$\mathcal{N}_a(A, A)$	$t^{-\alpha-1/2}$	no, since $\alpha > 1/2$
$a^{-3}R_3(aA)$	$t^{-3\alpha/2}$	yes, since $\alpha < 2/3$

The Duhamel integral of the cubic term has size $t^{1-3\alpha/2} = t^\kappa$. The quadratic term is too singular to be integrated with these bounds, and its Duhamel integral cannot be estimated from bounds on x_a alone. This is why the quadratic Picard term y_a is part of the data: it is the Duhamel integral of the most singular source, and in the applications its bound is proved in Sections 26 to 28 using the probabilistic structure of x_a. After x_a and y_a are subtracted, every remaining source is bounded by a multiple of $(t + a^2)^{-3\alpha/2}$ (see the table in the proof below), and the remainder is of order $(t + a^2)^\kappa$. The restriction $\alpha > 1/2$ corresponds to the regularity of the initial data in the applications (see Section 3.5), and it makes $\beta = \alpha - 1/2$ positive.

Lemma 24.4. *Let $0 < p < 1$, $a^2 \le T \le 1/2$, and $K \ge 0$, and let f be a measurable path on $[0, T]$ with values in fields on Λ_n and $\|f(t)\|_\infty \le K(t + a^2)^{-p}$ for $0 \le t \le T$. Then $z(t) = \int_0^t P^a_{t-s} f(s)\, ds$ satisfies, for $0 \le t \le T$,*

$$\|z(t)\|_\infty \le C_{p,L} K (t + a^2)^{1-p}, \qquad \|D_a z(t)\|_\infty \le C_{p,L} K (t + a^2)^{1/2-p}. \tag{24.12}$$

One may take $C_{p,L} = 6(1 + C_L)/(1 - p)$, where C_L depends only on L; in particular $C_{p,L}$ is bounded uniformly for p in each interval $(0, 1 - \delta]$, $\delta > 0$.

Proof. Since the heat kernel is nonnegative with mass one, P^a_s contracts the supremum norm, and

$$\|z(t)\|_\infty \le K \int_0^t (s + a^2)^{-p}\, ds \le \frac{K}{1 - p} (t + a^2)^{1-p}.$$

By Lemma 16.1 with one difference and horizon one, $\|D_a P^a_s h\|_\infty \le C_L (s + a^2)^{-1/2} \|h\|_\infty$ for $0 \le s \le 1$, where C_L depends only on L; this applies since $0 \le t - s \le T \le 1/2$. Hence

$$\|D_a z(t)\|_\infty \le C_L K \int_0^t (t - s + a^2)^{-1/2} (s + a^2)^{-p}\, ds.$$

The integral is bounded by a multiple of $(t+a^2)^{1/2-p}$ by Lemma 16.8, whose hypotheses are $0 \le p < 1$ and exponent $1/2 < 1$. To see the dependence on p, we split the integral at $s = t/2$. For $s \le t/2$ we have $t - s + a^2 \ge (t+a^2)/2$, and the integral of $(s+a^2)^{-p}$ over $[0, t/2]$ is at most $(t+a^2)^{1-p}/(1-p)$. For $s \ge t/2$ we have $(s+a^2)^{-p} \le 2^p (t+a^2)^{-p}$, and the integral of $(t-s+a^2)^{-1/2}$ over $[t/2, t]$ is at most $2(t+a^2)^{1/2}$. Combining the two parts, we obtain

$$\int_0^t (t-s+a^2)^{-1/2}(s+a^2)^{-p}\,ds \le \Big(\frac{\sqrt{2}}{1-p} + 2^{p+1}\Big)(t+a^2)^{1/2-p} \le \frac{6}{1-p}(t+a^2)^{1/2-p}.$$

Measurable sources with the stated bound are integrable since $a > 0$, and no other property of f is used. □

Theorem 24.5. *Fix $L > 0$, $1/2 < \alpha < 2/3$, and $R < \infty$, and let $\kappa = 1 - 3\alpha/2$. There exist $T_R \in (0,1]$, $a_R > 0$, and $C_R < \infty$, depending only on L, α, R, and the stencil and chart of Lemma 24.2, such that the following holds for every mesh $a = L/n \le a_R$. Let A_0 be a field on Λ_n whose flow data on $[0, T_R]$ satisfy $\|(x_a, y_a)\|_{\mathrm{fl},a} \le R$. Then* (24.10) *has a unique solution on $[0, T_R]$ of the form $A_a = x_a + y_a + r_a$ with $r_a(0) = 0$ and finite remainder norm*

$$\|r\|_{\mathsf{R}_a} = \sup_{0 \le t \le T_R} \big\{ (t+a^2)^{-\kappa} \|r(t)\|_\infty + (t+a^2)^{1/2-\kappa} \|D_a r(t)\|_\infty \big\}, \tag{24.13}$$

and $\|r_a\|_{\mathsf{R}_a} \le C_R$. Uniqueness holds among mild solutions with these flow data and finite remainder norm.

Let A_0' be a second field on Λ_n whose flow data (x_a', y_a') satisfy the same bound, the two fields being compared as arrays, without a gauge transformation between them, and let $d_a = \mathsf{X}_\alpha^a (x_a - x_a') + \mathsf{Y}_\alpha^a (y_a - y_a')$. Then

$$\|r_a - r_a'\|_{\mathsf{R}_a} \le C_R d_a, \qquad \sup_{s \le t \le T_R} \|A_a(t) - A_a'(t)\|_{C_a^1} \le C_{R,s} d_a \qquad (0 < s < T_R).$$

After reducing a_R, the whole interval lies in the logarithm chart:

$$a \sup_{t \le T_R} \|A_a(t)\|_\infty \le R a^{1-\alpha} + R a^{2-2\alpha} + C_R a (T_R + a^2)^\kappa < r_*.$$

Consequently, by Lemma 24.2(6), $e^{aA_a(t)}$ is a periodic time-dependent gauge transform, equal to the identity at $t = 0$, of the Wilson flow $\Psi_t^{(n)}(e^{aA_0})$ at physical time t. The constants do not depend on the coupling, on n beyond the restriction $a \le a_R$, or on any probability law. They depend on R and s, and they are not uniform as $R \to \infty$ or $s \downarrow 0$.

Here a mild solution is a continuous path A on $[0, T_R]$ with $a\|A(t)\|_\infty < r_*$ and $A(t) = P_t^a A_0 + \int_0^t P_{t-s}^a (\mathcal{N}_a(A,A) + a^{-3} R_3(aA))(s)\,ds$. Uniqueness in Theorem 24.5 holds among the mild solutions A for which $A - x_a - y_a$ has finite remainder norm.

Proof. We construct r_a as the fixed point of a contraction on a ball for the norm (24.13). The equation for r is obtained by subtracting the equations satisfied by x_a and y_a; this removes the most singular source $\mathcal{N}_a(x_a, x_a)$. We then check, term by term, that the remaining sources are bounded by $(t + a^2)^{-3\alpha/2}$, choose the radius, the time, and the mesh threshold in this order, and prove uniqueness, Lipschitz dependence, and the chart bound. In Steps 2–6 the cubic term enters only through the bounds (24.15) on the set $\{B : a\|B\|_\infty \le r_*/2\}$; we use this in the proof of Theorem 24.12.

Step 1: bounds on the flow data. We write

$$\beta = \alpha - \tfrac{1}{2}, \qquad p = \tfrac{3}{2}\alpha < 1, \qquad \kappa = 1 - p, \qquad \delta = \frac{1-\alpha}{2} > 0.$$

We may assume $R \ge 0$, since otherwise no field satisfies the hypothesis. For a tentative $T \le 1/2$ and $a^2 \le T$, we set $v = t + a^2$. If the flow data satisfy $\|(x, y)\|_{\mathrm{fl},a} \le R$ on $[0, T]$, then

$$\begin{aligned} &\|x(t)\|_\infty \le R v^{-\alpha/2}, \quad \|D_a x(t)\|_\infty \le R v^{-(\alpha+1)/2}, \\ &\|y(t)\|_\infty \le R v^{-\beta}, \qquad \|D_a y(t)\|_\infty \le R v^{-\alpha}, \end{aligned} \tag{24.14}$$

and these bounds include all translations. Since $v \le 2T \le 1$ and $\alpha/2 - \beta = \delta > 0$, we have in particular $\|x(t) + y(t)\|_\infty \le 2R v^{-\alpha/2}$.

Step 2: the equation for the remainder. Recall that $F_a(A) = a^{-3} R_3(aA)$. We take $a \le 1$. By Lemma 24.2(5) and Lemma 24.1(1) and (3), on the set $\{B : a\|B\|_\infty \le r_*/2\}$,

$$\|F_a(B)\|_\infty \le C\|B\|_\infty^3, \qquad \|F_a(B) - F_a(B')\|_\infty \le C\big(\|B\|_\infty^2 + \|B'\|_\infty^2\big)\|B - B'\|_\infty, \tag{24.15}$$

with C independent of a. Since $\partial_t x = \Delta_a x$ and $\partial_t y = \Delta_a y + \mathcal{N}_a(x, x)$ with $x(0) = A_0$, $y(0) = 0$, the path $A = x + y + r$ solves (24.10) if and only if $r(0) = 0$ and $\partial_t r = \Delta_a r + \mathcal{N}_a(A, A) - \mathcal{N}_a(x, x) + F_a(A)$. Expanding $\mathcal{N}_a(A, A)$ by bilinearity, we obtain the source

$$\begin{aligned} \mathscr{F}_{x,y}(r) = {} & \mathcal{N}_a(x, y) + \mathcal{N}_a(y, x) + \mathcal{N}_a(y, y) \\ & + \mathcal{N}_a(x, r) + \mathcal{N}_a(r, x) + \mathcal{N}_a(y, r) + \mathcal{N}_a(r, y) + \mathcal{N}_a(r, r) + F_a(x + y + r), \end{aligned} \tag{24.16}$$

where every occurrence of $\mathcal{N}_a$ uses the bilinear map fixed in Lemma 24.2. The fixed-point equation is

$$\mathscr{M}_{x,y}(r)(t) = \int_0^t P^a_{t-s} \mathscr{F}_{x,y}(r)(s)\, ds, \qquad r = \mathscr{M}_{x,y}(r). \tag{24.17}$$

Step 3: bounds on the sources. If $\|r\|_{\mathsf{R}_a} \le S$, then $\|r(t)\|_\infty \le S v^\kappa$ and $\|D_a r(t)\|_\infty \le S v^{\kappa - 1/2}$. By (24.4), we have $\|\mathcal{N}_a(u, w)\|_\infty \le C\|u\|_\infty \|D_a w\|_\infty$. Together with (24.14), this

gives the following bounds for the quadratic sources, up to a constant depending only on the stencil:

source	amplitude	power of v
$\mathcal{N}_a(x,y),\ \mathcal{N}_a(y,x)$	R^2	$-p$
$\mathcal{N}_a(y,y)$	R^2	$-p+\delta$
$\mathcal{N}_a(x,r),\ \mathcal{N}_a(r,x)$	RS	$-p+\delta$
$\mathcal{N}_a(y,r),\ \mathcal{N}_a(r,y)$	RS	$-p+2\delta$
$\mathcal{N}_a(r,r)$	S^2	$-p+3\delta$

For example, in the third row $\mathcal{N}_a(x,r)$, with the difference on r, has exponent $-\alpha/2+\kappa-1/2 = 1/2-2\alpha = -p+\delta$, and $\mathcal{N}_a(r,x)$, with the difference on x, has exponent $\kappa-(\alpha+1)/2$, which is the same number. In the fourth row the exponents of $\mathcal{N}_a(y,r)$ and $\mathcal{N}_a(r,y)$ are $-\beta+\kappa-1/2$ and $\kappa-\alpha$, both equal to $-p+2\delta$. In the first row the exponents of $\mathcal{N}_a(x,y)$ and $\mathcal{N}_a(y,x)$ are $-\alpha/2-\alpha$ and $-\beta-(\alpha+1)/2$, both equal to $-p$. In this way each quadratic term is estimated with its arguments in the order displayed in (24.16).

By (24.14) and (24.15), the cubic source at $r=0$ is at most CR^3v^{-p}. For r, r' in the ball of radius S, by (24.15) we have

$$\begin{aligned}\|F_a(x+y+r)-F_a(x+y+r')\|_\infty &\le C\{R^2v^{-\alpha}+S^2v^{2\kappa}\}v^{\kappa}\|r-r'\|_{\mathsf{R}_a}\\ &\le C(R^2+S^2)v^{-p+2\delta}\|r-r'\|_{\mathsf{R}_a},\end{aligned}$$

where we used $-\alpha+\kappa=-p+2\delta$ and $v^{3\kappa}\le v^{-p+2\delta}$, the exponents differing by $2-2\alpha = 4\delta>0$, with $v\le 1$. Subtracting each quadratic row gives the same table with one factor S replaced by $\|r-r'\|_{\mathsf{R}_a}$. Bounding every positive extra power of v by its maximum on $[0,T]$, we obtain

$$\begin{aligned}\|\mathscr{F}_{x,y}(0)(t)\|_\infty &\le K_R v^{-p},\\ \|\mathscr{F}_{x,y}(r)(t)-\mathscr{F}_{x,y}(r')(t)\|_\infty &\le K_{R,S}(2T)^{\delta}v^{-p}\|r-r'\|_{\mathsf{R}_a},\end{aligned}\tag{24.18}$$

where K_R depends only on R and the stencil and chart, and $K_{R,S}$ depends in addition on S.

Step 4: choice of the parameters. By Lemma 24.4 with $p=3\alpha/2$,

$$\|\mathscr{M}_{x,y}(0)\|_{\mathsf{R}_a}\le C_{\alpha,L}K_R,\qquad \|\mathscr{M}_{x,y}(r)-\mathscr{M}_{x,y}(r')\|_{\mathsf{R}_a}\le C_{\alpha,L}K_{R,S}(2T)^{\delta}\|r-r'\|_{\mathsf{R}_a}.$$

We choose $S=1+2C_{\alpha,L}K_R$, and then $T_R\in(0,1/2]$ so that $C_{\alpha,L}K_{R,S}(2T_R)^{\delta}\le 1/2$. Neither choice involves the mesh. We then reduce a_R so that $a_R\le\min(1,\sqrt{T_R})$ and

$$Ra_R^{1-\alpha}+Ra_R^{2-2\alpha}+Sa_R(2T_R)^{\kappa}<r_*/2.\tag{24.19}$$

All three exponents of a_R are positive. Since $v\ge a^2$, we have $av^{-\alpha/2}\le a^{1-\alpha}$, $av^{-\beta}\le a^{2-2\alpha}$, and $av^{\kappa}\le a(2T_R)^{\kappa}$, so every candidate $x+y+r$ with $\|r\|_{\mathsf{R}_a}\le S$ satisfies $a\|x+y+r\|_\infty < r_*/2$ for $a\le a_R$. In particular, (24.15) is never used outside its domain.

Step 5: existence and uniqueness. On a fixed lattice, the continuous paths r on $[0, T_R]$ with $r(0) = 0$ and finite R_a norm form a complete space: v is bounded below by $a^2 > 0$, there are finitely many coordinates, and the differences are continuous linear maps. By Step 4 and the choice of S, $\mathscr{M}_{x,y}$ maps the closed ball of radius S into itself and is a contraction with constant $1/2$ there. Starting from zero, successive iterates differ by at most 2^{-m} times the first difference, so they converge in this space to a fixed point. The same estimate gives uniqueness inside the ball. The heat convolution vanishes at $t = 0$, so $r(0) = 0$. This constructs the solution, and we take $C_R \geq S$.

Uniqueness in the larger class of the theorem does not require an a priori bound on the radius of a second remainder. On a fixed lattice, a continuous mild solution in the chart is differentiable, since its heat integral is finite dimensional, and it satisfies the ordinary differential equation (24.10). On a compact subinterval of the time interval on which both solutions stay in the chart, the analytic vector field has a finite Lipschitz constant K_a. For two solutions with the same initial value, $\sup_{u \leq t} |A(u) - A'(u)| \leq K_a t \sup_{u \leq t} |A(u) - A'(u)|$. Taking $K_a t < 1$ and restarting at time t proves equality on that interval, and finitely many such intervals give equality on the whole common interval. The flow data are determined by the initial value, so this proves uniqueness among mild solutions with the given flow data and finite remainder norm. The argument needs no bound on K_a that is uniform in a.

Step 6: Lipschitz dependence. For two flow data in the ball, (24.14) applies to their differences with R replaced by d_a. In each quadratic term of (24.16), we write the difference by changing first the first argument and then the second. The first three terms are then bounded by $C_R d_a v^{-p}$, and the terms involving a fixed remainder of norm at most S by $C_{R,S} d_a v^{-p}$, since $v \leq 1$. For the cubic term, the difference of $x + y$ is at most $2 d_a v^{-\alpha/2}$ and both arguments are bounded by $(2R + S) v^{-\alpha/2}$, so by (24.15) its difference is also at most $C_{R,S} d_a v^{-p}$. Writing $r - r' = (\mathscr{M}_{x,y}(r) - \mathscr{M}_{x',y'}(r)) + (\mathscr{M}_{x',y'}(r) - \mathscr{M}_{x',y'}(r'))$ and applying Lemma 24.4 to the first difference and the contraction estimate to the second, we obtain

$$\|r - r'\|_{\mathsf{R}_a} \leq C_{R,S,\alpha,L} d_a + \tfrac{1}{2} \|r - r'\|_{\mathsf{R}_a}.$$

We enlarge C_R to absorb the factor two. On $[s, T_R]$ all weights in (24.14) and in (24.13) are bounded by constants depending only on s, R, α, and L. Adding the bounds for $x - x'$, $y - y'$, and $r - r'$, we obtain the estimate for $\|A(t) - A'(t)\|_{C^1_a}$.

Step 7: the chart and the identification. Since the value bounds for x and y decrease in time and the value bound for the remainder increases, we have

$$a \sup_{t \leq T_R} \|x(t) + y(t) + r(t)\|_\infty \leq R a^{1-\alpha} + R a^{2-2\alpha} + C_R a (T_R + a^2)^\kappa.$$

If necessary we reduce a_R again after the last enlargement of C_R, so that this bound is less than r_* on the whole interval. The last term is of order a; it is not replaced by its smaller

value at $t = 0$. Part (6) of Lemma 24.2 now applies on $[0, T_R]$ and identifies $e^{aA_a(t)}$ with the gauge transform of the Wilson flow by the periodic damping gauge transformation, which is the identity at $t = 0$. All choices above have the stated dependence. The proof gives $T_R \le 1/2$ and $a_R \le \min(1, \sqrt{T_R})$. □

24.4 Bilinear estimates for the Duhamel integral

The probabilistic estimates of Sections 26 to 28 decompose the flow data into many pieces and estimate the Duhamel terms of their products. The following lemma bounds such a term when one argument is a heat path with the regularity of x_a and the other a heat path with the better exponent $\sigma < 1 - \alpha$. Since $\mathcal{N}_a$ is not symmetric, we estimate $\mathcal{Q}_a(u, v)$ and $\mathcal{Q}_a(v, u)$ separately.

Lemma 24.6. *Fix $L, T > 0$, $1/2 < \alpha = \alpha_{\mathrm{fl}} < 2/3$, and $0 < \sigma < 1 - \alpha$. For every mesh $a = L/n$, $n \ge 4$, and all fields f, g on Λ_n, let $u(t) = P_t^a f$ and $v(t) = P_t^a g$. Then, with the norms* (24.9) *on $[0, T]$,*

$$\mathsf{Y}_\alpha^a\big(\mathcal{Q}_a(u, v)\big) + \mathsf{Y}_\alpha^a\big(\mathcal{Q}_a(v, u)\big) \le C_{L,T,\alpha,\sigma}(T + a^2)^{(\alpha-\sigma)/2}\, \mathsf{X}_\alpha^a(u)\, \mathsf{H}_\sigma^a(g).$$

In particular the same right side bounds $\mathsf{Y}_\alpha^a(\mathcal{B}_a(u, v))$. The constant depends only on L, T, α, σ, and the stencil of $\mathcal{N}_a$; it does not depend on the mesh, the fields, the coupling, or any probability law. The estimate includes $t = 0$, all translations in the stencil, and every first difference. For $a \le 1$ it follows from heat kernel estimates uniformly in a; the finitely many lattices with $1 < a \le L/4$ are included by a finite maximum.

Proof. We first assume $a \le 1$. The horizon T is the same in the norms and in Lemma 16.1; every heat time below is $t - s \in [0, T]$, so the heat estimates are used only on this fixed horizon, with the constant mode included. Let $w(t) = t + a^2$, $K_u = \mathsf{X}_\alpha^a(u)$, and $K_g = \mathsf{H}_\sigma^a(g)$. By the definition of the norms, for $0 \le s \le T$,

$$\begin{aligned} \|u(s)\|_\infty &\le K_u w(s)^{-\alpha/2}, \quad \|D_a u(s)\|_\infty \le K_u w(s)^{-(\alpha+1)/2}, \\ \|v(s)\|_\infty &\le K_g w(s)^{-\sigma/2}, \quad \|D_a v(s)\|_\infty \le K_g w(s)^{-(\sigma+1)/2}. \end{aligned}$$

By (24.4), both $\mathcal{N}_a(u(s), v(s))$ and $\mathcal{N}_a(v(s), u(s))$ are bounded by $C K_u K_g w(s)^{-p}$, where

$$p = \frac{\alpha + \sigma + 1}{2} < 1.$$

The bound for $\mathcal{N}_a(u(s), v(s))$ uses the displayed bound on $D_a v$, and the bound for $\mathcal{N}_a(v(s), u(s))$ uses the displayed bounds on v and $D_a u$.

By Lemma 16.1 with zero and one difference, for either Duhamel term z,

$$\|z(t)\|_\infty \le C K_u K_g \int_0^t w(s)^{-p}\, ds \le C K_u K_g w(t)^{1-p},$$

$$\|D_a z(t)\|_\infty \le C_{L,T} K_u K_g \int_0^t (t - s + a^2)^{-1/2} w(s)^{-p}\, ds \le C_{L,T,p} K_u K_g w(t)^{1/2-p}.$$

In the last inequality we used Lemma 16.8, whose hypotheses are $0 < p < 1$ and exponent $1/2 < 1$. The weight of the value in Y_α^a adds $\beta = \alpha - 1/2$, and the weight of the difference adds α; both resulting powers of $w(t)$ equal $(\alpha - \sigma)/2 > 0$. Their suprema on $[0, T]$ are bounded by $(T + a^2)^{(\alpha-\sigma)/2}$. At $t = 0$ both integrals vanish. Every translation in the stencil is an isometry and commutes with the heat semigroup and with differences. Adding the bounds for $\mathcal{Q}_a(u, v)$ and $\mathcal{Q}_a(v, u)$ proves the inequality, and the triangle inequality implies the bound for $\mathcal{B}_a$. For $a \le 1$ the constant consists of the constant of the stencil, the two heat kernel constants on the horizon T, and the constant of the scalar convolution estimate.

It remains to include $a > 1$ at the fixed side L. Let

$$\mathcal{I}_L = \{n \in \mathbb{N} : 4 \le n < L\}, \qquad a_n = L/n.$$

This finite set consists of the possible coarse lattices, and it is empty when $L \le 4$. The formula (24.4) and its bound hold for every $a > 0$, since they use no smallness of a; let C_{st} be the constant in that bound. For every field h, each difference satisfies $\|D^{\pm}_{a,j} h\|_\infty \le 2a^{-1}\|h\|_\infty$, since translations preserve the supremum, and the heat semigroup contracts the supremum. Hence, for the two argument orders displayed below,

$$\|\mathcal{N}_a(P_s^a f, P_s^a g)\|_\infty,\ \|\mathcal{N}_a(P_s^a g, P_s^a f)\|_\infty \le 2C_{\mathrm{st}} a^{-1}\|f\|_\infty \|g\|_\infty.$$

For either Duhamel term z, we obtain

$$\|z(t)\|_\infty \le 2C_{\mathrm{st}} T a^{-1}\|f\|_\infty\|g\|_\infty, \qquad \|D_a z(t)\|_\infty \le 2a^{-1}\|z(t)\|_\infty,$$

and the second inequality holds for all translated difference components. With $\beta = \alpha - 1/2 > 0$ and $\eta = (\alpha - \sigma)/2 > 0$, the two weights of Y_α^a are maximal at $t = T$. The terms at $t = 0$ of the input norms give $K_u \ge a^\alpha \|f\|_\infty$ and $K_g \ge a^\sigma \|g\|_\infty$. The sum of the two output norms is then at most

$$4C_{\mathrm{st}} T a^{-1-\alpha-\sigma}\big\{(T + a^2)^\beta + 2a^{-1}(T + a^2)^\alpha\big\} K_u K_g. \tag{24.20}$$

We define

$$C_{\mathrm{coarse}} = \max_{n \in \mathcal{I}_L} 4C_{\mathrm{st}} T a_n^{-1-\alpha-\sigma}\big\{(T + a_n^2)^{\beta-\eta} + 2a_n^{-1}(T + a_n^2)^{\alpha-\eta}\big\},$$

with value zero if $\mathcal{I}_L$ is empty. It is finite and depends only on L, T, α, σ, and the stencil, and (24.20) is at most $C_{\mathrm{coarse}}(T + a^2)^\eta K_u K_g$ on every coarse lattice. Taking the maximum of C_{coarse} and the constant for $a \le 1$ proves the lemma. □

24.5 Gauge transformations, energy, and loop observables

We next control changes of gauge, holonomies, the lattice energy, and exponential transforms of bounded observables.

For a closed lattice path based at z, the holonomy of a configuration changes by conjugation at z under a lattice gauge transformation, so only conjugation-invariant functions of it, such as characters, are gauge invariant. For a smooth connection b and a smooth gauge transformation k we use $b^k = kbk^{-1} - (dk)k^{-1}$, as in Definition 4.10, and we write $b|_a$ for the field $(b|_a)_i(x) = b_i(x)$ obtained by restriction to the sites. The parallel transport along a path ℓ solves $H'(s) = H(s)b(\ell(s))\dot{\ell}(s)$, $H(0) = I$.

Lemma 24.7. *The following deterministic statements hold on the periodic lattice.*

1. *Let k be a smooth periodic gauge transformation and b a smooth connection. For a field A define*
$$\mathscr{G}_{a,k}(A)_i(x) = a^{-1}\operatorname{Log}\big(k(x)e^{aA_i(x)}k(x+ae_i)^{-1}\big),$$
the logarithm of the lattice gauge transform of e^{aA} by the restriction of k to the sites. On every fixed ball $\{\|A\|_{C^1_a} \le \rho\}$, for sufficiently small a,
$$\|\mathscr{G}_{a,k}(A) - \mathscr{G}_{a,k}(A')\|_{C^1_a} \le C_k\|A - A'\|_{C^1_a}, \qquad \|\mathscr{G}_{a,k}(b|_a) - (b^k)|_a\|_{C^1_a} \le C_{k,b}a.$$
The constants and the threshold for a depend on ρ, $\|k\|_{C^3}$, and, for the second bound, $\|b\|_{C^2}$; they do not depend on the mesh. For a coordinate edge from x to $x + ae_i$, the parallel transport of b along the edge and $e^{ab_i(x)}$ differ by at most $C\|b\|_{C^1}a^2$ in operator norm. The products of these matrices along a lattice path of physical length at most ℓ differ by at most $C_{\ell,b}a$, and so do their normalized traces.
2. *Let A_a and A'_a be the solutions of Theorem 24.5 for two fields A_0, A'_0 on the same lattice, compared as arrays, and let d_a be as there. For every closed lattice path of physical length at most ℓ and $s \le t \le T_R$, the normalized traces of the holonomies of $\Psi^{(n)}_t(e^{aA_0})$ and $\Psi^{(n)}_t(e^{aA'_0})$ along the path differ by at most $C_{R,s,\ell}d_a$. Moreover,*
$$\|D_a(A_a - A'_a)(t)\|_\infty \le C_R d_a\big\{(t+a^2)^{-(\alpha+1)/2} + (t+a^2)^{-\alpha} + (t+a^2)^{\kappa-1/2}\big\}.$$
Let $\lambda_a = a^{-2}\phi(aA_a)$ and λ'_a be the physical damping generators (24.8) *of the two solutions. Then $\|\lambda_a - \lambda'_a\|_\infty \le C\|D_a(A_a - A'_a)\|_\infty$ and $\int_0^{T_R}\|\lambda_a(t) - \lambda'_a(t)\|_\infty\,dt \le C_R d_a$, uniformly in a. The two damping gauge transformations $k, \widetilde{k}$ of Lemma 24.2(6), both equal to the identity at $t = 0$, satisfy $\|k_x(t) - \widetilde{k}_x(t)\|_{\mathrm{op}} \le C_R d_a$ for every site x and $0 \le t \le T_R$. For a closed path based at z, the holonomies $H_{\mathrm{d}}(t)$ of the damped links $e^{aA_a(t)}$ and $H_{\mathrm{W}}(t)$ of $\Psi^{(n)}_t(e^{aA_0})$ satisfy $H_{\mathrm{d}}(t) = k_z(t)H_{\mathrm{W}}(t)k_z(t)^{-1}$. Consequently the based holonomy matrices of the two Wilson flows along such a path differ by at most $C_{R,s,\ell}d_a$ for $s \le t \le T_R$.*

The constants in part (2) have the dependence of Theorem 24.5, and depend in addition on s and ℓ as indicated.

Proof. We use the operator norm for matrix products; it is equivalent to the norm on $\mathfrak{su}(2)$ with numerical constants.

Part (1): smooth gauge transformations. We define

$$h_{a,i}(x) = k(x)k(x + ae_i)^{-1}, \qquad q_{a,i}(x) = a^{-1} \operatorname{Log} h_{a,i}(x).$$

These are defined for all sufficiently small a, depending on $\|k\|_{C^1}$ and a fixed margin of the logarithm chart. We claim that $\|q_{a,i}\|_{C^2} \le C_k$ and

$$\|q_{a,i} + (\partial_i k)k^{-1}\|_{C^1} \le C_k a, \tag{24.21}$$

where here and below C^j norms of functions depending on the parameter a are norms of continuous functions on $\mathbb{T}^3_L$, taken before restriction to the sites. To verify this without dividing a remainder by a, we set $h_i(u,x) = k(x)k(x+ue_i)^{-1}$. Then $h_i(0,x) = I$ and $\partial_u h_i(0,x) = -(\partial_i k)k^{-1}$. Taylor's formula with integral remainder for $\operatorname{Log} h_i(u,x)$ in u gives (24.21), using two derivatives in u and one in x. For the bound in C^2, we use instead $q_{a,i} = \int_0^1 \partial_u \operatorname{Log} h_i(ua,x)\,du$ with two spatial derivatives. These derivatives involve at most three derivatives of k; since $k^{-1} = k^*$, the inverse has the same derivative bounds.

Let $B_i(x) = \operatorname{Ad}(k(x))A_i(x)$. The transformed link is $k(x)e^{aA_i(x)}k(x+ae_i)^{-1} = e^{aB_i(x)}e^{aq_{a,i}(x)}$. The function

$$F_a(B,q) = a^{-1}\operatorname{Log}\bigl(e^{aB}e^{aq}\bigr) = B + q + aK_a(B,q)$$

has a removable singularity at $a = 0$, and K_a and its derivatives of fixed order are bounded on each fixed bounded set of (B,q), for sufficiently small a. Indeed, the convergent product and logarithm series have linear term $a(B+q)$, all other terms carry at least a^2, and their geometric majorants can be differentiated on a smaller ball. We conclude that $\mathscr{G}_{a,k}(A)_i(x) = F_a(B_i(x), q_{a,i}(x))$, and the transformed links lie in the logarithm chart.

For the first bound of part (1), let A, A' lie in the ball. Then B, D_aB, and the corresponding quantities for A' are bounded in terms of ρ and k. We write

$$F_a(B,q) - F_a(B',q) = \int_0^1 \partial_B F_a\bigl(B' + u(B-B'),q\bigr)(B-B')\,du.$$

By the shifted product rule, a difference D_a of this expression falls either on $B - B'$ or on the coefficient under the integral. In the second case, the integral form of the chain rule used in the proof of Lemma 24.1 bounds it by $C(\|D_aB\|_\infty + \|D_aB'\|_\infty + \|D_aq\|_\infty)\|B - B'\|_\infty$. It follows that the C^1_a norm of the difference is at most $C_k\|A - A'\|_{C^1_a}$. Forward and backward differences obey the same calculation, with a backward translation in place of a forward one. For a sample $A = b|_a$ of a smooth connection, (24.21) in $F_a = B + q + aK_a$ shows that $\mathscr{G}_{a,k}(b|_a)_i$ is the restriction of $\operatorname{Ad}(k)b_i - (\partial_i k)k^{-1} + O_{k,b}(a) = (b^k)_i + O_{k,b}(a)$, the error being of order a in continuous C^1. Restriction to the sites preserves this bound for both differences, since $D^+_{a,j}f(x) = \int_0^1 \partial_j f(x + uae_j)\,du$ and the backward difference is the average of $\partial_j f$ over the preceding segment. This proves both bounds.

For the transport, let $V(s)$ solve $V' = Vb_i(x + se_i)$, $V(0) = I$, and let $E(s) = e^{sb_i(x)}$. The derivative of $V(s)E(a-s)$ is $V(s)(b_i(x+se_i) - b_i(x))E(a-s)$, whose outer factors are unitary. Integrating from 0 to a, we obtain

$$\|V(a) - E(a)\|_{\mathrm{op}} \le \int_0^a \|b_i(x+se_i) - b_i(x)\|_{\mathrm{op}}\, ds \le Ca^2\|b\|_{C^1}.$$

Reversed edges use inverses, and $\|V^{-1} - E^{-1}\| = \|V - E\|$. For a product of m such factors, we replace the factors one at a time; the other factors are unitary, so the errors add up to at most $mCa^2\|b\|_{C^1}$, and $ma \le \ell$ gives $C_{\ell,b}a$. A normalized trace has absolute value at most the operator norm, so the same bound holds for traces.

Part (2): holonomies and damping gauge transformations. For skew-Hermitian X, Y, differentiating $e^{(1-u)X}e^{uY}$ in u, we find

$$e^X - e^Y = \int_0^1 e^{(1-u)X}(X - Y)e^{uY}\, du,$$

and hence $\|e^{aA_e} - e^{aA'_e}\|_{\mathrm{op}} \le Ca|A_e - A'_e|$; inverses satisfy the same bound. Telescoping along a closed path with at most ℓ/a links, we obtain the bound $C\ell\|A(t) - A'(t)\|_\infty$ for the difference of the holonomies of the damped links. By Theorem 24.5 on $[s, T_R]$, this is at most $C_{R,s,\ell}d_a$. The holonomy of the Wilson flow is conjugate to the damped holonomy at the basepoint, so the two have the same trace, and the trace bound follows.

Before the time weights are suppressed, Step 6 of the proof of Theorem 24.5 gives exactly

$$\|D_a(A - A')(t)\|_\infty \le C_R d_a\big\{(t+a^2)^{-(\alpha+1)/2} + (t+a^2)^{-\alpha} + (t+a^2)^{\kappa-1/2}\big\},$$

the three terms coming from $x - x'$, $y - y'$, and $r - r'$. By (24.8), the damping generator is a linear combination of differences of A, so $\|\lambda_a - \lambda'_a\|_\infty$ is at most a numerical constant times the last display. The three negative powers have exponents $(\alpha+1)/2$, α, and $1/2 - \kappa$, all strictly less than one. For $0 \le q < 1$,

$$\int_0^{T_R} (t+a^2)^{-q}\, dt \le \int_0^{T_R} t^{-q}\, dt = \frac{T_R^{1-q}}{1-q},$$

which yields the bound on the integral of $\|\lambda_a - \lambda'_a\|_\infty$, uniformly in a.

Let k and $\widetilde{k}$ solve $\dot{k} = \lambda k$ and $\dot{\widetilde{k}} = \lambda'\widetilde{k}$ with identity initial values. Direct differentiation gives

$$\frac{d}{dt}\big(k^{-1}\widetilde{k}\big) = k^{-1}(\lambda' - \lambda)\widetilde{k},$$

and the outer factors are unitary. Integrating, we obtain $\sup_x\|k_x(t) - \widetilde{k}_x(t)\|_{\mathrm{op}} = \sup_x\|I - k_x(t)^{-1}\widetilde{k}_x(t)\|_{\mathrm{op}} \le \int_0^t\|\lambda - \lambda'\|_\infty \le C_R d_a$. No exponential factor depending

on the individual generators appears. For a closed path based at z, the damped links are $k_x U_{xy} k_y^{-1}$ by Lemma 24.2(6), so $H_{\mathrm{d}} = k_z H_{\mathrm{W}} k_z^{-1}$. Undoing the two dampings adds at most $2\|k_z - \widetilde{k}_z\|_{\mathrm{op}} \le 2C_R d_a$ to the difference of the damped holonomies, which implies the bound for the based holonomy matrices of the Wilson flows. Here we used that both damping gauge transformations start at the identity. □

Lemma 24.8. *Write*

$$\mathcal{E}_a(U) = \frac{4}{a}\sum_p q(U_p), \qquad F_{a,p} = a^{-2}\operatorname{Log} U_p, \qquad \|F_a\|_{2,a}^2 = a^3\sum_p |F_{a,p}|^2.$$

There exist numerical constants $n_{\mathrm{cov}}, r_{\mathrm{cov}}, c_0, c, C > 0$ such that the following holds for $n \ge n_{\mathrm{cov}}$. If $|\operatorname{Log} U_p| \le r_{\mathrm{cov}}$ for every plaquette, then $c\|F_a\|_{2,a}^2 \le \mathcal{E}_a(U) \le C\|F_a\|_{2,a}^2$. The Wilson flow $U(t) = \Psi_t^{(n)}(U(0))$ exists for all $t \ge 0$, and $\mathcal{E}_a(U(t))$ is nonincreasing. If the plaquette bound holds at a time t_0, $\mathcal{E}_a(U(t_0)) \le E_0$, and $aE_0 \le c_0$, then $|\operatorname{Log} U_p(t)| \le r_{\mathrm{cov}}/2$ for every plaquette and every $t \ge t_0$. No smallness of E_0 itself is assumed.

The normalization of $\mathcal{E}_a$ differs by a factor two from the lattice energy (2.2): $\mathcal{E}_a = \mathsf{E}_a/2$. For $U = e^{aA}$ with $A = b|_a$ the sample of a smooth connection, $\operatorname{Log} U_{p_{ij}(x)} = a^2 F_{ij}(x) + O(a^3)$ and $q(e^X) = |X|^2/8 + O(|X|^4)$, so $\mathcal{E}_a(U)$ approximates $(1/2)\sum_{i<j}\int_{\mathbb{T}_L^3}|F_{ij}|^2\,dx = E_L(b)/2$ and $\mathsf{E}_a(U)$ approximates $E_L(b)$; see Lemma 29.14.

Proof of Lemma 24.8. By Lemma 5.1, on the principal chart of the plaquette variables, $|\operatorname{Log} U_p|^2/(2\pi^2) \le q(U_p) \le |\operatorname{Log} U_p|^2/8$. Since $\|F_a\|_{2,a}^2 = a^{-1}\sum_p |\operatorname{Log} U_p|^2$, we may take $c = 2/\pi^2$ and $C = 1/2$. We choose any numerical $0 < r_{\mathrm{cov}} < 1$ and take $n_{\mathrm{cov}} = 4$.

On a fixed lattice the configuration space is a compact manifold and the Wilson vector field is smooth, so its flow exists for all times by the standard theorem on smooth vector fields on compact manifolds: a solution on a maximal interval with a finite endpoint would, by the bounded speed, have a limit at that endpoint, from which it could be continued. Along the flow,

$$\frac{d}{dt}\mathcal{E}_a(U(t)) = -\frac{16}{a^3}\|\nabla E_W(U(t))\|_2^2 \le 0, \qquad E_W = \sum_p q(U_p), \tag{24.22}$$

since $\mathcal{E}_a = 4E_W/a$ and $U(t)$ moves with velocity $-(4/a^2)\nabla E_W$. An added gauge velocity contributes zero to this derivative, since E_W is invariant under lattice gauge transformations at the link endpoints. Under the assumptions at t_0, each nonnegative plaquette term satisfies $q(U_p(t)) \le aE_0/4$ for $t \ge t_0$. We fix $0 < c_0 \le 2(1 - \cos(r_{\mathrm{cov}}/4))$. Then $q(U_p(t)) < 1 - \cos(r_{\mathrm{cov}}/4)$. Since $q(U) = 1 - \cos(\rho_G(U)/2)$ and this function is strictly increasing for $0 \le \rho_G(U) \le 2\pi$, we obtain $\rho_G(U_p(t)) < r_{\mathrm{cov}}/2$. These plaquette variables avoid $-I$, and their principal logarithms have norm $\rho_G(U_p(t)) < r_{\mathrm{cov}}/2$. This argument uses only the energy of the compact configuration; it requires no representative with small link variables and no curvature estimate at later times, and E_0 may be large. □

Lemma 24.9. *Let $W = (W_i)_{i=1}^m$ and $W' = (W_i')_{i=1}^m$ be random vectors in $\mathbb{R}^m$ on a common probability space with $|W_i|, |W_i'| \le 1$. For a number $U \ge 0$ and $u \in \mathbb{C}^m$ with $\sum_i |u_i| \le U$,*

$$\left|\mathbb{E}e^{u\cdot W} - \mathbb{E}e^{u\cdot W'}\right| \le e^U U\, \mathbb{E}\|W - W'\|_\infty.$$

More generally, for every event $\mathcal{O}$,

$$\left|\mathbb{E}e^{u\cdot W} - \mathbb{E}e^{u\cdot W'}\right| \le e^U U\, \mathbb{E}\left[\|W - W'\|_\infty \mathbf{1}_{\mathcal{O}^c}\right] + 2e^U \mathbb{P}(\mathcal{O}).$$

For real u with $\sum_i |u_i| \le U$, $\mathbb{E}e^{u\cdot W} \ge e^{-U}$. Let $U_* > 0$ satisfy $e^{U_*} - 1 < 1/2$. On the complex neighborhood $\mathcal{V} = \{u : \sum_i |u_i| < U_*\}$, the transform $\mathbb{E}e^{u\cdot W}$ has an analytic logarithm vanishing at $u = 0$, and if a sequence of such transforms converges uniformly on compact subsets of $\mathcal{V}$, then every partial derivative of fixed order of their logarithms converges uniformly on compact subsets of $\mathcal{V}$. For characters of representations of dimensions d_i, the same statements hold with the bounds $|W_i|, |W_i'| \le d_i$ and with $\sum_i |u_i|$ replaced by $\sum_i d_i |u_i|$.

Proof. The segment from W to W' stays in the unit cube. For complex u with $\sum_i |u_i| \le U$, by the fundamental theorem of calculus we have

$$\left|e^{u\cdot W} - e^{u\cdot W'}\right| \le \int_0^1 e^{\mathrm{Re}(u\cdot((1-v)W + vW'))} \sum_i |u_i||W_i - W_i'|\, dv \le e^U U \|W - W'\|_\infty.$$

Taking expectations, we obtain the first bound. On $\mathcal{O}$ each of the two integrands has modulus at most e^U, which gives the second bound. For real u the integrand is at least e^{-U}.

Since the observables are bounded, the exponential series and each of its derivatives converge uniformly on bounded sets of u, so $M(u) = \mathbb{E}e^{u\cdot W}$ is entire. Moreover $|M(u) - 1| \le e^{\sum_i |u_i|} - 1$, which is less than $1/2$ on $\mathcal{V}$. Hence

$$\log M(u) = \sum_{m \ge 1} \frac{(-1)^{m+1}}{m} \big(M(u) - 1\big)^m$$

converges uniformly on $\mathcal{V}$ and vanishes at the origin. Integrating $1/w$ along the segment between two points of the disc $\{|w - 1| < 1/2\}$ shows that the logarithms of two such transforms differ by at most twice the difference of the transforms. In particular, uniform convergence of transforms on a compact subset of $\mathcal{V}$ implies uniform convergence of their logarithms there. For a multi-index ν and a compact set in $\mathcal{V}$, we choose closed polydiscs of radii $\rho_j > 0$ around its points lying in a compact subset of $\mathcal{V}$. The Cauchy integral formula bounds the difference of the derivatives ∂^ν at the center by $\nu! \prod_j \rho_j^{-\nu_j}$ times the supremum of the difference of the logarithms on the distinguished boundary, and the convergence of derivatives follows. For characters of dimensions d_i, the same calculation applies with $\sum_i |u_i|$ replaced by $\sum_i d_i |u_i|$ and the bound 1 replaced by d_i. □

24.6 Smooth solutions of the Yang–Mills heat flow

In this subsection we work on the trivial periodic $\mathrm{SU}(2)$ bundle over $\mathbb{T}^3_L$. For an integer $r \geq 1$ let $\mathcal{A}^r = C^r(\mathbb{T}^3_L; \mathfrak{su}(2)^3)$, with the norm $\|b\|_{C^r}$ given by the maximum of all component derivatives of order at most r; replacing it by their finite sum changes only constants depending on r. We write $\mathcal{A}^\infty = \mathcal{A}_L$ for the smooth connections. The Yang–Mills heat flow $\partial_t A_i = \sum_j D_j F_{ji} = -(d_A^* F)_i$ and its semigroup Φ on smooth periodic gauge orbits are as in Definition 4.10. The DeTurck equation is

$$\partial_t b_i = \Delta b_i + \sum_j \big\{ 2[b_j, \partial_j b_i] - [b_j, \partial_i b_j] + [b_j, [b_j, b_i]] \big\}, \tag{24.23}$$

and we write its right side as $\Delta b + \mathcal{N}(b)$, with $\mathcal{N} = \mathcal{N}_2 + \mathcal{N}_3$ the sum of its quadratic and cubic parts. A mild solution on $[0, d]$ is a path $b \in C([0,d]; \mathcal{A}^r)$ with $b(t) = P_t b_0 + \int_0^t P_{t-s} \mathcal{N}(b(s))\, ds$, where P_t is the continuum heat semigroup acting on each component.

Inputs from the literature. We use the following deterministic statements; page numbers refer to the arXiv versions cited. These papers work on the unit torus with a compact Lie group and the trivial bundle, and $\mathrm{SU}(2)$ is allowed.

(C1) [43, Definition 3.13, pp. 24–25, and Theorem 3.14, p. 25]. For every initial connection in H^1 there exists a unique solution of the Yang–Mills heat flow in the following class: it is continuous with values in H^1, its curvature $F(t)$ lies in H^1 for $t > 0$, it has a strong L^2 time derivative equal to $-d_A^* F$, its curvature is bounded in L^∞ on compact intervals of positive times, and $t^{3/4}\|F(t)\|_\infty$ is bounded near $t = 0$. Smooth initial data give a solution that is smooth up to $t = 0$. The proof of this theorem [43, Appendix B, p. 58] obtains existence from Charalambous and Gross [47, Theorem 2.5] or Råde [139, Theorem 1], uniqueness from [47, Theorem 9.15], and smoothness for smooth data from [139, Theorem 1]; on the torus the boundary conditions of Charalambous and Gross are vacuous.

(C2) [42, Theorem 1.2 and Lemma 1.3, p. 3]: local existence and uniqueness of smooth solutions of the DeTurck equation for smooth periodic initial data.

(C3) [42, Lemma C.3, p. 56]: for $f \in C^q$, with $q \geq 0$ an integer, $\|P_t f\|_{C^q} \leq \|f\|_{C^q}$ and $\|P_t f\|_{C^{q+u}} \leq C_u t^{-u/2} \|f\|_{C^q}$ for $u > 0$ and $0 < t \leq 1$.

(C4) [42, Lemma C.2, p. 55]: $\|\mathcal{N}_2(b)\|_{C^q} \leq C_q \|b\|_{C^q} \|b\|_{C^{q+1}}$ and $\|\mathcal{N}_3(b)\|_{C^q} \leq C_q \|b\|^3_{C^q}$, and, with $M_q = \max(\|b\|_{C^q}, \|c\|_{C^q})$,

$$\|\mathcal{N}_2(b) - \mathcal{N}_2(c)\|_{C^q} \leq C_q \big\{ M_q \|b - c\|_{C^{q+1}} + M_{q+1} \|b - c\|_{C^q} \big\},$$
$$\|\mathcal{N}_3(b) - \mathcal{N}_3(c)\|_{C^q} \leq C_q M_q^2 \|b - c\|_{C^q}.$$

(C5) [42, (C.9) and Corollary C.6, p. 58; Lemmas C.12 and C.13, p. 61]: for a smooth initial datum and $0 < T \leq 1$, a fixed point in $C([0,T]; C^1)$ of the Duhamel map

(C.9) belongs to $C([0,T];C^q)$ for every q and is a smooth solution of the DeTurck equation on $[0,T)$; conversely, a smooth solution satisfies the Duhamel equation on each closed subinterval $[0,T']$ with $T'<T$.

All connections to which we apply these statements are smooth periodic connections on the trivial SU(2) bundle, and hence belong to H^1. The statements are transferred from the unit torus to $\mathbb{T}^3_L$ by

$$\widetilde{b}(y)=Lb(Ly),\qquad \widetilde{t}=t/L^2,\qquad F_{\widetilde{b}}(y)=L^2F_b(Ly),\qquad E_1(\widetilde{b})=LE_L(b).$$

Differentiating the first formula shows that both evolution equations are preserved under this change of variables, and C^j norms change by the factors L^{1+m}, $0\le m\le j$. Constants may depend on L; no coupling is rescaled. With the convention of Definition 4.10, our gauge transformation k corresponds to k^{-1} in [43, (1.1), p. 2]; the statements (C1)–(C5) involve no gauge transformation, and all gauge calculations below use our convention. The local estimates in C^r, the removal of the gauge fixing, and the construction of the neighborhoods in the following theorem are proved here.

Theorem 24.10. *The following statements hold.*

1. *For every integer $r\ge 1$ and $R<\infty$ there exists $d=d(r,R,L)>0$ such that, for every $b_0\in\mathcal{A}^r$ with $\|b_0\|_{C^r}\le R$, the equation* (24.23) *has a unique mild solution $D.b_0\in C([0,d];\mathcal{A}^r)$ (here D_t denotes the solution map, not a covariant derivative), and, for two such initial data,*

$$\sup_{t\le d}\|D_tb_0\|_{C^r}\le 2(R+1),\qquad \sup_{t\le d}\|D_tb_0-D_tb_0'\|_{C^r}\le 2\|b_0-b_0'\|_{C^r}.$$

   If b_0 is smooth, then, after reducing d once if necessary (depending only on r, R, and L), the solution is the restriction to $[0,d]$ of a smooth solution on $[0,2d)$. If b is such a smooth solution, then the solution k of

$$\partial_tk=-k\,d^*b=k\sum_i\partial_ib_i,\qquad k(0)=I,$$

   is a smooth periodic gauge transformation, and $b(t)^{k(t)}=\Phi_t(b_0)$. Finally, for every integer $q\ge 0$ there exists a polynomial $P_{q,L}$ with nonnegative coefficients such that every smooth periodic gauge transformation k with $B=A^k$, for smooth connections A and B, satisfies

$$\|k^{\pm1}\|_{C^{q+1}}\le P_{q,L}\bigl(1+\|A\|_{C^q}+\|B\|_{C^q}\bigr).$$

2. *For every integer $r\ge 1$, every finite horizon $T>0$, and every set $\mathcal{K}\subset\mathcal{A}^\infty$ that is compact in the C^r topology, there exist a C^r-open neighborhood $\mathcal{U}$ of $\mathcal{K}$, a finite open cover $(\mathcal{U}_\lambda)$ of $\mathcal{U}$, and a partition $0=t_0<\cdots<t_Q=T$ with the following property. For every smooth $b_0\in\mathcal{U}_\lambda$ there exist smooth solutions $b_{\lambda,i}(s;b_0)$, $0\le s\le t_{i+1}-t_i$, of* (24.23), *with*

$b_{\lambda,0}(0;b_0) = b_0$, *and smooth periodic gauge transformations* $k_{\lambda,i}$ *that do not depend on* $b_0 \in \mathscr{U}_\lambda$, *such that*

$$b_{\lambda,i+1}(0;b_0) = b_{\lambda,i}(t_{i+1}-t_i;b_0)^{k_{\lambda,i}}, \qquad [b_{\lambda,i}(s;b_0)] = [\Phi_{t_i+s}(b_0)].$$

The numbers of cover members and of intervals, the C^r *bounds of the* $b_{\lambda,i}$, *and their Lipschitz constants as maps from* $\mathscr{U}_\lambda$, *with the* C^r *norm, to* $C([0,t_{i+1}-t_i];\mathcal{A}^r)$ *are finite and uniform on* $\mathscr{U}$. *For every* q, *the* C^q *norms of the finitely many* $k_{\lambda,i}^{\pm 1}$ *are bounded. These constants depend on* L, T, r, $\mathscr{K}$, *and the construction, and on* q *where indicated; they do not depend on any coupling, lattice mesh, lattice side,* M, *or* J.

3. *Fix an integer* $r \geq 3$ *and a finite horizon* $T > 0$, *and let* b_0, b_0' *be smooth. As* $b_0' \to b_0$ *in* C^r, *or* $b_0' \to b_0^h$ *in* C^r *for a fixed smooth time-independent gauge transformation* h, *every finite vector of values* $W_{\ell_i,\chi_i,t}$ *of loops and characters along the trajectory of* b_0', *and the energies* $E_L(\Phi_t b_0')$, *converge to the corresponding quantities for* b_0 *uniformly for* $t \in [0,T]$, *and*

$$\sup_{0\leq t\leq T} \inf_{k\in C^\infty(\mathbb{T}^3_L;\mathrm{SU}(2))} \|\Phi_t b_0 - (\Phi_t b_0')^k\|_\infty \longrightarrow 0.$$

The map $b_0 \mapsto ([\Phi_t b_0])_{t>0}$ *from the smooth connections, with the* C^r *topology, to* $(\mathcal{X}_L, \mathcal{T}_W)$ *is continuous, and hence Borel. The energy is nonincreasing along the flow, and*

$$E_L(\Phi_t b_0) \leq E_L(b_0) \leq CL^3(K_1 + K_1^2)^2, \qquad K_1 = \|b_0\|_{C^1}.$$

4. *If* $\mathscr{K}$ *is a set of smooth connections that is compact in the* C^3 *topology, then there exist a neighborhood* $\mathscr{U}$ *as in part (2) with* $r = 3$ *and* $\eta > 0$ *such that every smooth connection at* C^3 *distance less than* η *from* $\mathscr{K}$ *lies in* $\mathscr{U}$. *In particular, smooth connections approaching* $\mathscr{K}$ *in* C^3 *eventually lie in* $\mathscr{U}$; *no assumption on the closure of the approximating family is needed.*

In part (2), the members $\mathscr{U}_\lambda$ of the cover are neighborhoods of initial data, while the index i labels time intervals; the construction is not a chart on the space of gauge orbits. On one member of the cover, the representative of the trajectory is obtained by alternating local solutions of the DeTurck equation and fixed gauge transformations:

$$b_0 = c_0 \xrightarrow{D_{h_0}} D_{h_0}c_0 \xrightarrow{(\cdot)^{k_0}} c_1 \xrightarrow{D_{h_1}} D_{h_1}c_1 \xrightarrow{(\cdot)^{k_1}} c_2 \longrightarrow \cdots \longrightarrow c_{Q-1} \xrightarrow{D_{h_{Q-1}}} D_{h_{Q-1}}c_{Q-1}, \tag{24.24}$$

where $h_i = t_{i+1} - t_i$ and c_i represents the orbit at time t_i.

Proof. We first prove the local estimates in C^r and identify smooth solutions with the solutions of (C2) and (C5). Next we remove the gauge fixing and prove the bounds on gauge transformations. The neighborhoods of part (2) are then constructed around one reference trajectory, by propagating errors through (24.24), and finally around a compact family. The remaining steps prove parts (3) and (4).

Step 1: the local solution map in C^r. By the product rule and $|[X,Y]| \le |X||Y|$, for $r \ge 1$ and $\|b\|_{C^r}, \|c\|_{C^r} \le S$,

$$\|\mathscr{N}(b)\|_{C^{r-1}} \le C_r(S^2+S^3), \qquad \|\mathscr{N}(b)-\mathscr{N}(c)\|_{C^{r-1}} \le C_r(S+S^2)\|b-c\|_{C^r}. \tag{24.25}$$

Indeed, for $|\nu| \le r-1$, $\partial^\nu[b_j, \partial_k b_i] = \sum_{\mu\le\nu} \binom{\nu}{\mu}[\partial^\mu b_j, \partial^{\nu-\mu}\partial_k b_i]$, and both factors involve at most r derivatives. For the cubic brackets, we distribute ν over the three factors. For differences, we replace one factor at a time by the corresponding factor of $b-c$ and keep the other factors at b or c. The constants depend only on r and the conventions for directions and $\mathfrak{su}(2)$; these formulas also give the estimates (C4).

By (C3), after the rescaling to $\mathbb{T}^3_L$, for $0 < h \le \min(1, L^2)$,

$$\|P_h f\|_{C^r} \le \|f\|_{C^r}, \qquad \|P_h f\|_{C^r} \le C_{r,L} h^{-1/2}\|f\|_{C^{r-1}}.$$

The heat semigroup is strongly continuous at zero in C^r: each derivative of order at most r is continuous and periodic, and convolution with the positive approximate identity converges uniformly to it. For a continuous path f with values in C^{r-1} and bounded by K, the heat convolution $\int_0^t P_{t-s} f(s)\, ds$ has C^r norm at most $2C_{r,L}\sqrt{t}\,K$. It is also continuous with values in C^r, including at $t = 0$. To see this, we split off the upper part of the integral, of length η, whose norm is at most $2C_{r,L}\sqrt{\eta}\,K$. On the remaining interval the heat times are bounded below, so the kernel and all derivatives needed are continuous and bounded, and dominated convergence applies. We then let $\eta \to 0$.

For $R \ge 0$ we set $S = 2(R+1)$ and use the Banach space $C([0,2d]; \mathcal{A}^r)$ with the supremum norm. On its closed ball of radius S, we consider

$$\mathscr{M}_{b_0}(b)(t) = P_t b_0 + \int_0^t P_{t-s}\mathscr{N}(b(s))\, ds.$$

We choose $d > 0$ such that $2d \le \min(1, L^2)$ and

$$2C_{r,L}C_r\sqrt{2d}\,(S^2+S^3) \le S - R, \qquad 2C_{r,L}C_r\sqrt{2d}\,(S+S^2) \le \tfrac{1}{2}. \tag{24.26}$$

These choices depend only on r, R, and L. By (24.25), the map preserves the ball and is a contraction with constant $1/2$. Its iterates converge, since successive differences form a geometric series. Subtracting the fixed-point equations for two initial data, we find

$$\sup_{t\le 2d}\|D_t b_0 - D_t b_0'\|_{C^r} \le \|b_0 - b_0'\|_{C^r} + \tfrac{1}{2}\sup_{t\le 2d}\|D_t b_0 - D_t b_0'\|_{C^r},$$

which implies the Lipschitz bound with constant two; the ball gives the size bound. Any two mild solutions in C^r are bounded on a common compact interval. On an interval of length h, by (24.25), their difference is at most $C\sqrt{h}$ times its supremum when the initial values agree. Choosing h so that this coefficient is less than one and restarting the mild equation by the semigroup property, finitely many intervals give uniqueness. (If $R < 0$ there are no initial data, and any choice made for $R = 0$ will do.)

Step 2: smooth initial data. Let b_0 be smooth. The solution just constructed is a fixed point in $C([0,2d];C^1)$ of the map (C.9) of [42, p. 58], and the time $2d$ corresponds to a unit-torus time at most one. By (C5) it belongs to $C([0,2d];C^q)$ for every q and is a smooth solution on $[0,2d)$; conversely, a smooth solution satisfies the mild equation on every closed subinterval of its interval of definition. The local smooth existence and uniqueness of (C2) describe the same solution. Restriction to $[0,d]$ leaves a smooth solution beyond the right endpoint, which is used at the endpoints of the intervals below.

Step 3: removal of the gauge fixing. Let $v = \sum_i \partial_i b_i = -d^* b$. Expanding the curvature and the covariant derivatives gives

$$\Delta b + \mathscr{N}(b) = -d_b^* F_b + d_b v. \tag{24.27}$$

Indeed, in components $\sum_j D_j F_{ji}$ has linear part $\Delta b_i - \partial_i v$, quadratic part $[v,b_i] + 2\sum_j [b_j,\partial_j b_i] - \sum_j [b_j,\partial_i b_j]$, and cubic part $\sum_j [b_j,[b_j,b_i]]$, and adding $(d_b v)_i = \partial_i v + [b_i,v]$ cancels the two terms $-\partial_i v$ and $[v,b_i]$.

At every point, we solve $\dot{k} = kv$, $k(0) = I$. The ordered integral series converges on each finite interval on which b is smooth. Its spatial derivatives also converge: after any fixed number of derivatives, their absolute majorant is a polynomial in the index of the iterated integral times the same factorially convergent series, with constants from finitely many derivatives of v. It follows that k is smooth in space and time. Its coefficient is traceless and skew-Hermitian, and differentiating kk^* and $\det k$ shows that $k \in \mathrm{SU}(2)$. Uniqueness for the matrix integral equation and periodicity of v give periodicity of k.

For a time-dependent gauge transformation, we set $\lambda = \dot{k}k^{-1}$. Differentiating the gauge action, we find

$$\partial_t (b^k) = \mathrm{Ad}(k)\partial_t b - d_{b^k}\lambda. \tag{24.28}$$

For example, the derivative of $-\partial_i k\, k^{-1}$ is $-\partial_i \lambda - [\lambda, \partial_i k\, k^{-1}]$, and combining it with the derivative $[\lambda, k b_i k^{-1}] + \mathrm{Ad}(k)\partial_t b_i$ of $k b_i k^{-1}$ gives the covariant term. Since $\dot{k} = kv$, we have $\lambda = \mathrm{Ad}(k)v$, and the covariance $\mathrm{Ad}(k) d_b v = d_{b^k} \mathrm{Ad}(k) v$ cancels the last term of (24.27). Hence b^k solves the Yang–Mills heat flow with initial value b_0.

The initial datum is a smooth periodic connection on the trivial $\mathrm{SU}(2)$ bundle, so (C1) applies, and the global solution is smooth up to $t = 0$. The connection b^k belongs to the same solution class on the interval where it is defined: it is smooth on a compact initial time interval, its strong time derivative is given by the equation, and its curvature is bounded there, which also bounds $t^{3/4}\|F(t)\|_\infty$ near zero. Uniqueness in (C1) implies that $b(t)^{k(t)} = \Phi_t(b_0)$.

Step 4: fixed gauge transformations. For a smooth time-independent gauge transformation h, differentiating the gauge formula, we find $F(A^h) = \mathrm{Ad}(h)F(A)$ and $d_{A^h}\mathrm{Ad}(h)z = \mathrm{Ad}(h)d_A z$. In particular, a fixed gauge transformation maps smooth solutions of the Yang–Mills heat flow to smooth solutions, and by the uniqueness in (C1)

we have $\Phi_t(A^h) = \Phi_t(A)^h$. Time translation and uniqueness give the semigroup property. These two consequences identify the orbits on successive intervals below.

If $B = A^k$, rearranging the formula for the gauge action in our convention, we obtain

$$\partial_i k = kA_i - B_i k, \qquad \partial_i k^{-1} = k^{-1}B_i - A_i k^{-1}. \tag{24.29}$$

The norms of order zero of k and k^{-1} are fixed. Applying ∂^ν to the first identity, we obtain

$$\partial^\nu \partial_i k = \sum_{\mu \le \nu} \binom{\nu}{\mu} \big((\partial^\mu k)(\partial^{\nu-\mu} A_i) - (\partial^\mu B_i)(\partial^{\nu-\mu} k) \big).$$

By induction on $|\nu| \le q$, all derivatives of k of order at most $q+1$ are bounded by a polynomial with nonnegative coefficients in $1 + \|A\|_{C^q} + \|B\|_{C^q}$. The second identity gives the same bound for k^{-1}, after enlarging the polynomial. This defines $P_{q,L}$; no normalization at a point is needed. For a fixed k, the identity $A^k - B^k = k(A-B)k^{-1}$ and the Leibniz rule give a Lipschitz bound in C^r for the action of k, involving at most r derivatives of k. The inhomogeneous term of the action involves at most $r+1$ derivatives of k.

Step 5: a neighborhood of one reference trajectory. Fix a smooth reference $b_* \in \mathscr{K}$. By (C1), $A_*(t) = \Phi_t b_*$ is smooth on $[0,T]$; we set

$$R_* = 1 + \sup_{t \le T} \|A_*(t)\|_{C^r} < \infty.$$

We choose a partition whose lengths $h_i = t_{i+1} - t_i$ are at most $d(r, R_*, L)$. On the ith interval, let $b_i^*(s)$ be the solution of the DeTurck equation started from $A_*(t_i)$. By Step 3 and the semigroup property, there exists a smooth periodic gauge transformation $k_i^*(s)$ with $(b_i^*(s))^{k_i^*(s)} = A_*(t_i + s)$. For each $i < Q-1$ set $k_i = k_i^*(h_i)$. These fixed gauge transformations depend only on the reference and the partition, and they map the right endpoints exactly: $(b_i^*(h_i))^{k_i} = A_*(t_{i+1})$. They and their inverses have bounded derivatives of every fixed order, by smoothness and compactness, or quantitatively by (24.29).

Let $L_i \ge 1$ be a Lipschitz constant in C^r for the action of k_i, and set $K_0 = 1$ and $K_{i+1} = 2L_iK_i$. We fix $\rho_* > 0$ so small that $K_i\rho_* < 1/2$ for every i. For b_0 in the open ball $\|b_0 - b_*\|_{C^r} < \rho_*$ define successively

$$c_0(b_0) = b_0, \qquad b_i(s; b_0) = D_s c_i(b_0), \qquad c_{i+1}(b_0) = \big(D_{h_i} c_i(b_0)\big)^{k_i}, \tag{24.30}$$

as in (24.24). By induction, $\|c_i(b_0) - A_*(t_i)\|_{C^r} \le K_i \|b_0 - b_*\|_{C^r} < 1/2$. Indeed, $c_i(b_0)$ lies in the ball of radius R_*, the local solution map has Lipschitz constant two by Step 1 and maps $A_*(t_i)$ to b_i^*, and the fixed gauge transformation k_i then contributes the factor L_i.

This proves the induction step, and it shows that every map in (24.30) is defined on the whole ball. Arguing in the same way for two data in the ball, we obtain

$$\|c_i(b_0) - c_i(b_0')\|_{C^r} \le K_i \|b_0 - b_0'\|_{C^r}, \qquad \sup_{s \le h_i} \|b_i(s; b_0) - b_i(s; b_0')\|_{C^r} \le 2K_i \|b_0 - b_0'\|_{C^r}.$$

The solutions on the intervals have C^r norm at most $2(R_* + 1)$. For smooth initial data all the solutions b_i and all the transformed endpoints are smooth.

On the first interval, Step 3 shows that $b_0(s; b_0)$ represents the orbit of $\Phi_s(b_0)$. If the right endpoint of the ith interval represents $[\Phi_{t_{i+1}} b_0]$, then the fixed gauge transformation k_i preserves this orbit, and by Step 3, Step 4, and the semigroup property the next solution represents $[\Phi_{t_{i+1}+s} b_0]$. By induction, the orbit identity holds on every interval. This argument provides, for each interval, a smooth periodic gauge transformation relating the representative to the Yang–Mills heat flow; no continuous choice of such gauge transformations in b_0 is needed.

Step 6: compact families. The open balls of Step 5 around the points of $\mathscr{K}$ cover $\mathscr{K}$. By compactness in C^r finitely many of them suffice; let $\mathscr{U}$ be their union and let these balls be the $\mathscr{U}_\lambda$. We take maxima of the finitely many bounds and Lipschitz constants; for each q, the finitely many fixed gauge transformations and their inverses have a finite maximal C^q norm. To obtain one partition for all members of the cover, we take the union of the finitely many partitions. When a new time subdivides an interval, we restrict the solution and translate its time origin; it still solves the autonomous DeTurck equation. We use the identity gauge transformation at each new endpoint and keep the original fixed gauge transformation at each old endpoint. The recursion, the orbit identities, and all bounds persist, and the number of intervals remains finite. This proves part (2). Only the finitely many references, their smooth trajectories, the fixed gauge transformations, and the local constants in C^r enter the dependence of the constants. Compactness in C^r is not used to bound higher derivatives of the whole family.

Step 7: observables and continuity. Let $r \ge 3$ and let smooth $b_0' \to b_0$ in C^r. We use one member of the cover containing b_0. All sufficiently close data lie in it, and by the bounds of Step 5 the representatives on each interval converge in C^r uniformly in time. For two representatives b, c and a piecewise C^1 loop ℓ, we subtract their transport equations in a fixed unitary representation ϱ. By the variation-of-constants argument of Lemma 24.7(1), we have

$$\|\mathrm{Hol}_\ell(b) - \mathrm{Hol}_\ell(c)\|_{\mathrm{op}} \le C_\varrho \,\mathrm{length}(\ell) \|b - c\|_\infty,$$

where C_ϱ is the norm of the differential of ϱ, a linear map on the finite-dimensional Lie algebra. Taking the trace costs at most the dimension of ϱ. By gauge invariance, these characters coincide at the endpoints of the intervals with the characters of the Yang–Mills heat flow. We conclude that every finite vector of loop and character values converges uniformly on $[0, T]$.

On a bounded set in C^1, by the formula for the curvature, we have

$$\|F_b - F_c\|_\infty \le C(1 + \|b\|_{C^1} + \|c\|_{C^1})\|b - c\|_{C^1}, \qquad \|F_b\|_\infty \le C(\|b\|_{C^1} + \|b\|_{C^1}^2).$$

Using $||X|^2 - |Y|^2| \le (|X| + |Y|)|X - Y|$ and integrating over the volume L^3, the energies of the representatives converge uniformly. By gauge invariance they are the energies of the Yang–Mills heat flow, also at the endpoints of the intervals.

To check the convergence of the orbit infimum without using any later result on metrics, we write the two representatives at time t as $b = (\Phi_t b_0)^h$ and $c = (\Phi_t b_0')^{h'}$ for smooth periodic gauge transformations h, h'. We apply h^{-1} to both. The inhomogeneous terms cancel in the difference, and the linear part is a pointwise isometry, so

$$\|\Phi_t b_0 - (\Phi_t b_0')^{h^{-1}h'}\|_\infty = \|b - c\|_\infty.$$

The infimum in part (3) is at most this quantity, and the bounds are uniform in t, which implies the uniform limit. If instead $b_0' \to b_0^h$ for a fixed smooth time-independent h, first use $\Phi_t(b_0^h) = \Phi_t(b_0)^h$ from Step 4; characters, energies, and the infimum take the same values.

By the global smooth semigroup of (C1), $t \mapsto [\Phi_t b_0]$ is a compatible trajectory at positive times, that is, a point of $\mathcal{X}_L$. Each function $W_{\ell,\chi,t}$ that generates $\mathcal{T}_W$ is a continuous function of b_0 by what we have just proved. Since $\mathcal{T}_W$ is the weakest topology for which these functions are continuous, the trajectory map is continuous; preimages of open sets are open, so it is Borel. No completeness or separability of a metric on orbits enters this argument.

Step 8: the energy. For a smooth solution of the Yang–Mills heat flow, differentiation and periodic integration by parts give

$$\begin{aligned}\frac{d}{dt}E_L(A) &= 2\sum_{i<j}\int \langle F_{ij}, D_i\dot{A}_j - D_j\dot{A}_i\rangle\, dx \\ &= -2\sum_i \int \Big\langle \sum_j D_j F_{ji}, \dot{A}_i \Big\rangle\, dx = -2\sum_i \int |\dot{A}_i|^2\, dx \le 0.\end{aligned}$$

The integration by parts for the brackets uses the invariance of the inner product, and periodicity eliminates boundary terms. The bound on $\|F_b\|_\infty$ in Step 7 at $t = 0$ then implies $E_L(b_0) \le CL^3(K_1 + K_1^2)^2$.

Step 9: approximation of a compact family. Let $\mathscr{K}$ be compact in C^3 and consist of smooth connections, and apply part (2) with $r = 3$. For each point of $\mathscr{K}$, we choose a ball around it contained in $\mathscr{U}$, cover $\mathscr{K}$ by finitely many of the balls with half these radii, and let η be smaller than half the least chosen radius. Every point within η of $\mathscr{K}$ then lies in one of the original balls, hence in $\mathscr{U}$. Smooth connections approaching $\mathscr{K}$ in C^3 eventually lie in $\mathscr{U}$. □

24.7 Modified plaquette actions

In this subsection $c \geq 0$ is a parameter of the action. For a fixed upper bound $C_0 \geq 0$ and $0 \leq c \leq C_0$ set

$$\mathcal{A}_c(U) = \sum_{p \in \mathcal{P}_n} \{q(U_p) + c\, q(U_p)^2\}, \qquad \Psi_t^{(n,c)} = \Phi^{\mathcal{A}_c}_{4t/a^2}, \qquad a = L/n,$$

where $\Phi^{\mathcal{A}_c}$ is the flow of $-\nabla \mathcal{A}_c$ for the product metric of Section 24.1. In particular $\Psi^{(n,0)} = \Psi^{(n)}$, and these are the flows of Theorem 2.6. The vector field is smooth on the compact configuration space, so its flow exists for all times, as for the Wilson flow. Since the action is gauge invariant and the metric is invariant under gauge transformations, the flow commutes with lattice gauge transformations.

The Taylor expansion of $q(U_p)^2$ in link logarithms starts in degree four, so its force begins in degree three. The linear operator and the bilinear map of the damped equation are unchanged, and the modified flows have the same flow data. On every fixed bounded C^1_a ball, the plaquette logarithms are $O(a^2)$ and the added physical force is $O(a^3)$, by (24.34) below. In Theorem 24.12 we use this factor near rough initial data by measuring the difference of the solutions in a norm with a slightly weaker time weight, which leaves a positive power of the mesh.

Lemma 24.11. *Let $C_0 \geq 0$, and use the stencil, $\mathcal{J}$, the gauge velocity, $\mathcal{N}_a$, and R_3 of Lemma 24.2. Decreasing r_* if necessary, depending only on the stencil, the following holds. The damped equation for $\mathcal{A}_c$, obtained as in Lemma 24.2(3) with $\sum_p q(U_p)$ replaced by $\mathcal{A}_c$ and the same gauge velocity, is, for $a\|A\|_\infty \leq r_*$,*

$$\partial_t A = \Delta_a A + \mathcal{N}_a(A, A) + F_a(A) + E_{a,c}(A), \qquad F_a(A) = a^{-3} R_3(aA). \tag{24.31}$$

For $0 \leq c \leq C_0$ and $0 < a \leq 1$, the following statements hold uniformly in the mesh and the volume.

1. *$E_{a,c}(A) = a^{-3}\mathscr{E}_c(aA)$, where $\mathscr{E}_c$ is a local analytic map whose Taylor coefficients vanish through degree two; after rescaling, its term of degree m carries the factor a^{m-3}, $m \geq 3$. If $M = \|A\|_\infty$ and aM lies in a fixed smaller ball, then for every $j \geq 0$*

$$\|D^j E_{a,c}(A)[V_1, \dots, V_j]\|_\infty \leq K_{j,C_0} \begin{cases} M^{3-j}, & 0 \leq j \leq 3, \\ a^{j-3}, & j > 3, \end{cases} \cdot \prod_{r=1}^{j} \|V_r\|_\infty, \tag{24.32}$$

   with the usual conventions for $j = 0$ and M^0. In particular,

$$\|E_{a,c}(A)\|_\infty \leq K_{C_0} M^3, \qquad \|E_{a,c}(A) - E_{a,c}(B)\|_\infty \leq K_{C_0}\big(\|A\|_\infty^2 + \|B\|_\infty^2\big)\|A - B\|_\infty.$$

2. *All forward and backward differences obey the composition rule of Lemma 24.1, with the exact lattice translations: for $m \geq 1$,*

$$\|D_a^m E_{a,c}(A)\|_\infty \leq K_{m,C_0} \sum_{j=1}^{m} b_j(M,a) \sum_{\substack{\nu_1+\cdots+\nu_j=m \\ \nu_r \geq 1}} \prod_{r=1}^{j} \|D_a^{\nu_r} A\|_\infty, \tag{24.33}$$

where $b_j(M,a) = M^{3-j}$ for $j \leq 3$ and $b_j(M,a) = a^{j-3}$ for $j > 3$. For two fields in the same smaller ball, with $M = \max(\|A\|_\infty, \|B\|_\infty)$,

$$\|D_a(E_{a,c}(A) - E_{a,c}(B))\|_\infty \leq K_{C_0}\big\{M^2 \|D_a(A-B)\|_\infty + M(\|D_a A\|_\infty + \|D_a B\|_\infty)\|A-B\|_\infty\big\}.$$

3. *For A in the smaller ball,*

$$\|E_{a,c}(A)\|_\infty \leq K_{C_0} a^3 \big(\|D_a A\|_\infty + \|A\|_\infty^2\big)^3. \tag{24.34}$$

Consequently $E_{a,c}(A) = O_{C_0,\rho}(a^3)$ on $\{\|A\|_{C_a^1} \leq \rho\}$.

The constants depend only on the stencil, the margin of the smaller ball, the orders, and C_0, and not on L, n, the coupling, or any probability law. Part (6) of Lemma 24.2 holds for (24.31) *with $\Psi^{(n,c)}$ in place of $\Psi^{(n)}$, with the same damping equation, started at the identity.*

Proof. We first compute the added force exactly on the group, then bound it with Lemma 24.1, prove the bound (24.34) from the size of the plaquette logarithms, and identify the flow.

Let e be a positive link and p a plaquette containing it. We vary U_e to $e^{\varepsilon X} U_e$. If P is the product preceding the entry of e in the oriented plaquette word, then

$$\frac{d}{d\varepsilon} U_p(\varepsilon)\Big|_{\varepsilon=0} U_p^{-1} = B_{p,e} X, \qquad B_{p,e} = \begin{cases} \mathrm{Ad}(P), & \text{if } e \text{ enters positively,} \\ -\mathrm{Ad}(P U_e^{-1}), & \text{if } e \text{ enters negatively.} \end{cases}$$

Each $B_{p,e}$ is an isometry. Direct differentiation, with $\langle X, Y\rangle = -2\,\mathrm{tr}(XY)$, gives

$$h(V) = \nabla q(V) = \frac{V - V^{-1}}{8}, \qquad h(e^X) = \frac{\sin(|X|/2)}{2|X|} X, \qquad \nabla_e q(U_p) = B_{p,e}^* h(U_p),$$

the quotient being continuous at $X = 0$. Since $\nabla(c\, q_p^2) = 2c\, q_p \nabla q_p$, the added velocity in logarithmic coordinates, in the variable $s = t/a^2$ and with the factor four, is exactly

$$\mathscr{E}_{c,e}(\theta) = -8c\, \mathcal{J}(\theta_e)^{-1} \sum_{p \ni e} q(U_p(\theta))\, B_{p,e}(\theta)^* h(U_p(\theta)). \tag{24.35}$$

This is the additional negative-gradient velocity expressed in logarithmic coordinates: the factor $\mathcal{J}(\theta_e)^{-1}$ converts the velocity on the group into the logarithmic velocity, and

the Euclidean gradient in the coordinates θ is not used. The gauge velocity is unchanged. Substituting $\theta = aA$ and $s = t/a^2$ and multiplying by a^{-3}, we obtain (24.31).

On a fixed small ball all functions of the finite plaquette words in (24.35) are analytic, and $\operatorname{Log} U_p = O(\|\theta\|_{\infty,p})$, $q(U_p) = O(\|\theta\|_{\infty,p}^2)$, $h(U_p) = O(\|\theta\|_{\infty,p})$. The inverse $\mathcal{J}^{-1}$ is analytic on a smaller fixed ball. We conclude that the Taylor coefficients of (24.35) vanish through degree two. Its Taylor series at an output link is a series in a fixed finite stencil, and, extending the finite exponential, inverse, and trace formulas to a smaller complex polydisc and using the Cauchy estimates there, its homogeneous part of degree m has coefficient sum at most $K_1 K_2^m C_0$. Lemma 24.1, with $K_0 = K_1 C_0$ and the smaller ball chosen so that $K_2 aM \le \eta < 1$, implies (24.32), the bound on the values and their differences, (24.33), and the estimate for the difference of two fields. In these estimates every intermediate stencil is a convex combination of translates of the fields, hence lies in the same ball, and no factor a^{-1} remains outside a difference of A.

For (24.34), note that the four entries of the plaquette $p_{ij}(x)$ for $\theta = aA$ have sum $a^2(D^+_{a,i}A_j - D^+_{a,j}A_i)(x)$. The Baker–Campbell–Hausdorff formula on the fixed ball, with quadratic error bounded by a constant times the square of the largest entry, gives

$$|\operatorname{Log} U_p| \le K a^2 \big(\|D_a A\|_\infty + \|A\|_\infty^2\big).$$

On the plaquette chart, $|q(e^X)| \le K|X|^2$ and $|h(e^X)| \le K|X|$. Inserting these bounds into (24.35), and using bounded incidence and the boundedness of $\mathcal{J}^{-1}$, we obtain $|\mathscr{O}_{c,e}(aA)| \le K C_0 a^6 (\|D_a A\|_\infty + \|A\|_\infty^2)^3$; multiplication by a^{-3} gives (24.34).

Finally, we remove the damping by solving the same equation for the damping gauge transformation, started at the identity. Gauge equivariance of $\nabla \mathcal{A}_c$ cancels the gauge velocity exactly, as in Step 7 of the proof of Lemma 24.2. The remaining ordinary differential equation is the one that defines $\Psi^{(n,c)}$, and uniqueness identifies the flows. This argument uses the force (24.35), not a truncation of it. All formulas involve boundedly many links, which gives the stated dependence of the constants. □

Theorem 24.12. *Fix $L > 0$, $1/2 < \alpha < 2/3$, $0 \le R < \infty$, and $0 \le C_0 < \infty$, and let $\kappa = 1 - 3\alpha/2$. There exist $T_{R,C_0} \in (0, 1/2]$, $a_{R,C_0} > 0$, and $K_{R,C_0} < \infty$ such that the following holds for every mesh $a \le a_{R,C_0}$, every $c \in [0, C_0]$, and every field A_0 whose flow data, as in Definition 24.3, satisfy $\|(x_a, y_a)\|_{\mathrm{fl},a} \le R$ on $[0, T_{R,C_0}]$. The equation* (24.31) *with $A(0) = A_0$ has a unique solution of the form*

$$A_a^c = x_a + y_a + r_a^c, \qquad r_a^c(0) = 0, \qquad \|r_a^c\|_{\mathsf{R}_a} \le K_{R,C_0},$$

where the remainder norm (24.13) *is taken on $[0, T_{R,C_0}]$; uniqueness holds in the class of Theorem 24.5. The Lipschitz bounds of Theorem 24.5 for two fields, at the same c, hold uniformly in $c \in [0, C_0]$. These solutions represent the flows $\Psi^{(n,c)}$ in their damping gauges, started at the identity.*

For every fixed $0 < \varepsilon < 2 - 3\alpha$ *put* $\kappa_\varepsilon = \kappa - \varepsilon/2 > 0$ *and*

$$\|w\|_{\mathsf{R}_a^{\kappa_\varepsilon}} = \sup_{0 \le t \le T_{R,C_0}} \big\{ (t+a^2)^{-\kappa_\varepsilon} \|w(t)\|_\infty + (t+a^2)^{1/2-\kappa_\varepsilon} \|D_a w(t)\|_\infty \big\}.$$

The time T_{R,C_0} *can be chosen independently of* ε *such that, for the same field* A_0 *and uniformly in* $c \in [0, C_0]$,

$$\|A_a^c - A_a^0\|_{\mathsf{R}_a^{\kappa_\varepsilon}} \le K_{R,C_0,\varepsilon} a^\varepsilon. \tag{24.36}$$

In particular, for every fixed $t_0 \in (0, T_{R,C_0}]$, $\|A_a^c(t_0) - A_a^0(t_0)\|_{C_a^1} \to 0$ *as* $a \to 0$, *uniformly in* c. *The damping gauge transformations of* A_a^c *and* A_a^0, *both equal to the identity at* $t = 0$, *differ by* $O_{R,C_0,\varepsilon}(a^\varepsilon)$ *at every site, uniformly on* $[0, T_{R,C_0}]$ *and in* c. *The constants depend only on* L, α, R, C_0, ε, *and the stencil and chart, and not on any coupling or probability law.*

Proof. The existence part repeats the contraction of Theorem 24.5 with the cubic term F_a replaced by $F_a + E_{a,c}$. The new information is the comparison: the difference of the two solutions satisfies a difference equation with the inhomogeneous source $E_{a,c}(A_a^c)$, which (24.34) bounds by a^ε times a power of $t + a^2$ that is still integrable.

Step 1: construction. We write $p = 3\alpha/2 < 1$, $\delta = (1-\alpha)/2$, and $v = t + a^2$, and let r_* be as in Lemma 24.11. By Lemma 24.2(5), Lemma 24.1, and Lemma 24.11(1), the map $F_a + E_{a,c}$ satisfies the bounds (24.15) on $\{B : a\|B\|_\infty \le r_*/2\}$, with a constant depending also on C_0 and uniform in $c \in [0, C_0]$. Subtracting the equations for x_a and y_a from (24.31) leaves the source

$$\begin{aligned} &\mathcal{N}_a(x,y) + \mathcal{N}_a(y,x) + \mathcal{N}_a(y,y) \\ &\quad + \mathcal{N}_a(x,r) + \mathcal{N}_a(r,x) + \mathcal{N}_a(y,r) + \mathcal{N}_a(r,y) + \mathcal{N}_a(r,r) + (F_a + E_{a,c})(x+y+r). \end{aligned}$$

The linear operator and the map $\mathcal{N}_a$ are the same as in Theorem 24.5. The five types of quadratic sources therefore have the exponents $-p$, $-p+\delta$, $-p+\delta$, $-p+2\delta$, and $-p+3\delta$, with the amplitudes KR^2, KR^2, KRS, KRS, and KS^2, respectively, as in the table in Step 3 of that proof, with the arguments in the displayed order. The cubic source at $r = 0$ is at most $K_{R,C_0} v^{-p}$, and its Lipschitz constant in r is at most $K_{R,S,C_0} v^{-p+2\delta} \|r - r'\|_{\mathsf{R}_a}$. For the latter, the possible term $S^2 v^{3\kappa}$ is bounded by this power, since $3\kappa - (-p+2\delta) = 4\delta > 0$ and $v \le 1$. Steps 3–7 of the proof of Theorem 24.5 now apply with constants depending also on C_0: the heat integral of the source at $r = 0$ has norm at most K_{R,C_0}, and on a ball of fixed radius S the contraction constant is at most $K_{R,S,C_0}(2T)^\delta$. We choose S larger than twice the first bound, then $T \le 1/2$ such that the second is at most $1/2$, and then $a_{R,C_0} \le \min(1, \sqrt{T})$ such that

$$R a^{1-\alpha} + R a^{2-2\alpha} + S a (2T)^\kappa < r_*/2.$$

Every candidate then stays in the ball where the estimates hold. The complete space of remainders on a fixed lattice and the Picard iteration give the fixed point. Subtracting the

sources for two fields with distance d_a gives an additional source bounded by $K_{R,S,C_0} d_a v^{-p}$, and the contraction yields the Lipschitz bound for the same c. Uniqueness in the class of Theorem 24.5, outside the ball, follows from uniqueness for the finite-dimensional ordinary differential equation on successive compact subintervals of the chart, as in Step 5 of that proof. After reducing a_{R,C_0} as in Step 7, the solution stays in the chart, and Lemma 24.11 identifies it with $\Psi^{(n,c)}$ in its damping gauge. The construction applies on every shorter time interval, so T_{R,C_0} may be decreased further below.

Step 2: bounds on the solutions and on the added force. For $v \le 1$ the constructed solutions satisfy

$$\|A_a^c(t)\|_\infty \le K v^{-\alpha/2}, \qquad \|D_a A_a^c(t)\|_\infty \le K v^{-(\alpha+1)/2}.$$

Indeed, the value bounds of x, y, and r^c are $Rv^{-\alpha/2}$, $Rv^{-\beta}$, and Sv^κ, and $-\beta > -\alpha/2$, $\kappa > 0$. The difference bounds are $Rv^{-(\alpha+1)/2}$, $Rv^{-\alpha}$, and $Sv^{\kappa-1/2}$; here $\alpha < (\alpha+1)/2$ since $\alpha < 1$, and $\kappa - 1/2 + (\alpha+1)/2 = 1 - \alpha > 0$. By (24.34) and $v^{-\alpha} \le v^{-(\alpha+1)/2}$, we obtain

$$\|E_{a,c}(A_a^c(t))\|_\infty \le K a^3 v^{-p-3/2} \le K a^\varepsilon v^{-p-\varepsilon/2},$$

where in the last inequality we used $a/\sqrt{v} \le 1$ and $\varepsilon < 2 - 3\alpha < 3$. Let $p_\varepsilon = p + \varepsilon/2$. Then $p_\varepsilon < 1$ exactly because $\varepsilon < 2 - 3\alpha$, and $\kappa_\varepsilon = 1 - p_\varepsilon$.

Step 3: the comparison. For $0 < \kappa' < 1$ define $\|\cdot\|_{\mathsf{R}_a^{\kappa'}}$ as in the statement with κ' in place of κ_ε; thus $\mathsf{R}_a^\kappa = \mathsf{R}_a$. By Lemma 24.4, for $0 < q < 1$,

$$\|f(t)\|_\infty \le H(t + a^2)^{-q} \quad \Longrightarrow \quad \Big\| \int_0^\cdot P^a_{\cdot - u} f(u)\, du \Big\|_{\mathsf{R}_a^{1-q}} \le K_{L,q} H, \tag{24.37}$$

including $t = 0$, where $K_{L,q} = 2C_{q,L}$ is bounded uniformly for q in every interval $(0, 1 - \delta']$, $\delta' > 0$.

The flow data cancel in $w = A_a^c - A_a^0 = r_a^c - r_a^0$, and $w(0) = 0$. Subtracting the two equations and treating $E_{a,c}(A_a^c)$ as an inhomogeneous source, we write the remaining source for this difference w as $\mathcal{L}(w)$, so that

$$\partial_t w = \Delta_a w + \mathcal{L}(w) + E_{a,c}(A_a^c), \qquad \mathcal{L}(w) = \mathcal{N}_a(w, A_a^c) + \mathcal{N}_a(A_a^0, w) + F_a(A_a^c) - F_a(A_a^0).$$

Expanding $A_a^c = x + y + r^c$ and $A_a^0 = x + y + r^0$, the terms of $\mathcal{L}(w)$ are $\mathcal{N}_a(w, x)$, $\mathcal{N}_a(x, w)$, $\mathcal{N}_a(w, y)$, $\mathcal{N}_a(y, w)$, $\mathcal{N}_a(w, r^c)$, $\mathcal{N}_a(r^0, w)$, and the difference of F_a.

Let $W = \|w\|_{\mathsf{R}_a^{\kappa_\varepsilon}}$, so that $\|w(t)\|_\infty \le W v^{\kappa_\varepsilon}$ and $\|D_a w(t)\|_\infty \le W v^{\kappa_\varepsilon - 1/2}$. The quadratic terms containing x and w have exponent $-p_\varepsilon + \delta$: for instance $-\alpha/2 + \kappa_\varepsilon - 1/2 = -p_\varepsilon + \delta$ and $\kappa_\varepsilon - (\alpha+1)/2 = -p_\varepsilon + \delta$. Those containing y and w have exponent $-p_\varepsilon + 2\delta$, and those containing r^c and w, or w and r^0, have exponent $-p_\varepsilon + 3\delta$. By (24.15) and the value bound of Step 2 for both solutions, the difference of F_a is at most $K v^{-\alpha} W v^{\kappa_\varepsilon}$, with exponent $-p_\varepsilon + 2\delta$. Since $v \le 1$, we obtain $\|\mathcal{L}(w)(t)\|_\infty \le K_{R,S,C_0} W v^{-(p_\varepsilon - \delta)}$.

We apply (24.37) with $q = p_\varepsilon - \delta$; the output is bounded in $\mathsf{R}_a^{\kappa_\varepsilon+\delta}$, and multiplying by $(2T)^\delta$ bounds it in $\mathsf{R}_a^{\kappa_\varepsilon}$, since $v^{-\kappa_\varepsilon} = v^\delta v^{-\kappa_\varepsilon-\delta}$. The constants $K_{L,q}$ are bounded uniformly, because $q = p_\varepsilon - \delta \in [p-\delta, 1-\delta)$ and $p - \delta = 2\alpha - 1/2 > 1/2$. Hence, decreasing T_{R,C_0} once, independently of ε, we may assume that the heat integral of $\mathcal{L}(w)$ has $\mathsf{R}_a^{\kappa_\varepsilon}$ norm at most $W/2$.

For the inhomogeneous term, (24.37) with $q = p_\varepsilon < 1$ and Step 2 give the bound $K_\varepsilon a^\varepsilon$ in $\mathsf{R}_a^{\kappa_\varepsilon}$. On a fixed lattice W is finite, since w is continuous, $w(0) = 0$, and $v \geq a^2$; so the inequality $W \leq W/2 + K_\varepsilon a^\varepsilon$ implies $W \leq 2K_\varepsilon a^\varepsilon$, which is (24.36). At a fixed $t_0 > 0$, this implies $\|w(t_0)\|_{C_a^1} \leq 2K_\varepsilon a^\varepsilon (1 + t_0^{\min(\kappa_\varepsilon - 1/2, 0)})$, which tends to zero uniformly in c.

Step 4: the damping gauge transformations. The gauge velocity is the same for all c, so by (24.8) both damping generators are the same linear combination of differences of the respective solutions. Their difference is bounded by $3\|D_a w(t)\|_\infty \leq K a^\varepsilon v^{\kappa_\varepsilon - 1/2}$. Since $\kappa_\varepsilon - 1/2 > -1/2$ and $T_{R,C_0} \leq 1/2$, the integral of $v^{\kappa_\varepsilon - 1/2}$ over $[0, T_{R,C_0}]$ is bounded uniformly in a, so the integral of the difference of the generators is $O(a^\varepsilon)$. For skew-Hermitian generators, the variation-of-constants argument in the proof of Lemma 24.7(2) bounds the difference of the two gauge transformations, started at the identity, by this integral. Together with Step 1, this proves the statements on the gauges and the identification of the flows. The choices of S, T_{R,C_0}, and a_{R,C_0} were made in this order and have the stated dependence. □

SECTION 25

Consistency and continuation of the Wilson flow

This section completes the deterministic theory of the Wilson flow used in the rest of the paper. It turns bounds on the flow data of a lattice initial potential, which the stochastic estimates of Part VIII provide, into statements about flowed Wilson loops at fixed positive times. Section 24 solved the damped Wilson equation on a short time interval for initial potentials with bounded flow data (Theorem 24.5). For a compact set of smooth initial data, it also constructed a continuation of the Yang–Mills heat flow using a finite reference family: finitely many smooth DeTurck solutions on consecutive time intervals, joined by fixed gauge transformations (Theorem 24.10). At a fixed mesh the Wilson flow exists for all times, since it is the gradient flow of a smooth function on a compact manifold. The problem is to obtain estimates in physical units that are uniform as $a \to 0$, together with logarithmic representatives of the flowed configuration in which these estimates hold.

We prove that every initial potential with bounded flow data can be continued to any fixed time interval $[\tau, T]$ with $\tau > 0$, uniformly in the mesh. We also prove that the based holonomy matrices and the characters of flowed Wilson loops are Lipschitz functions of the flow data (Lemma 25.9, Theorem 25.10, , and Corollary 25.11). For initial potentials depending on finitely many real parameters, we bound two parameter derivatives of the based holonomy matrices of the coordinate cycles uniformly in the mesh. For fixed smooth families of initial data, we identify the limits of these matrices and their derivatives (Theorem 25.13). Finally, we show that the flows of the plaquette potentials $q + cq^2$, $0 \le c \le C_0$, give asymptotically the same flowed loops as the Wilson flow (Lemma 25.15). The main tools are the consistency of the lattice vector field on smooth fields (Lemma 25.3 and Theorem 25.4), stability in C^1_a near smooth solutions (Lemma 25.5), and smoothing after a positive time together with compactness (Theorem 25.7 and Lemma 25.6).

The section contains three kinds of comparison, with different kinds of error.

Comparison	Hypothesis	Conclusion
Wilson flow from the exponentials of a sampled smooth solution, versus that solution	initial link-logarithm error $O(a^2)$	link-logarithm error $O(a^2)$; error $O(a)$ for loops of bounded length
Lattice solution versus a selected smooth DeTurck solution	initial error η in C_a^1	error $C(\eta + a)$ in C_a^1
Two lattice solutions on the same lattice	difference d_a of the flow data	difference Cd_a in C_a^1 after a waiting time, and in the based holonomy matrices

Only the last comparison has no additive error in the mesh; this makes the flowed loops Lipschitz functions of the flow data. For matrices, as opposed to characters, we must track every gauge transformation applied at the basepoint.

Two observations organize the proofs. First, we expand the lattice vector field completely before taking the continuum limit. The contributions of the two plaquettes on either side of a link cancel at order a^2, and their common part also cancels at order a^3; what remains at order a^3 is the DeTurck vector field. Second, after smoothing for a positive time, all solutions whose flow data obey a fixed bound are uniformly close to a compact set of smooth connections. Finitely many selected smooth DeTurck solutions then give continuation and stability uniformly over these solutions, without assuming that the initial potentials converge as the mesh varies. We work both in dimensionless units, with link logarithms $\theta = aA$ and time $s = t/a^2$, where the lattice structure is simplest, and in physical units. Since $\partial_s \theta = a^3 \partial_t A$, a dimensionless error $O(a^4)$ is a physical error $O(a)$, which explains the factors a^{-3} below.

We use the local formulas for the Wilson vector field, the local solution, the sampled gauge transformations, and the continuation of the smooth flow from Lemmas 24.2 and 24.7, Definition 24.3, , and Theorems 24.5 and 24.10; the estimates for the modified plaquette potential in Lemma 24.11 and Theorem 24.12; and the heat estimates Lemmas 16.3 and 16.9. All existence statements for the continuum flow used here are contained in Theorem 24.10, which rests on the deterministic smooth-data results of Cao and Chatterjee [42, 43]; no result about random initial data is used. The Wilson flow was introduced by Lüscher [128]. The damping gauge transformation that turns it into a parabolic equation is in the spirit of the method of Zwanziger [157], DeTurck [66], and Donaldson [76], and for the Wilson flow it is described in [128, Section 2]. The arguments are standard parabolic ones (weakly singular Volterra estimates, a bootstrap for higher differences, and compactness by the Arzelà–Ascoli theorem), carried out on the exact lattice equation with constants independent of the mesh. The results are used in Sec-

tions 28 and 29 for the convergence of flowed loops and energies and for the construction of the limiting measure, in Section 32 for macroscopic loops in the short-distance analysis, and in Sections 34 to 36 for holonomy matrices and their parameter derivatives at weak coupling.

25.1 Conventions and heat estimates

Throughout this section $a = L/n$, with $n \geq 4$, is a lattice mesh, and $\Lambda_{L/a}$ is the corresponding periodic lattice. For a continuous field f on $\mathbb{T}^3_L$ we write $S_a f = f|_{\Lambda_{L/a}}$ for its sample on this lattice. A link field A has components $A_i(x) \in \mathfrak{su}(2)$ on the positively oriented links $(x, x + ae_i)$. We locate each component at the starting vertex x of its link, and we write T_i for translation by ae_i. We write D_a for any physical forward or backward difference $D^{\pm}_{a,j}$, and D^{ν}_a for an ordered composition of such differences. In a norm, D^m_a stands for the maximum over all ordered compositions of order m and over all link and color components. For a composition ν we write ∂^ν for the corresponding composition of partial derivatives. As in Theorem 24.5, we use the norm

$$\|A\|_{C^1_a} = \|A\|_\infty + \max_{j,\epsilon\in\{+,-\}} \|D^\epsilon_{a,j} A\|_\infty.$$

Translations do not change these norms, since they permute the sites of the periodic lattice. In dimensionless coordinates we write $\nabla_i = T_i - I$ and $H_0 = \sum_i \nabla_i^* \nabla_i$, so that $\Delta_a = -a^{-2} H_0$, and $S^a_s = e^{-sH_0} = P^a_{a^2 s}$ for the heat semigroup in dimensionless time. This semigroup differs from the sampling S_a.

Flow data. As in Definition 24.3, the flow data of a lattice initial potential A_0 on mesh a are the linear heat evolution and the quadratic Picard term

$$x_a(t) = P^a_t A_0, \qquad y_a(t) = \mathcal{Q}_a(x_a, x_a)(t) = \int_0^t P^a_{t-r} \mathcal{N}_a(x_a(r), x_a(r))\, dr.$$

Here $\mathcal{N}_a$ is the ordered bilinear map fixed in Lemma 24.2; it is not symmetric, and we always take its arguments in the displayed order. On a time interval $[0, T_0]$ we write

$$\|(x_a, y_a)\|_{\mathrm{fl},a} = \mathsf{X}^a_\alpha(x_a) + \mathsf{Y}^a_\alpha(y_a),$$

with the norms of Definition 4.8 taken on $[0, T_0]$. These norms contain the weighted first differences, with all translated components. Differences of flow data on the same lattice are measured by the same norms applied to the difference. Throughout, $1/2 < \alpha < 2/3$, and we write

$$\beta = \alpha - \tfrac{1}{2}, \qquad \kappa = 1 - \tfrac{3}{2}\alpha, \qquad v_a(t) = t + a^2.$$

The remainder norm of Theorem 24.5 is

$$\|r\|_{\mathsf{R}_a} = \sup_{0\leq t\leq T_R} \{ v_a(t)^{-\kappa} \|r(t)\|_\infty + v_a(t)^{1/2-\kappa} \|D_a r(t)\|_\infty \}.$$

The chart and damped representatives. Let r_* be the radius of the link-logarithm chart in Lemma 24.2. A potential A on mesh a lies in the chart if $a\|A\|_\infty < r_*$. All local analytic bounds below are used on a fixed smaller chart $\{a\|A\|_\infty \le r'\}$ with $r' < r_*$, and the corresponding constants may depend on $r_* - r'$. In the chart, the damped Wilson equation in physical units reads

$$\partial_t A = \Delta_a A + \mathcal{N}_a(A, A) + a^{-3} R_3(aA),$$

with the analytic remainder R_3 of Lemma 24.2. By that lemma, a solution in the chart is related to the Wilson flow by

$$e^{aA_i(x,t)} = k(x,t)\,\big(\Psi_t^{(n)} U\big)_i(x)\,k(x + ae_i, t)^{-1}, \qquad U = e^{aA(0)},$$

where the damping gauge transformation k solves $\partial_t k\, k^{-1} = a^{-2}\phi(aA(t))$ with $k(0) = I$, and ϕ is the damping parameter of Lemma 24.2. As in Section 24, we call A the damped representative of the Wilson flow. The Wilson flow is used at physical time t, that is, at time $4t/a^2$ for the vector field $-\nabla \sum_p q(U_p)$; there is no coupling factor in this conversion. When the flow is restarted at a time t_0 from a gauge-transformed configuration, the new damping gauge transformation has value I at t_0.

Constants. A constant that comes only from the finite local formulas (the finitely many terms of $\mathcal{N}_a$, the analytic remainder R_3, and their derivatives) depends only on the chart radius r' and on the order of differentiation, as in item (1) of Definition 4.14. Other constants may in addition depend on L, on the displayed bounds, waiting times, and horizons, and on finitely many smooth DeTurck solutions selected in the proofs; this is the dependence described in item (7) of Definition 4.14. No constant in this section depends on the coupling, on a probability measure, on the number of averaging steps, or on M and J. When applying the local results of Section 24, we may decrease the chart radius and the local existence time, and increase the minimal lattice side; we do this once, before choosing the constants below. Every restriction $a \le a_*$ on the mesh is chosen after the displayed data and before the particular initial potentials to which it is applied.

Lemma 25.1. *Fix $L, H_1 > 0$ and an integer $q \ge 0$. The lattice heat semigroup P_u^a is positivity preserving, preserves constants, is a contraction for the supremum norm, and commutes with every translation and every difference. Further,*

$$\|D_a^q P_u^a f\|_\infty \le C_{q,H_1/L^2}(u + a^2)^{-q/2}\|f\|_\infty, \qquad 0 \le u \le H_1.$$

In particular, for $a \le 1$ and $0 \le s \le H_1/a^2$,

$$\|S_s^a\|_{\infty\to\infty} \le 1, \qquad \|\nabla S_s^a\|_{\infty\to\infty} \le C_{H_1/L^2}(1+s)^{-1/2}.$$

For $p < 1$, $0 \le q < 1$, and $\epsilon > 0$,

$$\int_0^t (r+\epsilon)^{-p}(t-r+\epsilon)^{-q}\,dr \le C_{p,q}(t+\epsilon)^{1-p-q}, \tag{25.1}$$

and the same bound holds for $\epsilon = 0$ and $t > 0$.

Proof. We have $\Delta_a = a^{-2}(\sum_i (T_i + T_i^{-1}) - 6I)$. Factoring out e^{-6u/a^2} and expanding the exponential of the remaining sum of translations shows that P_u^a is positivity preserving and preserves constants; in particular it is a contraction for the supremum norm. It commutes with translations and differences, since all translations commute. For the difference bound we apply Lemma 16.3 with equal input and output meshes, physical horizon $T = H_1$, and refinement ratio one. The cardinal interpolation is then the identity, and the heat estimate of that lemma is the displayed bound for every lattice array. (Where the lemma is used below for fixed smooth interpolants, the refinement ratio is the integer H/a, and the horizon is the displayed finite T.) Multiplying by a and setting $u = a^2 s$, we obtain the dimensionless bounds.

We now prove (25.1). Suppose first that $p < 0$. Then $(r+\epsilon)^{-p} \le (t+\epsilon)^{-p}$, and the integral of the remaining factor is at most $(t+\epsilon)^{1-q}/(1-q)$, which gives the bound. Suppose now that $p \ge 0$. If $t \ge \epsilon$, we bound the integrand by $r^{-p}(t-r)^{-q}$ and substitute $r = tv$. The integral of $v^{-p}(1-v)^{-q}$ over $[0,1]$ is finite, as we see by bounding $(1-v)^{-q}$ by 2^q on $[0,1/2]$ and v^{-p} by 2^p on $[1/2,1]$. Since $t \le t+\epsilon \le 2t$, we obtain the bound, and the same argument proves the case $\epsilon = 0$. If $t < \epsilon$, the integral is at most $t\epsilon^{-p-q} \le \epsilon^{1-p-q}$, which is at most a constant times $(t+\epsilon)^{1-p-q}$ because $\epsilon \le t+\epsilon \le 2\epsilon$. These arguments apply for either sign of $1-p-q$. □

We use the ordered expansion of $\mathcal{N}_a$ fixed in Lemma 24.2: a fixed finite sum of brackets of translated components, with one physical difference in the second argument of each bracket. Differences of brackets obey the exact product rules

$$D^+_{a,k}[u,v] = [D^+_{a,k}u, T_k v] + [u, D^+_{a,k}v], \qquad D^-_{a,k}[u,v] = [D^-_{a,k}u, T_k^{-1}v] + [u, D^-_{a,k}v]. \tag{25.2}$$

Repeated application distributes a fixed number of differences among the factors and produces finitely many terms with bounded translations. Whenever we take differences of a discrete nonlinearity, we use these identities and never differentiate an interpolated product.

25.2 Consistency for fixed smooth interpolants

The first consistency statement concerns the flow data of a fixed finite family of smooth cardinal interpolants. Such families arise in Section 28 from finite-scale reconstructions, the fields reconstructed from finitely many RG steps. The point is that the constants do not depend on the finer mesh on which the flow is computed.

Lemma 25.2. *Fix $L, T, H > 0$ with $L/H \in \mathbb{N}$, and $M_H < \infty$. Let $f = I_H v$ and $g = I_H w$ be the smooth cardinal interpolants, as in Lemma 16.3, of link fields v, w on the lattice of mesh H with $\|v\|_\infty + \|w\|_\infty \le M_H$. For every mesh $a = H/m$ with $m \in \mathbb{N}$, set*

$$x_a = P_\cdot^a(S_a f), \qquad z_a = P_\cdot^a(S_a g), \qquad x = P_\cdot f, \qquad z = P_\cdot g.$$

Let $\mathcal{N}_0$ be the continuum bilinear map obtained from the fixed expansion of $\mathcal{N}_a$ by replacing every translation by the identity and every physical difference by the corresponding partial derivative. Then

$$(\mathcal{N}_0(b,b))_i = \sum_j \{2[b_j, \partial_j b_i] - [b_j, \partial_i b_j]\}.$$

Uniformly over this family of inputs and over $0 \le t \le T$, the values and all first differences of $\mathcal{N}_a(x_a, z_a)$ differ from the samples of $\mathcal{N}_0(x, z)$ and of its corresponding first derivatives by at most $C_{H,M_H,L,T}\, a$, and the same holds for $\mathcal{N}_a(z_a, x_a)$ and $\mathcal{N}_0(z, x)$. The same estimate holds for

$$\mathcal{Q}_a(x_a, z_a)(t) - S_a \int_0^t P_{t-s} \mathcal{N}_0(x(s), z(s))\, ds$$

and its first differences, and for the reversed order of the arguments. Consequently, for every bounded finite sum f of such interpolants, the flow data of $S_a f$ converge, after separate interpolation of value and difference arrays, to the continuum pair $(x, \int_0^t P_{t-s}\mathcal{N}_0(x(s), x(s))\, ds)$ in the four weighted uniform norms of Definition 24.3, whose weights are powers of t, and $\|(x_a, y_a)\|_{\mathrm{fl},a}$ is bounded uniformly in a. The constants are deterministic, do not depend on a, and may grow arbitrarily as $H \downarrow 0$. The lemma compares two discretizations of the same smooth input on the mesh a; it does not compare the quadratic term $\mathcal{Q}_H$ on the mesh H with $\mathcal{Q}_a$.

The diagonal formula for $\mathcal{N}_0$ is the quadratic part of the DeTurck form of the Yang–Mills heat flow, written in Theorem 24.10; compare the gauge-fixed flow of Lüscher [128, Section 2.2]. We verify it from the lattice formula, since its sign and the factor two must match the lattice map exactly.

Proof. Step 1: bounds on the inputs. For each integer $q \ge 0$, by the bounds for cardinal interpolants in Lemma 16.3, we have

$$\|f\|_{C^q} + \|g\|_{C^q} \le C_q(1 + H^{-q}) M_H.$$

By heat contraction on differentiated smooth data, and its discrete counterpart, every fixed spatial difference of the input fields is bounded uniformly in a and $t \le T$. Applying Lemma 16.9 through order two, and not only through order one, we obtain

$$\max_{0 \le q \le 2} \sup_{t \le T} \big(\|D_a^q x_a - S_a \partial^q x\|_\infty + \|D_a^q z_a - S_a \partial^q z\|_\infty \big) \le C_{H,M_H,L,T}\, a. \tag{25.3}$$

The maximum includes every ordered choice of differences; for $q = 0$ the stronger error $O(a^2)$ is available. A translation by any vector of the fixed stencil changes a sampled smooth qth derivative by at most $Ca\|\partial^{q+1}x\|_\infty$, and the same holds for z.

Step 2: the diagonal of $\mathcal{N}_0$. Recall that $\mathcal{N}_0$ is defined by the termwise replacement in the statement. To identify its diagonal, let $(Cb)_{ij} = \partial_i b_j - \partial_j b_i$ and $Q(b)_{ij} = [b_i, b_j]$, extended antisymmetrically in i, j. At zero translation the logarithms of the four factors of the plaquette in Lemma 24.2 are $b_i, b_j, -b_i, -b_j$, and half the sum of their pairwise brackets is $Q(b)_{ij}$. By the adjoint formula in Lemma 24.2, we have

$$(C^*Q(b))_i = \sum_j \partial_j [b_i, b_j], \qquad (DQ(b)^*Cb)_i = \sum_j [b_j, \partial_i b_j - \partial_j b_i].$$

For the second identity, note that a variation h_i of b_i changes $[b_i, b_j]$ by $[h_i, b_j]$, and invariance of the inner product moves this bracket to $[b_j, (Cb)_{ij}]$. Combining the two orientations of each plaquette, we obtain the displayed formula. Further, since $d_0^*(ab)/a^2$ tends to $\sum_j \partial_j b_j$, the quadratic gauge term G_2 of Lemma 24.2, divided by a^3, tends to $[b_i, \sum_j \partial_j b_j]$. The diagonal coefficient is therefore

$$-C^*Q(b) - DQ(b)^*Cb + [b, \operatorname{div} b] = \Big(\sum_j \big\{ 2[b_j, \partial_j b_i] - [b_j, \partial_i b_j] \big\} \Big)_i,$$

where we used $[\partial_j b_i, b_j] = -[b_j, \partial_j b_i]$, and the terms $[b_i, \partial_j b_j]$ cancel. This verifies the sign and the factor two without symmetrizing the ordered map.

Step 3: the nonlinearity. Every summand of $\mathcal{N}_a(x_a, z_a)$ is a bracket of a factor of order zero and a factor of order one. Applying (25.2) once, we obtain factors of orders $(1,1)$ or $(0,2)$, with the corresponding translations. By (25.3) and Step 1, each factor differs from its continuum counterpart by $O(a)$, and every other factor is bounded by a constant depending on the family. Using the inequality $|[u, v]| \le |u||v|$ and subtracting the two products, we obtain the asserted $O(a)$ errors for the values and the first differences. Reversing the inputs replaces the factors by z_a, x_a in the same list; their bounds through order two and their errors are again those in (25.3), which gives the estimate for the reversed order.

Step 4: the Duhamel integrals. Let $h(t) = \mathcal{N}_0(x(t), z(t))$, a uniformly bounded smooth family at every fixed spatial order. In the value of the Duhamel integral we first replace $\mathcal{N}_a(x_a, z_a)$ by $S_a h$; by contraction this costs at most CTa. Then we replace $P^a_{t-r} S_a h(r)$ by $S_a P_{t-r} h(r)$. By the general smooth-input bound of Lemma 16.9, applied separately at each r, this costs at most $CT^2a^2 \sup_r \|h(r)\|_{C^4}$. For a first difference of the integral, we commute the difference through P^a_{t-r} onto the source. The replacement of the source difference by $S_a \partial h$ costs CTa, and the heat comparison on $\partial h(r)$ together with the comparison of $D_a S_a$ with $S_a \partial$ cost at most $C_{H,M_H,L,T}\, a$ after integration. This order of comparisons avoids dividing a value error by a. Replacing h by $\mathcal{N}_0(z, x)$ gives the assertion for the reversed order.

Step 5: weighted norms and convergence. We first bound the flow data near time zero, without using any convergence. Let $B = \|f\|_\infty + \|g\|_\infty$. By Lemma 25.1 and the bound $\|\mathcal{N}_a(u,v)\|_\infty \le C\|u\|_\infty \|D_a v\|_\infty$, we have

$$\|x_a(t)\|_\infty + \|z_a(t)\|_\infty \le B, \qquad \|D_a x_a(t)\|_\infty + \|D_a z_a(t)\|_\infty \le CB(t+a^2)^{-1/2},$$
$$\|\mathcal{Q}_a(x_a,z_a)(t)\|_\infty \le CB^2\sqrt{t}, \qquad \|D_a \mathcal{Q}_a(x_a,z_a)(t)\|_\infty \le CB^2.$$

In the last inequality we used $\int_0^t (t-r+a^2)^{-1/2}(r+a^2)^{-1/2}\,dr \le \pi$. For a fixed family one can instead bound all input and source differences by its smooth bounds, which also covers $t = 0$. Since $a \le H$ and all four weights $v_a^{\alpha/2}$, $v_a^{(\alpha+1)/2}$, v_a^{β}, v_a^{α} have positive exponents, multiplying by them we obtain a bound on $\|(x_a, y_a)\|_{\mathrm{fl},a}$ depending only on the data of the family. Interpolation of each array separately is a contraction, since the cardinal weights are nonnegative and sum to one. Because of its support radius, it has error at most $Ca\|\partial F\|_\infty$ for a smooth F. Then the uniform errors already proved imply convergence in all four weighted uniform norms. For the quadratic Picard term we take $g = f$, and for a finite sum of interpolants we use the corresponding bounded smooth family. All constants have the asserted dependence, and $\mathcal{Q}_H$ is never compared with $\mathcal{Q}_a$. □

25.3 Consistency and stability for smooth initial data

We now expand the exact lattice vector field on sampled smooth potentials. This vector field consists of the Riemannian gradient of the plaquette action for the bi-invariant product metric and the damping term, written in logarithmic coordinates by means of the inverse differential of the exponential. All three parts enter the term of order a^3.

Lemma 25.3. *Let $\mathcal{F}$ be the dimensionless damped logarithmic vector field of Lemma 24.2, so that the damped Wilson equation reads*

$$\partial_s \theta = \mathcal{F}(\theta) = -H_0\theta + N_2(\theta) + R_3(\theta)$$

in dimensionless time $s = t/a^2$. Let $K_0 > 0$, and let b be a smooth periodic connection with $\|b\|_{C^3} \le K_0$. If a is so small that $K_0 a$ lies in a fixed smaller chart, then

$$a^{-3}\mathcal{F}(aS_a b) = S_a\{\Delta b + \mathcal{N}_0(b,b) + \mathcal{N}_3(b)\} + O_{K_0}(a), \qquad (\mathcal{N}_3(b))_i = \sum_j [b_j,[b_j,b_i]],$$

and

$$a^{-3}R_3(aS_a b) = S_a \mathcal{N}_3(b) + O(a).$$

More generally, for every integer $q \ge 0$ the errors in both identities remain $O(a)$ after any q physical differences, compared with the samples of the corresponding derivatives, uniformly over families of b bounded in C^{q+4}. The constants depend only on q, on the smooth bounds, and on the chart.

Proof. Step 1: the exact vector field. For $i \neq j$, let

$$P_{ij}(x) = U_i(x)U_j(x+ae_i)U_i(x+ae_j)^{-1}U_j(x)^{-1}, \qquad p(V)^c = -2\,\mathrm{tr}(\tau_c V),$$

and identify the color vector $p(V)$ with its Lie-algebra element. For $V = e^f$ in the plaquette chart, $p(e^f) = 2\sin(|f|/2)f/|f| = f + O(|f|^3)$. When $j < i$ we have $P_{ij}(x) = P_{ji}(x)^{-1}$ and $q(V^{-1}) = q(V)$, so each unoriented plaquette is counted once. Varying $U_i(x)$ by $e^{\varepsilon w}U_i(x)$ in $4\sum_p q(U_p)$ gives $\langle w, p(P_{ij}(x))\rangle$ from the plaquette $P_{ij}(x)$ and

$$-\big\langle w, \mathrm{Ad}(U_j(x-ae_j)^{-1})\, p(P_{ij}(x-ae_j))\big\rangle$$

from the plaquette $P_{ij}(x-ae_j)$; the second formula follows by moving the varied inverse factor cyclically inside the trace. The negative gradient for the bi-invariant metric, in left trivialization, is therefore

$$V_{\mathrm{W},i}(x) = \sum_{j\neq i}\big\{\mathrm{Ad}(U_j(x-ae_j)^{-1})\, p(P_{ij}(x-ae_j)) - p(P_{ij}(x))\big\}. \tag{25.4}$$

This is an identity at every configuration. By Lemma 24.2, with $U_i(x) = e^{\theta_i(x)}$, the damping parameter, the damping velocity, and the logarithmic vector field are

$$\begin{aligned} \phi(x) &= \sum_j \big(\theta_j(x-ae_j) - \theta_j(x)\big), \\ V_{\mathrm{g},i} = \phi(x) - \mathrm{Ad}(e^{\theta_i(x)})\phi(x+ae_i), &\qquad \mathcal{F}_i(\theta) = \mathcal{J}(\theta_i)^{-1}\big(V_{\mathrm{W},i} + V_{\mathrm{g},i}\big), \end{aligned} \tag{25.5}$$

where $\mathcal{J}(\theta) = (e^{\mathrm{ad}\,\theta} - I)/\,\mathrm{ad}\,\theta$ is the differential of the exponential in left trivialization.

Step 2: expansion of one plaquette. Let $\theta = aS_a b$, that is, $U_i(x) = e^{ab_i(x)}$, and write

$$F_{ij} = \partial_i b_j - \partial_j b_i + [b_i, b_j], \qquad v = \sum_j \partial_j b_j.$$

By Taylor expansion at x through order a^3, the logarithms of the four factors of $P_{ij}(x)$ are

$$\begin{aligned} ab_i, \quad & ab_j + a^2\partial_i b_j + \tfrac{1}{2}a^3\partial_i^2 b_j + O_{K_0}(a^4), \\ & -ab_i - a^2\partial_j b_i - \tfrac{1}{2}a^3\partial_j^2 b_i + O_{K_0}(a^4), \quad -ab_j. \end{aligned}$$

Taking the finite analytic product and the logarithm, we obtain

$$p(P_{ij}(x)) = a^2 F_{ij}(x) + a^3 B_{ij}(x) + O_{K_0}(a^4), \qquad \|B_{ij}\|_{C^1} \leq C_{K_0}. \tag{25.6}$$

Here B_{ij} is the homogeneous coefficient of a^3 in the product of the four factors, with their logarithms replaced by the displayed jets. It is a fixed polynomial in the two-jets of b, and its first derivative involves only three-jets. Taylor's integral remainder for each translated b and the analytic remainder of fourth order of the finite product are bounded by $C_{K_0}a^4$.

The coefficient of a^2 is F_{ij}: these logarithms add up to $a^2(\partial_i b_j - \partial_j b_i)$ modulo $O(a^3)$, and half the sum of their pairwise brackets is $a^2[b_i, b_j]$ modulo $O(a^3)$, as in Step 2 of the proof of Lemma 25.2. Replacing the logarithm by p changes the result only by $O_{K_0}(a^6)$. This proves (25.6) without computing the polynomial B_{ij}.

Step 3: cancellation between the two plaquettes. At the neighboring basepoint, $F_{ij}(x - ae_j) = F_{ij}(x) - a\partial_j F_{ij}(x) + O_{K_0}(a^2)$ and $B_{ij}(x - ae_j) = B_{ij}(x) + O_{K_0}(a)$, and the adjoint in (25.4) is $I - a\,\mathrm{ad}(b_j(x)) + O_{K_0}(a^2)$. Subtracting the contribution of $P_{ij}(x)$, we obtain

$$V_{\mathrm{W},i}(aS_a b) = -a^3 \sum_j \big(\partial_j F_{ij} + [b_j, F_{ij}]\big) + O_{K_0}(a^4).$$

The terms of order a^2 and the common terms $a^3 B_{ij}$ cancel before the inverse differential $\mathcal{J}^{-1}$ is applied. For the damping parameter we have

$$\phi = -a^2 v + a^3 w + O_{K_0}(a^4), \qquad w = \tfrac{1}{2}\sum_j \partial_j^2 b_j, \qquad \|w\|_{C^1} \le C_{K_0}.$$

The translated terms $a^3 w$ cancel in V_{g}, and expanding the adjoint gives $V_{\mathrm{g},i} = a^3(\partial_i v + [b_i, v]) + O_{K_0}(a^4)$. Then the total group velocity is $O_{K_0}(a^3)$. Since $\mathcal{J}(ab_i)^{-1} = I + O_{K_0}(a)$, applying this inverse changes it only by $O_{K_0}(a^4)$. Finally,

$$-\sum_j \big(\partial_j F_{ij} + [b_j, F_{ij}]\big) + \partial_i v + [b_i, v] = \Delta b_i + \sum_j \big\{2[b_j, \partial_j b_i] - [b_j, \partial_i b_j] + [b_j, [b_j, b_i]]\big\},$$

and by Lemma 25.2 the right side is $(\Delta b + \mathcal{N}_0(b,b) + \mathscr{N}_3(b))_i$. This proves the first identity. The only condition on a is that $K_0 a$ lie in a fixed smaller chart, and all spatial remainders used at most three derivatives of b.

Step 4: the analytic remainder. By Lemma 24.2,

$$a^{-3}\mathcal{F}(aS_a b) = \Delta_a S_a b + \mathcal{N}_a(S_a b, S_a b) + a^{-3} R_3(aS_a b).$$

Central-difference consistency gives $\Delta_a S_a b = S_a \Delta b + O(a)$, and the calculation of Step 3 of the proof of Lemma 25.2, applied to the smooth field b, implies that $\mathcal{N}_a(S_a b, S_a b) = S_a \mathcal{N}_0(b,b) + O(a)$. Subtracting these from the first identity, we obtain the second.

Step 5: differences. For a first difference, we regard the finite sampled formula for $a^{-3}\mathcal{F}(aS_a b)$ as a smooth function $B_a(u)$ of a continuous basepoint $u \in \mathbb{T}^3_L$, evaluating every stencil entry at $u + a\xi$ instead of $x + a\xi$ for the corresponding stencil vector ξ. Differentiating the Taylor calculation of Steps 2 and 3 in u, we find that $\partial_k B_a$ differs from $\partial_k\{\Delta b + \mathcal{N}_0(b,b) + \mathscr{N}_3(b)\}$ by $O(a)$, since this calculation uses one additional bounded spatial derivative of b. Using the exact identity

$$D^+_{a,k} B_a(x) = \int_0^1 \partial_k B_a(x + rae_k)\, dr$$

we compare the difference with the sampled continuum derivative, at error $O(a)$; for a backward difference we integrate over $x - rae_k$ instead. Repeating this argument at a fixed order q, we obtain the assertion through order q on families bounded in C^{q+4}. The same argument applies to $a^{-3}R_3(aS_ab)$. There is no negative power of a in the remainder: its term of degree d in the analytic series has coefficient a^{d-3}, $d \geq 3$, by Lemma 24.2. On a smaller chart, the derivatives of this series converge absolutely after multiplication by polynomial factors in d of fixed order. Hence the product-rule argument applies to the whole analytic remainder, not only to its cubic truncation. □

Theorem 25.4. *Fix $L, T, K_0, C_{\mathrm{init}} > 0$. Let b be a smooth periodic solution on $[0, T]$ of the DeTurck equation of Theorem 24.10, continuously differentiable in time, with $\sup_{t \leq T} \|b(t)\|_{C^3} \leq K_0$. For $a = L/n$ write $s = t/a^2$, $S = T/a^2$, and $\theta^{\mathrm{ref}}(s, x) = ab(a^2 s, x)$. There is $a_* > 0$ such that the following statements hold for all $a \leq a_*$.*

1. *The residual of θ^{ref} for the exact vector field $\mathcal{F}$ of Lemma 24.2 satisfies*

$$\sup_{s \leq S} \|\partial_s \theta^{\mathrm{ref}}(s) - \mathcal{F}(\theta^{\mathrm{ref}}(s))\|_\infty \leq C_{K_0} a^4.$$

   Here $\mathcal{F}$ contains the Riemannian gradient of the plaquette action, the damping term, and the inverse differential of the exponential.

2. *Let $\vartheta(s)$ be a path on $[0, S]$, not necessarily a solution, with $\|\vartheta\|_\infty \leq K_0 a$ and $\|\nabla\vartheta\|_\infty \leq K_0 a^2$. Its linearized lower-order operator $\mathsf{A}_\vartheta = D\mathcal{F}(\vartheta) + H_0$ satisfies*

$$\|\mathsf{A}_\vartheta z\|_\infty \leq C_{K_0}\big(a\|\nabla z\|_\infty + a^2\|z\|_\infty\big).$$

   Define

$$\|z\|_{\mathsf{R}_{\mathrm{sm}}} = \sup_{s \leq S} \|z(s)\|_\infty + \sup_{s \leq S} \sqrt{1+s}\, \|\nabla z(s)\|_\infty$$

   and

$$\mathsf{L}_\vartheta z(s) = \int_0^s e^{-(s-r)H_0} \mathsf{A}_\vartheta(r) z(r)\, dr.$$

   Then $\|(I - \mathsf{L}_\vartheta)^{-1}\|_{\mathsf{R}_{\mathrm{sm}} \to \mathsf{R}_{\mathrm{sm}}} \leq C_{L,T,K_0}$, uniformly in a. A forcing F enters through its whole Volterra integral, and if $\sup_s \|F(s)\|_\infty \leq c$, then

$$\Big\| \int_0^{\cdot} e^{-(\cdot - r)H_0} F(r)\, dr \Big\|_{\mathsf{R}_{\mathrm{sm}}} \leq C_{L,T}\, c\, (1 + S).$$

3. *If $\|\theta(0) - \theta^{\mathrm{ref}}(0)\|_\infty \leq C_{\mathrm{init}} a^2$, then the damped lattice solution θ with this initial value exists in the chart on $[0, S]$, is a damped representative of the Wilson flow, and satisfies*

$$\|\theta - \theta^{\mathrm{ref}}\|_{\mathsf{R}_{\mathrm{sm}}} \leq C_{L,T,K_0,C_{\mathrm{init}}}\, a^2.$$

4. *Let b_0 be smooth, and let the partition $0 = t_0 < \cdots < t_Q = T$, the DeTurck solutions b_i on $[0, t_{i+1} - t_i]$, and the fixed smooth gauge transformations k_i be those given by Theorem 24.10 for the initial value b_0. Start the Wilson flow from $\exp(aS_a b_0)$, and at each time t_{i+1} apply the gauge transformation k_i, sampled at the lattice sites, to the links before restarting the damped equation. Then at each time $t \in [t_i, t_{i+1}]$ the link logarithms differ from $aS_a b_i(t - t_i)$ by $O(a^2)$, and hence the links differ from $\exp(aS_a b_i(t - t_i))$ by $O(a^2)$.*

The constants and a_* depend only on $L, T, K_0, C_{\mathrm{init}}$, and in (4) also on the smooth bounds and margins of the continuation. The hypothesis of (3) is an initial error of order a^2; an initial link error that is only $o(a)$ is not covered.

The proof follows the usual pattern for semilinear parabolic equations: a consistency estimate for the residual, a bound on the linearized Volterra operator in a weighted norm, and a contraction argument for the error. The only delicate point is the scaling. In dimensionless units the coefficient of the first difference in A_ϑ is $O(a)$, the time interval has length T/a^2, and the weight $e^{-\lambda s}$ must be taken with λ of order a^2.

Proof. Step 1: the residual. By Lemma 25.3,

$$\mathcal{F}(\theta^{\mathrm{ref}}(s)) = a^3 S_a \big\{ \Delta b + \mathcal{N}_0(b, b) + \mathscr{N}_3(b) \big\}(a^2 s) + O_{K_0}(a^4).$$

By the DeTurck equation the bracket is $\partial_t b$, and $\partial_s \theta^{\mathrm{ref}} = a^3 S_a \partial_t b$. This proves (1). The threshold only requires that $K_0 a$ lie in a fixed smaller chart.

Step 2: the linearized operator. Let ϑ satisfy the two bounds in (2). We have $\mathsf{A}_\vartheta = DN_2(\vartheta) + DR_3(\vartheta)$. By Lemma 24.2, the quadratic part N_2 is a fixed sum of translated products of the form $[u, \nabla v]$. In $DN_2(\vartheta)z$, the terms with the difference on z are bounded by $CK_0 a \|\nabla z\|_\infty$, and the terms with the difference on ϑ by $CK_0 a^2 \|z\|_\infty$. The derivative of the remainder satisfies $\|DR_3(\vartheta)z\|_\infty \le C\|\vartheta\|_\infty^2 \|z\|_\infty$. This proves the bound for A_ϑ.

Step 3: the Volterra inverse. Let $k(u) = (1 + u)^{-1/2}$, and for $\lambda > 0$ consider the equivalent weighted norm

$$\|z\|_\lambda = \sup_{s \le S} e^{-\lambda s} \|z(s)\|_\infty + \sup_{s \le S} e^{-\lambda s} \sqrt{1 + s}\, \|\nabla z(s)\|_\infty.$$

For every $\lambda > 0$,

$$\int_0^\infty e^{-\lambda u} k(u)\, du \le C\lambda^{-1/2}, \qquad \sup_s \int_0^s e^{-\lambda(s-r)} k(r)\, dr \le C\lambda^{-1/2}. \tag{25.7}$$

The first bound follows from $k(u) \le u^{-1/2}$ and rescaling. For the second, if $s \le \lambda^{-1}$ we discard the exponential and integrate $r^{-1/2}$. If $s > \lambda^{-1}$, the intervals $r \le s/2$ and $r \ge s/2$ contribute at most $C\sqrt{s} e^{-\lambda s/2}$ and $C/(\lambda\sqrt{s})$ respectively, and each of these is at most $C\lambda^{-1/2}$. We also use the elementary inequality

$$\sqrt{1 + s}\, k(s - r) k(r) \le k(s - r) + k(r), \qquad 0 \le r \le s,$$

which follows from $\sqrt{1+s} \le \sqrt{1+r} + \sqrt{1+s-r}$. We insert the bound for A_ϑ into the Volterra integral. For the value we use that $e^{-(s-r)H_0}$ is a contraction, and for the first difference the bound $\|\nabla e^{-(s-r)H_0}\|_{\infty\to\infty} \le Ck(s-r)$ of Lemma 25.1 with $H_1 = T$. Using (25.7) and the elementary inequality for the term with $a\|\nabla z\|_\infty$ in the differentiated estimate, we obtain

$$\|\mathsf{L}_\vartheta\|_{\lambda\to\lambda} \le C_{L,T,K_0}\Big\{\frac{a}{\sqrt{\lambda}} + \frac{a^2}{\lambda} + \frac{a^2\sqrt{1+S}}{\sqrt{\lambda}}\Big\}. \tag{25.8}$$

The last term comes from the coefficient of order zero in the differentiated estimate. We take $\lambda = \kappa_0 a^2$ with $\kappa_0 = \kappa_0(L,T,K_0)$ so large that the right side is at most $1/2$; here we used $a\sqrt{1+S} = \sqrt{a^2+T} \le \sqrt{1+T}$ for $a \le 1$. The series $\sum_{j\ge0} \mathsf{L}_\vartheta^j$ then converges, with weighted norm at most two, and removing the weight costs at most $e^{\lambda S} = e^{\kappa_0 T}$. This proves the bound on $(I - \mathsf{L}_\vartheta)^{-1}$ in R_{sm}.

Step 4: the forcing. An initial heat term $e^{-sH_0}z_0$ has R_{sm} norm at most $C_{L,T}\|z_0\|_\infty$. A forcing of uniform norm c has a value integral at most cs, and its weighted first difference is at most

$$Cc\sqrt{1+s}\int_0^s (1+s-r)^{-1/2}\,dr \le 2Cc(1+s).$$

This proves the forcing bound in (2), including the constant Fourier mode, on which the heat semigroup does not decay.

Step 5: the error. Let θ be the damped solution with the initial value in (3), set $z = \theta - \theta^{\mathrm{ref}}$, and let $\mathcal{R} = \partial_s\theta^{\mathrm{ref}} - \mathcal{F}(\theta^{\mathrm{ref}})$ be the residual of (1). Since N_2 is quadratic, the difference satisfies the exact equation

$$z' = -H_0 z + \mathsf{A}_{\theta^{\mathrm{ref}}} z + N_2(z) + Q_{\theta^{\mathrm{ref}}}(z) - \mathcal{R}, \qquad Q_\vartheta(z) = R_3(\vartheta+z) - R_3(\vartheta) - DR_3(\vartheta)z. \tag{25.9}$$

By analytic Taylor expansion on a smaller chart, we have

$$\|Q_\vartheta(z)\|_\infty \le C\big(K_0 a\|z\|_\infty^2 + \|z\|_\infty^3\big),$$

and the difference of Q_ϑ at two points of a ball of radius δ has the corresponding factor $K_0 a\delta + \delta^2$. If $\|z\|_{\mathsf{R}_{\mathrm{sm}}} \le \delta$, the quadratic source $N_2(z)$ has size at most $C\delta^2 k(s)$. Its Volterra integral has R_{sm} norm at most $C\delta^2\sqrt{1+S}$; for the differentiated component we use $\int_0^s k(s-r)k(r)\,dr \le \pi$ and multiply by $\sqrt{1+s}$. By Step 4, the integral of $Q_{\theta^{\mathrm{ref}}}(z)$ costs at most $C(K_0 a\delta^2 + \delta^3)(1+S)$. After the Volterra inverse, the Lipschitz constant of these nonlinear terms on the ball of radius δ is at most

$$C_{L,T,K_0}\big\{\delta\sqrt{1+S} + K_0 a\delta(1+S) + \delta^2(1+S)\big\}. \tag{25.10}$$

The initial heat term and the residual in (25.9) have R_{sm} norm at most $C_{L,T,K_0,C_{\mathrm{init}}}(a^2 + a^4(1+S)) \le Ca^2$, by Step 4 and (1). Let D be twice this constant multiplied by the bound

for the Volterra inverse, and set $\delta = Da^2$. Every term in (25.10) then tends to zero: the first two are $O_{L,T,K_0,D}(a)$ and the last is $O_{T,D}(a^2)$. For a small enough, the mild form of (25.9) defines a map of the ball of radius δ into itself which is a contraction with factor at most $1/2$. Iteration from zero converges in the complete space defined by the norm R_{sm}; this proves existence of the mild solution and the error bound in (3). The mild solution solves the finite-dimensional differential equation. Since its amplitude is at most $K_0 a + Da^2 < r_*$, it does not leave the chart. Local uniqueness for the differential equation and the gauge identification of Lemma 24.2 show that it is the damped representative of the Wilson flow.

Step 6: continuation by restarts. We use the continuation of Theorem 24.10 with $r = 3$ and its fixed margins. On one interval, Step 5 gives an error $O(a^2)$ for the link logarithms, and thus $O(a^2)$ for the links. At a restart time we apply the fixed sampled gauge transformation to the links. Left and right multiplication are isometries, and the logarithm is Lipschitz on the next smaller chart. By Lemma 24.7, applying the gauge transformation to the exponentials of a sample differs from sampling the transformed smooth connection by $O(a^2)$ per link. Then the initial error on the next interval is again of the form $C_{\mathrm{init},i}a^2$, which is the hypothesis of (3). Iterating over the finite partition preserves this order, with the maximum of finitely many constants and the minimum of finitely many restrictions on the mesh. This proves (4). □

25.4 Continuation near smooth solutions

We now pass to physical units and to the norm C^1_a, and we write $S_a b = b|_a$. In physical time, the damped equation of Lemma 24.2 reads

$$\partial_t B = \Delta_a B + N_a(B), \qquad N_a(B) = \mathcal{N}_a(B,B) + \mathscr{C}_a(B), \qquad \mathscr{C}_a(B) = a^{-3} R_3(aB).$$

We write

$$\mathscr{B}_a(B)V = \mathcal{N}_a(B,V) + \mathcal{N}_a(V,B) + D\mathscr{C}_a(B)V$$

for the linearization of N_a at B. Here D on the cubic-and-higher remainder $\mathscr{C}_a$ differentiates in the field, and D_a is a physical spatial difference. On the smaller chart,

$$\|D^j \mathscr{C}_a(B)[V_1,\dots,V_j]\|_\infty \le C\|B\|_\infty^{3-j} \prod_{i=1}^{j} \|V_i\|_\infty, \qquad 0 \le j \le 3, \tag{25.11}$$

where for $j = 0$ the empty product is one. Indeed, the derivative is $a^{j-3} D^j R_3(aB)$, and since the Taylor coefficients of R_3 vanish through order two, $D^j R_3(aB)$ has a factor $(a\|B\|_\infty)^{3-j}$; for $j = 3$ we use the bounded analytic third derivative on the smaller chart. All translated components are included. We use these bounds to show that, on a bounded set of the norm C^1_a, say $\|B\|_{C^1_a}, \|B'\|_{C^1_a} \le K$ in the chart,

$$\|N_a(B) - N_a(B')\|_\infty \le C_K \|B - B'\|_{C^1_a}. \tag{25.12}$$

For the quadratic term, we write the difference as $\mathcal{N}_a(B, B - B') + \mathcal{N}_a(B - B', B')$ and use $\|\mathcal{N}_a(u, v)\|_\infty \le C\|u\|_\infty \|D_a v\|_\infty$ from Lemma 24.2. For the remainder we use the Lipschitz bound for R_3 in that lemma, rescaled to physical units. No interpolation enters (25.12).

Lemma 25.5. *The following statements hold.*

1. *Fix $L, h, K > 0$. Let $B_a(t)$ be a damped lattice solution on $[0, h]$ in the smaller chart with $\sup_{t \le h} \|B_a(t)\|_{C_a^1} \le K$. Then the solution of*

$$V(t) = P_t^a V_0 + \int_0^t P_{t-r}^a \big\{ \mathscr{B}_a(B_a(r)) V(r) + f(r) \big\}\, dr$$

satisfies

$$\sup_{t \le h} \|V(t)\|_{C_a^1} \le C_{L,h,K} \big(\|V_0\|_{C_a^1} + \sup_{r \le h} \|f(r)\|_\infty \big). \tag{25.13}$$

The same bound holds if the right side is replaced by $C_{L,h,K}$ times the norm in $C([0, h]; C_a^1)$ of the whole inhomogeneous term $P_t^a V_0 + \int_0^t P_{t-r}^a f(r)\, dr$. The constant is uniform in small meshes, and no derivative of f is needed.

2. *Let b be a fixed smooth DeTurck solution on $[0, h]$ whose spatial derivatives through order five are bounded by K_b. There are $\eta_b, a_b > 0$ and $C_b < \infty$, depending only on L, h, K_b, and the chart, such that every lattice initial field with $\|B_a(0) - S_a b(0)\|_{C_a^1} \le \eta \le \eta_b$, on a mesh $a \le a_b$, has a damped solution through time h with*

$$\sup_{t \le h} \|B_a(t) - S_a b(t)\|_{C_a^1} \le C_b(\eta + a), \qquad \sup_{t \le h} \|B_a(t)\|_{C_a^1} \le C_b. \tag{25.14}$$

The same holds on each time interval of a fixed continuation as in Theorem 24.10, when the flow is restarted with its fixed sampled gauge transformations. In particular, this comparison supplies the C_a^1 bound that is the hypothesis of the smoothing on later time intervals in Theorem 25.7.

3. *If two initial fields satisfy the hypothesis of (2) with respect to the same solution b, and their solutions are restarted with the same fixed sampled gauge transformations, then*

$$\max_i \sup_{t \in I_i} \|B_a^{(i)}(t) - B_a'^{(i)}(t)\|_{C_a^1} \le C_b \|B_a(0) - B_a'(0)\|_{C_a^1}. \tag{25.15}$$

Here I_i are the finitely many time intervals of the continuation (or the single interval $[0, h]$), $B_a^{(i)}$ and $B_a'^{(i)}$ are the representatives on I_i, and the constant may also depend on the continuation.

4. *Fix $L, h > 0$ and a set $\mathscr{K} \subset C^\infty(\mathbb{T}_L^3; \mathfrak{su}(2)^3)$ that is compact in the C^3 topology. There are $\eta_{\mathscr{K}}, a_{\mathscr{K}} > 0$, $C_{\mathscr{K}} < \infty$, and finitely many continuations as in Theorem 24.10 with the following property. For every $b_0 \in \mathscr{K}$, every $a \le a_{\mathscr{K}}$, and any two lattice initial fields with*

$$\max\big(\|B_a(0) - S_a b_0\|_{C_a^1}, \|B_a'(0) - S_a b_0\|_{C_a^1} \big) \le \eta_{\mathscr{K}},$$

one of these continuations gives the bound $\sup \|B_a(t)\|_{C^1_a} \le C_{\mathscr{K}}$ *through time* h *for both solutions, and* (25.15) *with constant* $C_{\mathscr{K}}$*. The constants depend on* $L, h, \mathscr{K}$*, on the bounds of the finitely many selected smooth DeTurck solutions, and on the margins of the chart and of the continuations. Higher derivatives are only bounded for these finitely many selected solutions, not on a* C^3 *neighborhood of* $\mathscr{K}$*.*

In (2)–(4), every representative is gauge equivalent to the Wilson flow from its initial links.

Proof. Part (1). By the bound on $\mathcal{N}_a$ and (25.11), we have $\|\mathscr{B}_a(B)V\|_\infty \le C_K\|V\|_{C^1_a}$. We use Lemma 25.1 with physical horizon h. The heat semigroup is a contraction for C^1_a, since it commutes with differences, and for $t > 0$

$$\|P^a_t f\|_{C^1_a} \le C_{L,h}\big(1 + (t + a^2)^{-1/2}\big)\|f\|_\infty \le C_{L,h}(1 + t^{-1/2})\|f\|_\infty.$$

In the weighted norm $\|V\|_\lambda = \sup_{t\le h} e^{-\lambda t}\|V(t)\|_{C^1_a}$, the integral operator $V \mapsto \int_0^t P^a_{t-r}\mathscr{B}_a(B_a(r))V(r)\,dr$ has norm at most

$$C_{L,h,K}\int_0^\infty e^{-\lambda v}(1 + v^{-1/2})\,dv = C_{L,h,K}\big(\lambda^{-1} + \sqrt{\pi}\lambda^{-1/2}\big).$$

We choose λ, independently of the mesh, so that this is at most $1/2$. The Neumann series then gives an inverse of weighted norm at most two, and removing the weight costs $e^{\lambda h}$. The initial heat term has norm at most $\|V_0\|_{C^1_a}$, and the integral of the forcing has unweighted norm at most $C_{L,h}(h + 2\sqrt{h})\sup\|f\|_\infty$. This proves both linear assertions.

Part (2). Set $b_a = S_a b$ and $e_a = \partial_t b_a - \Delta_a b_a - N_a(b_a)$. The residual in Theorem 25.4(1) is $O(a^4)$ in dimensionless link-logarithm units. Since $\theta = ab$ and physical time is a^2 times dimensionless time, we divide by a^3 and obtain $\sup_t \|e_a(t)\|_\infty \le C_{K_b}a$. For $Z = B_a - b_a$ the mild difference equation is

$$Z(t) = P^a_t Z(0) + \int_0^t P^a_{t-u}\big\{N_a(b_a(u) + Z(u)) - N_a(b_a(u)) - e_a(u)\big\}\,du.$$

Up to the first time at which $\|Z\|_{C^1_a} = 1$, the difference of the nonlinear terms is at most $C_{K_b}\|Z\|_{C^1_a}$ by (25.12). Using the weighted estimate of Part (1) on every such interval, we obtain

$$\sup_t \|Z(t)\|_{C^1_a} \le C_b(\eta + a).$$

We choose the constants in the following order: first the reference solution and the horizon; then λ and C_b; then η_b and a_b so small that $C_b(\eta_b + a_b) \le 1/2$ and $a_b(\sup\|b\|_\infty + 1)$ is strictly below the radius of the smaller chart. No first time with $\|Z\|_{C^1_a} = 1$ exists, since it would contradict the bound $1/2$. At fixed mesh, the finite-dimensional analytic differential equation can be continued as long as the solution stays in a compact part of the chart, which gives existence through time h. The gauge identification of Lemma 24.2 applies through time h. This proves (25.14).

Part (3) and continuations. For two solutions we subtract their exact equations. The source is $N_a(B_a) - N_a(B'_a)$, and there is no residual. Using the common bound in C^1_a already proved and the estimate of Part (1), we obtain (25.15) on one interval. By Lemma 24.7, at a restart with the fixed smooth gauge transformation k of the continuation, we have

$$\|\mathscr{G}_{a,k}(B_a) - S_a(b^k)\|_{C^1_a} \le C_k \|B_a - S_a b\|_{C^1_a} + C_{k,b}\, a,$$
$$\|\mathscr{G}_{a,k}(B_a) - \mathscr{G}_{a,k}(B'_a)\|_{C^1_a} \le C_k \|B_a - B'_a\|_{C^1_a},$$

where $\mathscr{G}_{a,k}(A)_i(x) = a^{-1}\operatorname{Log}(k(x)e^{aA_i(x)}k(x+ae_i)^{-1})$. Let L_i be the constant of (25.14) or (25.15) on the ith interval, let C_i, C'_i be the Lipschitz constants of the restart, and let $d_i = C_{k_i,b_i}$ be the coefficient of a in the first restart estimate. For the errors e_i relative to the selected DeTurck solution at the restart times, we have the finite affine recurrence $e_{i+1} \le L_i C_i (e_i + a) + d_i a$. For the differences δ_i of a pair at the restart times, we have the homogeneous recurrence $\delta_{i+1} \le L_i C'_i \delta_i$. Their finite products and sums give the asserted constants. We choose the initial error and the mesh only afterwards, below the threshold of every interval divided by the resulting finite multiplier. This proves the assertions for continuations. It also provides the C^1_a bound needed for the later smoothing, without using that smoothing.

Part (4). For each $c \in \mathscr{K}$ we take one continuation through time h from Theorem 24.10. Its finitely many DeTurck solutions are smooth on their closed time intervals and have finite C^5 bounds, and its gauge transformations are fixed and smooth. Parts (2) and (3) give an initial radius $\varepsilon_c > 0$, a threshold $a_c > 0$, and finite constants for this continuation. The sets $\{b_0 : \|b_0 - c\|_{C^1} < \varepsilon_c/4\}$ are open in the C^3 topology and cover $\mathscr{K}$; we select a finite subcover. By the fundamental theorem of calculus along coordinate segments, sampling is a contraction from the norm of values and first derivatives into C^1_a. Thus, if $\eta_{\mathscr{K}} \le \min_c \varepsilon_c/4$ and $\|b_0 - c\|_{C^1} < \varepsilon_c/4$ for a selected c, both lattice initial fields are within $\varepsilon_c/2$ of $S_a c$. We apply Parts (2) and (3) with this c and take the maximum of the finitely many constants and the minimum of the finitely many thresholds. This proves Part (4). □

25.5 Smoothing after a positive waiting time

In the statements about loops below, a closed lattice path ℓ_a approximating a continuum loop ℓ is required to have bounded physical length. It must also be joined to ℓ by a based piecewise smooth homotopy whose swept area, counted with multiplicity, tends to zero, as in Definition 2.1. An area bound $O(a)$ suffices, and coordinate polygons whose vertices lie on the lattice can be taken exactly. The following estimate for a smooth connection b explains this condition.

Let $\Gamma(h,r)$, $h, r \in [0,1]$, be a smooth homotopy with $\Gamma(h,0)$ and $\Gamma(h,1)$ equal to a fixed basepoint, and let $V(h,r)$ be the parallel transport along $\Gamma(h,\cdot)$ up to r, so

that $\partial_r V = V\, b(\partial_r \Gamma)$ and $V(h,0) = I$, where $b(\xi) = \sum_i b_i \xi^i$. We define $X = \partial_h V - V\, b(\partial_h \Gamma)$. Differentiating the transport equation in h and subtracting the r-derivative of $V\, b(\partial_h \Gamma)$, we find $\partial_r X = X\, b(\partial_r \Gamma) + V\, F_b(\partial_h \Gamma, \partial_r \Gamma)$, where $F_b(\xi,\zeta) = \sum_{i,j} F_{ij} \xi^i \zeta^j$ and $F_{ij} = \partial_i b_j - \partial_j b_i + [b_i, b_j]$. Since the basepoint is fixed, $X(h,0) = 0$ and $\partial_h V(h,1) = X(h,1)$. Solving for XV^{-1}, we obtain that $\partial_h V(h,1) V(h,1)^{-1}$ is the integral over $r \in [0,1]$ of the conjugate $V F_b(\partial_h \Gamma, \partial_r \Gamma) V^{-1}$. Since conjugation by unitary matrices has norm one and $\|X\|_{\mathrm{op}} = |X|/2$ for $X \in \mathfrak{su}(2)$, this proves

$$\| \operatorname{Hol}_b(\Gamma(1,\cdot)) - \operatorname{Hol}_b(\Gamma(0,\cdot)) \|_{\mathrm{op}} \le C \|F_b\|_\infty \iint |\partial_h \Gamma \wedge \partial_r \Gamma|\, dr\, dh, \tag{25.16}$$

where C only converts the componentwise curvature norm into the norm of a two-form. Subdivision gives the same estimate for piecewise smooth homotopies. A moving basepoint only adds a conjugation, which does not change traces. The approximation error therefore tends to zero uniformly on each bounded set of smooth connections.

The next lemma is a compactness statement for lattice arrays with bounded differences. In its proof, limits of difference arrays are identified with derivatives by discrete summation by parts, not by differentiating an interpolation of the arrays.

Lemma 25.6. *Let $a_k \to 0$ be meshes, and let A_k be $\mathfrak{su}(2)$-valued link fields on Λ_{L/a_k}. Suppose that for every integer $m \ge 0$ there are $K_m < \infty$ and k_m such that $\max_{|\nu| \le m} \|D^\nu_{a_k} A_k\|_\infty \le K_m$ for all $k \ge k_m$, where ν ranges over ordered compositions of forward and backward differences.*

1. *There are a subsequence (k_j) and a smooth $b \in C^\infty(\mathbb{T}^3_L; \mathfrak{su}(2)^3)$ with $\|\partial^\nu b\|_\infty \le K_{|\nu|}$ for all ν such that, for every ν,*
$$\|D^\nu_{a_{k_j}} A_{k_j} - S_{a_{k_j}} \partial^\nu b\|_\infty \longrightarrow 0.$$
Equivalently, the cardinal interpolants of Lemma 16.3, applied separately to each difference array $D^\nu_{a_{k_j}} A_{k_j}$, converge to $\partial^\nu b$ uniformly on $\mathbb{T}^3_L$.
2. *Let $\mathscr{K}$ be the set of all $b \in C^\infty(\mathbb{T}^3_L; \mathfrak{su}(2)^3)$ with $\|\partial^\nu b\|_\infty \le K_{|\nu|}$ for every ν. Then $\mathscr{K}$ is compact in the C^3 topology, and it contains 0.*
3. *Suppose that for each mesh a a set $\mathcal{F}_a$ of link fields on $\Lambda_{L/a}$ is given such that, for every m, the bound $\max_{|\nu| \le m} \|D^\nu_a A\|_\infty \le K_m$ holds for all $A \in \mathcal{F}_a$ whenever $a \le a_m$. Then*
$$\sup_{A \in \mathcal{F}_a} \inf_{b \in \mathscr{K}} \|A - S_a b\|_{C^1_a} \longrightarrow 0 \qquad (a \to 0).$$

Proof. Part (1). An array g on mesh a whose first differences are bounded by K has oscillation at most $CK(|x-y| + a)$ between two lattice sites x, y, as we see by following a shortest coordinate path on the torus. Since cardinal interpolation is a convex combination of samples within distance Ca, the interpolated array has the same modulus of continuity, up to a fixed constant and an additional CKa. It also takes the given values at the lattice sites. Applying this to $D^\nu A_k$ with the bound $K_{|\nu|+1}$, we find that the interpolants

of the arrays of order $|\nu|$ are bounded by $K_{|\nu|}$ and have modulus $CK_{|\nu|+1}(|x-y|+a_k)$. We choose finite nets of $\mathbb{T}_L^3$ with spacing tending to zero. The bounded values at the points of one net have a convergent subsequence, and the modulus of continuity extends the convergence uniformly over the torus up to an error that vanishes as the spacing and a_k tend to zero. By successive extractions and a diagonal subsequence, we obtain, for every one of the countably many ν, a continuous limit b_ν of the interpolants of $D^\nu A_{k_j}$, with $\|b_\nu\|_\infty \le K_{|\nu|}$. Since the interpolants take the given values at the lattice sites, $\|D^\nu A_{k_j} - S_{a_{k_j}} b_\nu\|_\infty \to 0$.

Let $b = b_\varnothing$ be the limit of the arrays themselves. For a smooth periodic test function φ, discrete summation by parts gives

$$a^3 \sum_x D_a^\nu A(x)\varphi(x) = (-1)^{|\nu|} a^3 \sum_x A(x) \widetilde{D}_a^\nu \varphi(x),$$

where $\widetilde{D}_a^\nu$ reverses the order of the differences and exchanges forward and backward differences. By Taylor expansion of φ and Riemann sums, along the subsequence the left side tends to $\int b_\nu \varphi$ and the right side to $(-1)^{|\nu|} \int b\, \partial^\nu \varphi$. We conclude that $b_\nu = \partial^\nu b$ in the sense of distributions, for every forward or backward choice in ν. Further, the left side is bounded by $K_{|\nu|} a^3 \sum_x |\varphi(x)|$, which gives

$$|\langle \partial^\nu b, \varphi \rangle| \le K_{|\nu|} \|\varphi\|_{L^1}, \tag{25.17}$$

with all direction and color components included. To see that these derivatives are classical, we convolve b with a nonnegative smooth periodic approximate identity χ_ϵ of mass one. Then $\partial^\nu (b * \chi_\epsilon) = b_\nu * \chi_\epsilon$ is bounded by $K_{|\nu|}$ by (25.17), and it converges uniformly to b_ν as $\epsilon \to 0$, because b_ν is continuous; also $b * \chi_\epsilon \to b$ uniformly. By the fundamental theorem of calculus along coordinate segments, when a sequence of functions and their first derivatives converge uniformly, the limit is continuously differentiable with the limiting derivatives. Applying this order by order, we conclude that b is smooth, with $\partial^\nu b = b_\nu$ and $\|\partial^\nu b\|_\infty \le K_{|\nu|}$. The equivalence with uniform convergence of the interpolants follows from the modulus of continuity and the fact that the interpolants take the sampled values at the lattice sites.

Part (2). The bounds on the derivatives of order four imply that the derivatives of order at most three of the elements of $\mathscr{K}$ are bounded and equicontinuous. By the Arzelà–Ascoli theorem, $\mathscr{K}$ is relatively compact in C^3. Let $b_n \in \mathscr{K}$ converge in C^3 to b. The uniform bounds at every higher order allow a diagonal subsequence along which every derivative of b_n converges uniformly. The fundamental theorem of calculus along coordinate segments identifies the limits with the derivatives of b. Hence b is smooth and satisfies the same bounds, and $\mathscr{K}$ is closed in C^3. This uses the bounds at every order; a family controlled at only one finite order need not have a closure consisting of smooth fields.

Part (3). If the assertion fails, there are $\epsilon > 0$, meshes $a_k \to 0$, and $A_k \in \mathcal{F}_{a_k}$ with $\inf_{b \in \mathscr{K}} \|A_k - S_{a_k} b\|_{C^1_{a_k}} \geq \epsilon$. Part (1) implies that a subsequence satisfies $\|A_k - S_{a_k} b\|_\infty \to 0$ and $\|D_{a_k} A_k - S_{a_k} \partial b\|_\infty \to 0$ for some $b \in \mathscr{K}$. Since $\|D_a S_a b - S_a \partial b\|_\infty \leq Ca \|b\|_{C^2} \leq CaK_2$, it follows that $\|A_k - S_{a_k} b\|_{C^1_{a_k}} \to 0$, a contradiction. □

Theorem 25.7. *Fix L, $1/2 < \alpha < 2/3$, and R, and let T_R be the local existence time of Theorem 24.5. For every integer $m \geq 0$ and every $0 < s < T_R$ there are $a_{m,R,s} > 0$ and $C_{m,L,R,s,T_R} < \infty$ such that*

$$\sup_{a \leq a_{m,R,s}} \sup_{s \leq t \leq T_R} \max_{|\nu| \leq m} \|D_a^\nu A_a(t)\|_\infty \leq C_{m,L,R,s,T_R}$$

for all solutions A_a given by Theorem 24.5 whose flow data satisfy $\|(x_a, y_a)\|_{\mathrm{fl},a} \leq R$ on $[0, T_R]$. All ordered compositions of forward and backward differences and all translated components are included. More generally, the same conclusion holds on any smaller interval that begins after a positive waiting time inside a time interval on which a restarted damped representative is used, provided that this representative lies in the smaller chart and a uniform bound in C^1_a on the preceding interval is given. The constant then depends on that bound, on the waiting time, on the length of the interval, and on m.

Suppose that b is a continuous periodic field and that such solutions, along meshes $a_k \to 0$, satisfy $\|A_{a_k}(s) - S_{a_k} b\|_{C^1_{a_k}} \to 0$ at a fixed time $s \in (0, T_R)$. Then b is smooth, with bounds on its derivatives of every order depending only on the order and on L, R, s, T_R. The closure in C^3 of the set of all such limits is compact and consists of smooth connections, so Theorem 24.10 applies to it for every finite horizon. For each such limit b, the Wilson flow started from $\exp(aS_a b)$ has link error $O(a^2)$ on every time interval of a continuation as in Theorem 24.10, including the restarts with the sampled fixed gauge transformations. The normalized traces of its holonomies around closed lattice paths of bounded length that approximate continuum loops, in the sense described before Lemma 25.6, converge to the corresponding continuum traces.

On each later time interval of a continuation by restarts with fixed smooth gauge transformations, the first paragraph applies as soon as a uniform C^1_a bound for the restarted representative is known, for example from Lemma 25.5. Then every fixed difference order is bounded at every fixed positive later time. The C^1_a bound is a hypothesis of this statement; it is not deduced from the smoothing. The constants are deterministic and do not depend on the mesh below the stated thresholds. No bound is claimed as the waiting time tends to zero, and no bound on high norms at time zero follows from the compactness in C^3.

The proof of the first assertion is the standard parabolic bootstrap, carried out on the lattice equation. In a difference of order $m - 1$ of the nonlinearity, the only difference of order m of the solution appears linearly, with a bounded factor in front. The heat semigroup gains one difference at the integrable cost $(t - r)^{-1/2}$, and the resulting term can be absorbed on a short interval.

Proof. Step 1: the base case. By Theorem 24.5, on $[s/2, T_R]$ we have

$$\|A_a(t)\|_\infty + \|D_a A_a(t)\|_\infty \le K_1(L, R, s, T_R). \tag{25.18}$$

This proves the cases $m = 0, 1$. In the smaller chart the equation is

$$\partial_t A_a = \Delta_a A_a + \mathcal{N}_a(A_a, A_a) + a^{-3} R_3(a A_a). \tag{25.19}$$

Step 2: the highest difference. Let $m \ge 2$, and suppose that all differences through order $m-1$ are bounded on a preceding interval, by $K_1, \dots, K_{m-1}$. We show that

$$\big\| D_a^{m-1} \{ \mathcal{N}_a(A_a, A_a) + a^{-3} R_3(a A_a) \} \big\|_\infty \le B_m(K_1, \dots, K_{m-1}) + C_m K_1 \|D_a^m A_a\|_\infty. \tag{25.20}$$

Each summand of $\mathcal{N}_a$ contains exactly one physical difference. When we apply (25.2) $m-1$ times, a factor of order m occurs only when all these differences fall on the factor that already carries a difference; its companion is then a value of A_a, bounded by K_1. If at least one difference falls on the companion, both factors have orders at most $m-1$ and are bounded by the K_j. The number of terms and all translations depend only on m and on the fixed stencil. In the analytic remainder, the term of degree d in physical units has the factor a^{d-3}, $d \ge 3$, and a difference of order $m-1$ of a product involves differences of A_a of order at most $m-1$ only. To see that the series converges uniformly, we shrink the threshold so that aK_1 lies in a fixed smaller chart. A differentiated term of degree d is bounded by a fixed polynomial in d times its coefficient in the series times products of the finitely many K_j. The remaining undifferentiated factors keep a geometric factor from the smaller chart. The resulting series, even multiplied by the polynomial, is summable uniformly in a. This proves that the remainder contributes only to B_m, with no negative power of the mesh. These observations prove (25.20) for every ordered choice of forward and backward differences and all translated components.

Step 3: absorption. We start the mild equation at a time u_0 in the preceding interval, and define

$$Z_m(d) = \sup_{0 < v \le d} \sqrt{v}\, \|D_a^m A_a(u_0 + v)\|_\infty.$$

At each fixed mesh this number is finite, since the arrays are finite dimensional. We commute $m-1$ differences onto the initial value and onto the source, and place one difference on the heat semigroup, whose bound is $C(v + a^2)^{-1/2} \le C v^{-1/2}$. Multiplying the resulting mild estimate by $\sqrt{v}$ and using (25.20), we obtain

$$Z_m(d) \le C_m K_{m-1} + C_m B_m d + C_m K_1 \sqrt{d}\, Z_m(d). \tag{25.21}$$

For the last term we used $\int_0^v (v-r)^{-1/2} r^{-1/2}\, dr = \pi$, together with the additional factor $\sqrt{v} \le \sqrt{d}$; for the bounded source the corresponding factor is $2v \le 2d$. We choose $d \le 1$ such that $C_m K_1 \sqrt{d} \le 1/2$ and such that $[u_0, u_0 + d]$ lies in the preceding interval. Then

(25.21) implies that $Z_m(d) \le 2C_m(K_{m-1} + B_m d)$, and hence a uniform bound on $D_a^m A_a$ at time $u_0 + d$.

Step 4: the whole interval. For a given finite $m \ge 2$ we choose times $s/2 = s_1 < s_2 < \cdots < s_m = s$. At stage $j \ge 2$ we take $d_j > 0$ less than $s_j - s_{j-1}$ and satisfying the absorption condition of Step 3 for order j. For any $t \in [s_j, T_R]$ we apply Step 3 with $u_0 = t - d_j \ge s_{j-1}$ and evaluate at $v = d_j$. This gives one bound K_j for all such t. Since there are finitely many orders, the restrictions $a \le a_{j,R,s}$ have a positive minimum, and the constants are finite. This proves the first assertion. On a restarted time interval, the same proof starts from the given chart and the given C_a^1 bound on the preceding interval instead of (25.18). Inspection of the choices shows the stated dependence of the constant.

Step 5: limits at a positive time. Let $A_{a_k}(s)$ satisfy $\|A_{a_k}(s) - S_{a_k} b\|_{C^1_{a_k}} \to 0$. The first assertion implies that the arrays $A_{a_k}(s)$ satisfy the hypotheses of Lemma 25.6, with bounds $K_m = C_{m,L,R,s,T_R}$. By part (1) of that lemma, a subsequence converges, together with all its difference arrays, to a smooth field with these bounds. This field is b, since the arrays converge to $S_{a_k} b$. Hence every limit belongs to the set $\mathscr{K}$ of part (2) of that lemma, which is compact in C^3 and consists of smooth connections, and so does the C^3 closure of the limits.

Step 6: continuation and loops. We apply Theorem 24.10 with $r = 3$ to this compact set and a fixed horizon. Its open neighborhood contains every smooth connection sufficiently close to the compact set in C^3. Indeed, for each point of the compact set we choose a C^3 ball whose doubled radius lies in the neighborhood, take a finite subcover, and use the minimum of the finitely many radii. Theorem 25.4(4), applied on the finitely many time intervals, yields link error $O(a^2)$ for the Wilson flow started from $\exp(aS_a b)$, including the restarts with the sampled gauge transformations. The Wilson flow and its damped representatives have the same traces of holonomies around closed paths. Since a closed lattice path of length at most ℓ has at most ℓ/a links, unitary telescoping turns the link error $O(a^2)$ into an error $O(\ell a)$ for the holonomy. By Lemma 24.7, the product of the exponentials e^{ab_i} along the path differs from the smooth parallel transport along the same path by an error of the same order. Finally, (25.16) bounds the difference between the smooth transport along the lattice path and along the continuum loop. This proves the assertion on loops.

Step 7: later restarts. Suppose that lattice differences of A of order up to m are bounded and that k is a fixed smooth periodic gauge transformation. Then

$$Y_i(x) = k(x) e^{aA_i(x)} k(x + ae_i)^{-1} = I + O(a),$$

and every difference of fixed order of $Y - I$ keeps this factor a. To verify this, we split $Y - I$ into $k(x)(e^{aA_i(x)} - I)k(x + ae_i)^{-1}$ and $k(x)k(x + ae_i)^{-1} - I$. We handle the first part with the convergent exponential series and the exact product rule, and the second with $k(x + ae_i) - k(x) = \int_0^a \partial_i k(x + re_i)\, dr$. Both give a times a polynomial in the

given bounds and in smooth norms of k. In the analytic composition $a^{-1}\operatorname{Log} Y$, a term with $j \geq 1$ differentiated factors carries a^{j-1}, and the value is $a^{-1}O(a)$. The bounds for the composition are therefore uniform in the mesh, and such a gauge transformation preserves the bounds on lower differences. On each restarted interval, a given uniform C^1_a bound in the common gauge restarts the induction of Step 2, and waiting intervals before each given later time give every given finite order. At a restart time we use a preceding interval and the bound for the composition just proved to transfer the bounds on the differences. This proves the last assertion. □

The next lemma is the space-time version of Lemma 25.6, together with the passage to the limit in the Wilson equation.

Lemma 25.8. *Let $a_k \downarrow 0$, and let $J \subset (0,\infty)$ be a closed interval. Let B_{a_k} be time-dependent link fields on J such that, for every m, all differences of order at most m of B_{a_k} and their time derivatives are bounded on J uniformly in k. We interpolate each difference array separately by the cardinal interpolation of Lemma 16.3. Then every subsequence has a further subsequence along which these interpolated arrays converge, uniformly on $J \times \mathbb{T}^3_L$ at every fixed order, to the corresponding derivatives of one field B that is smooth in space for each time; by a diagonal argument the same holds for countably many intervals simultaneously. If, in addition, each B_{a_k} is a damped representative of the Wilson flow on J, that is, solves $\partial_t B = \Delta_a B + \mathcal{N}_a(B,B) + \mathscr{C}_a(B)$ in the smaller chart, then the limit B solves the DeTurck equation $\partial_t B = \Delta B + \mathcal{N}_0(B,B) + \mathscr{N}_3(B)$ on J. The same holds for the mild form of the equation with a fixed lower integration endpoint in J.*

The passage to the limit in the equation uses three properties of the Wilson equation. Its quadratic part is a fixed finite sum of translated brackets containing one difference (Lemma 24.2). The remainder $\mathscr{C}_a$ has local Lipschitz bounds that are uniform on bounded sets ((25.11)). Finally, $\mathscr{C}_a$ is consistent, uniformly on bounded families of smooth fields (Lemma 25.3). The same proof applies to any equation with these three properties.

Proof. We obtain the spatial modulus of continuity of each interpolated difference array from the bound on the next difference, as in the proof of Lemma 25.6(1). The bounds on the time derivatives give a uniform Lipschitz modulus in time. Using finite nets in space and time, successive subsequences of the bounded finite-dimensional values at their points, and a diagonal argument, we obtain uniform convergence on $J \times \mathbb{T}^3_L$, first for one array and then for the countable list of orders and positive intervals. As in the proof of Lemma 25.6(1), summation by parts against smooth test functions, mollification, and the fundamental theorem of calculus identify the limits with the corresponding classical derivatives.

For the nonlinear terms, every summand of $\mathcal{N}_a$ involves finitely many translations and one difference, and these converge to the corresponding untranslated value and

derivative. For the analytic remainder, the uniform bound on B_a on J implies that the analytic composition converges uniformly on the smaller chart. Its local Lipschitz constants are bounded by (25.11), and its values on the sample of the smooth limit converge to $S_a \mathscr{N}_3(B)$ by Lemma 25.3. Subtracting the value at the sample, we obtain the convergence at B_a itself. The same reasoning applies after any fixed difference for which bounds are given. The lattice Laplacian is a sum of second differences and converges to ΔB. Integrating the differential equations in time, and using uniform convergence to pass every term through the integral, we obtain the limiting equation.

For the mild form, the heat semigroup applied to a sampled smooth family converges by the explicit bounds for general smooth inputs in Lemma 16.9. For a convergent array, we first replace it by the sample of its smooth limit; the replacement error is controlled by contraction. For a first difference of the output, we either commute it onto a convergent difference of the source, or use the integrable heat bound of Lemma 25.1. These arguments pass each term of the mild equation with a positive lower endpoint to the limit. □

25.6 Continuation and stability for bounded flow data

We now apply smoothing and compactness to bounded flow data. After a short positive time u, Theorem 25.7 bounds all lattice differences of the solution, and Lemma 25.6 shows that the solutions at time u are uniformly close to samples of a compact set $\mathscr{K}$ of smooth connections. This compact set depends only on the bound R on the flow data, not on any convergence of the initial potentials. Part (4) of Lemma 25.5 then provides finitely many continuations, chosen before the initial potential. Along them we compare every solution with a selected smooth DeTurck solution, and two solutions with each other.

Lemma 25.9. *Fix $L, T_0, R > 0$, $1/2 < \alpha < 2/3$, and $0 < \tau \le T < \infty$. Let T_R be the local existence time of Theorem 24.5 for flow data of norm at most R, replaced by $\min(T_R, T_0)$, and choose $0 < u < \min(T_R, T_0, \tau)/4$. There are $a_*, K, C, \delta > 0$ and finitely many continuations as in Theorem 24.10, all chosen after these data, with the following properties. For every mesh $a = L/n \le a_*$ and every lattice initial potential whose flow data satisfy $\|(x_a, y_a)\|_{\mathrm{fl},a} \le R$ on $[0, T_0]$, the Wilson flow on $[u, T]$ has damped representatives, restarted at the times of one of these continuations with its sampled gauge transformations, whose C^1_a norms are at most K. If two such initial potentials on the same lattice, compared without any gauge transformation, satisfy*

$$d_a = \mathsf{X}^a_\alpha(x_a - x'_a) + \mathsf{Y}^a_\alpha(y_a - y'_a) \le \delta,$$

with both norms taken on $[0, T_0]$ and including all first differences and translated components, then the two flows can use the same continuation with the same sampled gauge transformations,

and on each of its time intervals

$$\sup_t \|B_a(t) - B'_a(t)\|_{C^1_a} \le C\, d_a.$$

Each representative is gauge equivalent to the Wilson flow $\Psi_t^{(n)}$. The constants and a_* depend only on $L, T_0, R, \alpha, \tau, T, u$, and the chart. In particular they do not depend on higher derivatives of the initial potentials, nor on any finite approximation from which these potentials are constructed. Only the finitely many selected smooth DeTurck solutions need bounds on higher derivatives.

Proof. Step 1: bounds at time u. By the individual bounds and the bound on differences in Theorem 24.5, we have

$$\|A_a(u) - A'_a(u)\|_{C^1_a} \le L_u d_a, \qquad \sup_{u/2\le t\le 2u} \|A_a(t)\|_{C^1_a} \le K_1,$$

and the same individual bound holds for the second initial potential. Theorem 25.7, applied with a preceding interval after a positive waiting time, yields for every fixed m a bound K_m on all differences of order m at time u, for all sufficiently small meshes. The restriction on the mesh may depend on m; along every sequence $a_j \to 0$ it is eventually satisfied at each fixed order.

Step 2: compactness. Let $\mathscr{K}$ be the set of smooth connections b with $\|\partial^\nu b\|_\infty \le K_{|\nu|}$ for all ν. By Lemma 25.6(2), $\mathscr{K}$ is compact in C^3 and contains 0; by part (1) of that lemma, it contains every possible limit of the endpoints $A_a(u)$. Applying part (3) of that lemma to the set $\mathcal{F}_a$ of all endpoints $A_a(u)$ of initial potentials with flow data bounded by R, we obtain

$$\sup \inf_{b\in\mathscr{K}} \|A_a(u) - S_a b\|_{C^1_a} \longrightarrow 0 \qquad (a \to 0),$$

where the supremum is over all such initial potentials.

Step 3: choice of the continuations. We apply part (4) of Lemma 25.5 to $\mathscr{K}$ with horizon $T - u$. Its neighborhood radius $\eta_{\mathscr{K}}$, its restriction $a \le a_{\mathscr{K}}$, its uniform bound, and its finitely many continuations are fixed before we choose either initial potential. We decrease a_* until every endpoint $A_a(u)$ lies within $\eta_{\mathscr{K}}/4$ of $S_a b_0$ for some $b_0 \in \mathscr{K}$, and we choose $\delta \le \eta_{\mathscr{K}}/(4\max(1, L_u))$. If $d_a \le \delta$, then $A'_a(u)$ lies within $\eta_{\mathscr{K}}/4 + L_u\delta \le \eta_{\mathscr{K}}/2$ of the same $S_a b_0$. Thus both endpoints lie in the neighborhood of one common element of $\mathscr{K}$.

Step 4: conclusion. The paired part of Lemma 25.5(4) propagates the initial difference $L_u d_a$ at time u through the finite continuation, using the same sampled gauge transformations for both flows. Its individual part bounds the representative of every initial potential, whether or not it is paired with another. All representatives are gauge equivalent to the Wilson flow by Lemma 24.2. Since the two compared equations are exact lattice equations, their difference has no consistency residual. This proves the asserted bounds and their dependence. □

For matrices, we must also compare the gauge transformations used to define the representatives. On the early interval the damping gauge transformation solves $\partial_t k = \lambda_a k$ with an anti-Hermitian generator. Since such equations have unitary propagators, the difference of two solutions is bounded by the integral of the difference of the generators, without any exponential of the size of the generators. By the estimates of Lemma 24.7, the difference of the generators has an integrable singularity at time zero.

Theorem 25.10. *Fix $L, T_0, R > 0$, $1/2 < \alpha < 2/3$, $0 < t_- \le t_+ \le T < \infty$, and $\mathfrak{l}_1, \dots, \mathfrak{l}_b > 0$. For each mesh $a = L/N$, let $\ell_{1,a}, \dots, \ell_{b,a}$ be closed paths in Λ_N with given basepoints and with physical lengths $aN_{\ell_{i,a}} \le \mathfrak{l}_i$, where N_ℓ is the number of links of ℓ. Let A_0, A_0' be lattice initial potentials on Λ_N whose flow data (x, y), (x', y') satisfy $\|(x,y)\|_{\mathrm{fl},a}, \|(x',y')\|_{\mathrm{fl},a} \le R$ on $[0, T_0]$, put $U = e^{aA_0}$ and $U' = e^{aA_0'}$, and let $d_a = \mathsf{X}^a_\alpha(x - x') + \mathsf{Y}^a_\alpha(y - y')$, with both norms on $[0, T_0]$. Then*

$$\sup_{t_- \le t \le t_+} \max_i \left\| \mathrm{Hol}_{\ell_{i,a}} \Psi^{(N)}_t U - \mathrm{Hol}_{\ell_{i,a}} \Psi^{(N)}_t U' \right\|_{\mathrm{op}} \le C\, d_a.$$

The holonomies are compared as matrices: no gauge transformation is applied to either configuration, and no conjugation at the basepoints is optimized. The constant depends only on $L, T_0, R, \alpha, t_\pm, T$, the lengths $\mathfrak{l}_i$, the chart, and the finitely many smooth DeTurck solutions selected in the proof. It holds for every mesh $a = L/N$ with $N \ge 4$, and it does not depend on the position or shape of the paths beyond their lengths, nor on higher derivatives of the initial potentials.

Let $h_R = \min(T_R, T_0)$, where T_R is the local existence time of Theorem 24.5. After decreasing the mesh bound a_R of that theorem if necessary, the following holds for $a \le a_R$ and $0 \le s \le h_R$. The damped representatives A, A' and their damping gauge transformations k, k' with initial value I satisfy, at every vertex,

$$\|D_a(A - A')(s)\|_\infty \le C_R d_a \big\{ v_a(s)^{-(\alpha+1)/2} + v_a(s)^{-\alpha} + v_a(s)^{\kappa - 1/2} \big\},$$

$$\|k(s) - k'(s)\|_\infty \le C \int_0^s \|D_a(A - A')(v)\|_\infty \, dv \le C_R d_a.$$

For $a \le a_*$ and $d_a \le \delta$, where a_* and δ are the constants of Lemma 25.9 with $\tau = t_-$, both flows can use the same continuation and the same sampled gauge transformations on the later intervals. The matrices are always expressed in the gauges of the initial configurations. For other pairs and meshes, the matrix bound follows from the diameter bound for unitary matrices or from the finite-dimensional Wilson flow, as in the proof.

Proof. Step 1: the early interval. Fix $u < \min(T_R, T_0, t_-)/4$. Since the flow data are bounded by R only on $[0, T_0]$, we apply Theorem 24.5 on $[0, h_R]$. Adding the bound on the difference of the remainders in Theorem 24.5 to the differences of the linear heat evolutions and of the quadratic Picard terms, we obtain exactly the three powers in the bound for $D_a(A - A')$. This bound is also stated in Lemma 24.7. By the formula for the generator in that lemma, the damping generator in physical units is the signed lattice

divergence of the potential, which gives $\|\lambda_a - \lambda'_a\|_\infty \le C\|D_a(A - A')\|_\infty$. The damping gauge transformations solve $\dot k = \lambda_a k$ and $\dot k' = \lambda'_a k'$ with $k(0) = k'(0) = I$. Since the generators are anti-Hermitian, the propagators are unitary, and variation of constants gives, at every vertex,

$$\|k(s) - k'(s)\|_\infty \le \int_0^s \|\lambda_a(v) - \lambda'_a(v)\|_\infty \, dv. \tag{25.22}$$

Indeed, $\partial_s(k^{-1}k') = k^{-1}(\lambda'_a - \lambda_a)k'$, and $\|k' - k\| = \|k^{-1}k' - I\|$. All three powers in the bound for $D_a(A - A')$ are integrable uniformly in the mesh, since $(\alpha + 1)/2 < 1$, $\alpha < 1$, and $1/2 - \kappa < 1$; for $0 < p < 1$ we have $\int_0^{h_R} (v + a^2)^{-p}\, dv \le h_R^{1-p}/(1-p)$. This proves the estimate for the gauge transformations on the early interval $[0, h_R]$. The representatives remain in the chart, since Theorem 24.5, applied on $[0, h_R]$, bounds the contribution of the remainder to the link angles by $C_R a(h_R + a^2)^\kappa$.

Step 2: later intervals and the composed gauge transformations. We apply Lemma 25.9 at time u. If $d_a \le \delta$, the paired estimate implies that $\sup \|B_a - B'_a\|_{C^1_a} \le C d_a$ on every later time interval. Let g, g' be the composed gauge transformations, from the initial configurations to the current damped representatives. At time u their difference is $O(d_a)$ by Step 1. On a time interval I_i of the continuation, $g = k_i g_i$, where g_i is the value at the start of I_i and k_i solves the damping equation with initial value I. The generators of k_i and k'_i differ by at most a constant times the C^1_a difference of the representatives. The inhomogeneous version of (25.22) therefore carries the incoming difference $\|g_i - g'_i\|$ with coefficient one and adds at most $C|I_i|d_a$. At a restart both composed gauge transformations are multiplied on the left by the same fixed unitary gauge transformation, which does not change the norm of their difference. By induction over the finitely many intervals, we obtain $\sup \|g - g'\|_\infty \le C d_a$ through time T, including the possibly different damping gauge transformations of the two flows.

Step 3: the matrices. On a common time interval, the exponential $e^{aB_{a,e}}$ of each link e changes by at most $Ca\|B_a - B'_a\|_\infty$, and unitary telescoping along a path with at most $\mathfrak{l}_i/a$ links gives

$$\|H_i(B_a) - H_i(B'_a)\|_{\mathrm{op}} \le C\mathfrak{l}_i \|B_a - B'_a\|_\infty,$$

where $H_i(B_a)$ is the holonomy of e^{aB_a} around $\ell_{i,a}$. The holonomy of the Wilson flow is $g(x_0)^{-1} H_i(B_a) g(x_0)$, where x_0 is the basepoint, and undoing the composed gauge transformation at x_0 adds at most $2\|g(x_0) - g'(x_0)\|_{\mathrm{op}}$. This proves the estimate for $d_a \le \delta$, in the gauge of the initial configurations. For $d_a > \delta$, the distance between the two matrices is at most two, and it suffices to take $C \ge 2/\delta$.

Step 4: coarse meshes. Only finitely many lattice sides have $a > a_*$. On each of them the Wilson vector field is smooth on the compact manifold $\mathrm{SU}(2)^{\mathcal{E}_N}$, and its solution map over a finite time is Lipschitz. To see this, we subtract the two integral equations, apply the integral form of Gronwall's inequality, and concatenate up to time $4T/a^2$. At $t = 0$

the first weighted norm implies that $\|A_0 - A_0'\|_\infty \le a^{-\alpha} d_a$. Then the initial links differ by at most $C a^{1-\alpha} d_a$. Telescoping after the finite-dimensional flow, with $N_{\ell_{i,a}} \le \mathfrak{l}_i / a$, gives a finite constant on each such side, and we take the maximum over these finitely many sides. This proves the estimate for all meshes. The assertions about the early damped representatives concern the interval $[0, h_R]$ and the mesh threshold of Theorem 24.5, as stated, and the common continuation is used only when $a \le a_*$ and $d_a \le \delta$. □

Corollary 25.11. *Fix $L, T_0, R > 0$, $1/2 < \alpha < 2/3$, $0 < \tau \le T < \infty$, lengths $\mathfrak{l}_1, \dots, \mathfrak{l}_b > 0$, and characters $\chi_1, \dots, \chi_b$ of finite-dimensional representations of $\mathrm{SU}(2)$. Let T_R be the local existence time of Theorem 24.5, replaced by $\min(T_R, T_0)$, and choose*

$$0 < u < \tfrac{1}{4} \min\{T_R, T_0, \tau\}.$$

There are $a_* > 0$ and $C < \infty$, chosen after these data, such that the following holds for every mesh $a = L/n \le a_*$. Let (x_a, y_a) and (x_a', y_a') be the flow data of two lattice initial potentials $A_a(0), A_a'(0)$ on the same lattice, with $\|(x_a, y_a)\|_{\mathrm{fl},a}, \|(x_a', y_a')\|_{\mathrm{fl},a} \le R$ on $[0, T_0]$. Write

$$d_a = \mathsf{X}_\alpha^a (x_a - x_a') + \mathsf{Y}_\alpha^a (y_a - y_a'),$$

with both norms on $[0, T_0]$ and including all first differences, and put $U_a = e^{a A_a(0)}$, $U_a' = e^{a A_a'(0)}$. Then for every choice of closed lattice paths $\ell_{r,a}$ with $a N_{\ell_{r,a}} \le \mathfrak{l}_r$ and every choice of times $t_r \in [\tau, T]$,

$$\Big(\sum_{r=1}^{b} \big| \chi_r\big(\mathrm{Hol}_{\ell_{r,a}} \Psi_{t_r}^{(n)} U_a\big) - \chi_r\big(\mathrm{Hol}_{\ell_{r,a}} \Psi_{t_r}^{(n)} U_a'\big) \big|^2 \Big)^{1/2} \le C\, d_a. \tag{25.23}$$

The threshold and the constant depend only on the displayed data, the chart, and the finitely many smooth DeTurck solutions selected in the proof. They do not depend on the position or shape of the paths beyond their lengths, nor on higher derivatives of the initial potentials or on any finite approximation from which they are constructed. No convergence of the flow data as the mesh varies is assumed, and there is no additive error in the mesh. For normalized fundamental traces, take $\chi_r(V) = (1/2) \operatorname{tr} V$.

Proof. We apply Theorem 25.10 with the given lengths and with $t_- = \tau$, $t_+ = T$. Every character χ of a finite-dimensional representation of $\mathrm{SU}(2)$ is a polynomial p_χ in $(1/2) \operatorname{tr} V$. Indeed, on the diagonal matrices $\operatorname{diag}(e^{i\theta}, e^{-i\theta})$ the character is $\sum_k m_k e^{ik\theta}$ with integer weights k and multiplicities $m_k = m_{-k}$, which is a combination of the functions $\cos(k\theta)$. The recurrence for $\cos(k\theta)$ expresses these as polynomials in $\cos\theta = (1/2) \operatorname{tr} V$. Then $\sup_{[-1,1]} |p_\chi'|$ bounds the Lipschitz constant of χ as a function of the normalized trace, and the normalized trace is Lipschitz in the matrix norm. Summing the finitely many bounds in Euclidean norm, we obtain (25.23). □

25.7 Parameter derivatives in a fixed initial gauge

In the weak-coupling analysis of Sections 34 to 36, the initial potential depends on finitely many real parameters, and we need two parameter derivatives of the flowed holonomy matrices, uniformly in the mesh. We first treat a single time interval on which the representative is bounded in C^1_a, and then the singular initial interval and the continuation.

Lemma 25.12. *Assume the hypothesis of Lemma 25.5(1) for every value of a finite-dimensional real parameter, and suppose that the initial field depends twice continuously differentiably on the parameter. For unit directions v, w write $V_v = \partial_v B_a$ and $W_{vw} = \partial_v \partial_w B_a$. If the initial C^1_a norms of V_v and W_{vw} are bounded by b_1 and b_2, then*

$$\sup_{t \le h} \|V_v(t)\|_{C^1_a} \le C_{L,h,K}\, b_1, \qquad \sup_{t \le h} \|W_{vw}(t)\|_{C^1_a} \le C_{L,h,K}(b_2 + b_1^2). \tag{25.24}$$

These estimates persist through finitely many restarts with fixed sampled smooth gauge transformations. After positive waiting times they also give bounds on every given fixed order of spatial differences of B_a, V_v, and W_{vw}. The corresponding assertions hold for smooth continuum solutions on the time intervals of a continuation as in Theorem 24.10.

Proof. Step 1: differentiability. At each fixed mesh, the initial fields and the finite-dimensional analytic vector field have two continuous derivatives. Difference quotients in the integral equation converge to the solutions of the differentiated linear integral equations. Indeed, Taylor's integral formula for the vector field leaves a remainder that tends to zero uniformly on compact sets of parameters and times, and the linear Volterra inverse of Lemma 25.5(1) bounds the effect of this remainder. Applying this first to the fields and then to their first derivatives, we obtain the differentiability. The uniform bounds below do not depend on the fixed mesh.

Step 2: the equations. The derivatives satisfy

$$\begin{aligned} \partial_t V_v &= \Delta_a V_v + \mathscr{B}_a(B_a) V_v, \\ \partial_t W_{vw} &= \Delta_a W_{vw} + \mathscr{B}_a(B_a) W_{vw} + f_{vw}, \\ f_{vw} &= \mathcal{N}_a(V_v, V_w) + \mathcal{N}_a(V_w, V_v) + D^2 \mathscr{C}_a(B_a)[V_v, V_w]. \end{aligned} \tag{25.25}$$

The Volterra estimate (25.13) implies the first bound in (25.24). By the bound on $\mathcal{N}_a$ and (25.11), we have $\|f_{vw}\|_\infty \le C_K \|V_v\|_{C^1_a} \|V_w\|_{C^1_a}$, and applying the Volterra estimate to the inhomogeneous second equation gives the second bound. Note that the second variation satisfies an inhomogeneous equation, and the forcing f_{vw} must be kept.

Step 3: restarts. For a fixed smooth gauge transformation k, the map $\mathscr{G}_{a,k}(B)_i(x) = a^{-1} \operatorname{Log}(k(x) e^{aB_i(x)} k(x + a e_i)^{-1})$ satisfies, on a bounded set of the norm C^1_a,

$$\|D^j \mathscr{G}_{a,k}(B)[Z_1, \dots, Z_j]\|_{C^1_a} \le C_{k,K} \prod_{i=1}^{j} \|Z_i\|_{C^1_a}, \qquad j = 1, 2, \tag{25.26}$$

where D differentiates in the field. The case $j = 1$ is the Lipschitz bound of Lemma 24.7; we check the case $j = 2$ directly. For $Y = k(x)e^{aB_i(x)}k(x + ae_i)^{-1}$ we have $Y - I = O_K(a)$, and the jth field derivative of Y has a factor a^j for $j = 1, 2$. By the exact product rule, the given C^1_a norms, and the bounded smooth differences of k, a further spatial difference keeps these factors. Since the derivatives of Log are bounded near I, a differentiated term in $a^{-1}\operatorname{Log} Y$ keeps at least one factor a to compensate the factor a^{-1}, also after one spatial difference. Terms with more differentiated factors carry further nonnegative powers of a. This proves (25.26), using only fixed smooth norms of k and a margin of the chart. Counting factors in the same way, with three field arguments, we bound $D^3\mathscr{G}_{a,k}$ on this set: it has the factor a^3 before the division by a, and products of derivatives of the logarithm have at least the same total number of field arguments; one spatial difference again keeps these factors. Hence the first two field derivatives in (25.26) are locally Lipschitz on this set, with uniform constants, which we use below to subtract second derivatives at restarts. The chain rule at a restart gives

$$V_v^+ = D\mathscr{G}_{a,k}(B)V_v, \qquad W_{vw}^+ = D\mathscr{G}_{a,k}(B)W_{vw} + D^2\mathscr{G}_{a,k}(B)[V_v, V_w].$$

These bounds and (25.24) can be composed finitely many times. Since the gauge transformations k are fixed, no parameter dependence of a gauge choice is differentiated in these formulas.

Step 4: higher differences. We apply Theorem 25.7 to B_a, whose C^1_a bound is given. After $m - 1$ differences of the first equation in (25.25), computed with the product rules (25.2), the only unknown term of highest order is bounded by $C_K\|D^m_a V_v\|_\infty$. The term containing $D^m_a B_a$ has the companion V_v, whose value is already bounded, and it belongs to the known forcing. Every other term contains only lower differences of V_v and bounded differences of B_a. The field derivative of the remainder involves no difference of order larger than $m - 1$ and no negative power of the mesh. This estimate has the form of (25.20), with a known bounded forcing. As in (25.21), the weighted quantity $\sup_v \sqrt{v}\|D^m_a V_v(u_0 + v)\|_\infty$ and the integral $\int_0^v (v - r)^{-1/2} r^{-1/2}\, dr = \pi$ then bound $D^m_a V_v$ after a positive waiting time. In the second equation the unknown term of highest order is bounded by $C_K\|D^m_a W_{vw}\|_\infty$. Its additional forcing involves differences of V_v and V_w of order at most m, which are already bounded by the argument for the first derivatives, and the same absorption gives order m for W_{vw}. Finitely many successive waiting intervals give any given finite list of orders, and the argument for restarts extends to these orders by the exact product rule.

Step 5: continuum solutions. For smooth continuum solutions on the time intervals of a continuation, the same proof applies, with the ordinary product rule and the heat estimates stated in Theorem 24.10, on a fixed physical horizon subdivided if necessary. Starting from a smooth finite-dimensional family of initial data, we take difference quotients of the continuum mild equation. The same Volterra inverse and Taylor's

integral remainder give their convergence, first at order one and then at order two. If bounds through a fixed order are needed up to the initial time, they hold for the smooth family at the initial time. We then apply the product rule one order below the highest desired derivative and the same Volterra estimate; the highest term is linear, with a bounded undifferentiated companion. Induction gives the required mixed bounds in space and in the parameters, down to the initial time of each such smooth solution. □

Theorem 25.13. *Fix $L > 0$, $1/2 < \alpha < 2/3$, $T_0 > 0$, a finite horizon $T > 0$, and $t_* \in (0, T]$, and consider the holonomies around the three coordinate cycles of $\mathbb{T}_L^3$, based at a fixed vertex x_0, at times in $[t_*, T]$. Let $U_0 \Subset U_1 \subset \mathbb{R}^d$ be bounded parameter domains, covered by finitely many smooth input charts with fixed positive margins; changes between these charts act on the initial potentials by gauge transformations equal to the identity at the basepoint. For each mesh $a = L/n$, let $u \mapsto \mathcal{E}_a(u) = (x_a(u), y_a(u))$ be the flow data of a lattice initial potential $A_{0,a}(u)$, twice continuously differentiable on U_1, with*

$$\sup_{a,\, u \in U_1} \sum_{r=0}^{2} \|D_u^r \mathcal{E}_a(u)\|_{\mathrm{fl},a} \le R_2 < \infty,$$

where the norms are taken on $[0, T_0]$ and contain both components and all their first physical differences, and the parameter derivatives are measured in a fixed Euclidean operator norm. For every u, start the damping gauge transformation at I, in the gauge of the initial configuration $e^{a A_{0,a}(u)}$. Let T_{R_2} be the local existence time of Theorem 24.5 for the bound R_2, replaced by $\min(T_{R_2}, T_0)$.

1. *There is $a_* > 0$, chosen after the displayed data and below the restrictions on the mesh in Theorem 24.5, such that the following holds for every mesh $a \le a_*$. On the early interval $[0, T_{R_2}]$, the remainder $r_a(u)$ and the damped representative $A_a(u, t)$ satisfy, for $r = 1, 2$,*

$$\sup_{a \le a_*,\, u \in U_0} \|D_u^r r_a(u)\|_{\mathsf{R}_a} \le C_{R_2},$$

$$\|D_u^r D_a A_a(u, t)\|_\infty \le C_{R_2} \big\{ (t + a^2)^{-(\alpha+1)/2} + (t + a^2)^{-\alpha} + (t + a^2)^{\kappa - 1/2} \big\}.$$

   All three powers of $t + a^2$ are integrable at zero, uniformly in the mesh. The first and second parameter derivatives of the damping gauge transformation are bounded uniformly at every vertex on this interval. The representatives remain in the chart, by the bound

$$a \sup_{t \le T_{R_2}} \|A_a(t)\|_\infty \le C_{R_2} \big\{ a^{1-\alpha} + a^{2-2\alpha} + a (T_{R_2} + a^2)^{\kappa} \big\} \longrightarrow 0.$$

2. *At a positive restart time, the solutions are smoothed by Theorem 25.7, and the continuations of Theorem 24.10 are used on a neighborhood of the compact closure of their possible limits; on each restart, the same fixed sampled gauge transformation is applied to all parameters in a neighborhood. The first and second parameter derivatives of the resulting based holonomy*

matrices of the three coordinate cycles on $[t_*, T]$, expressed in the gauge of the initial configuration, are bounded by a constant $C_{R_2,U_0,U_1,t_*,T}$ uniformly in the mesh. These matrices therefore have a uniform $C^{1,1}$ bound on smaller convex parameter charts. The conjugation at the basepoint by all damping and restart gauge transformations is included; this is a statement about matrices, not only about their traces.

3. *Let $f(u)$, $u \in U_1$, be a fixed compact family of finite sums of smooth cardinal interpolants, twice continuously differentiable in u, and let $A_{0,a}(u) = S_a f(u)$. Then the matrices of (2) converge, uniformly in $u \in U_0$ and $t \in [t_*, T]$, to the holonomy matrices, based at x_0, of the solution of $\partial_t A_i = \sum_j D_j F_{ji}$ with initial value $f(u)$; the proof shows that their first two parameter derivatives converge as well. The divergence generators of the damping gauge transformations converge on positive time intervals and in L^1 down to time zero, and the damping gauge transformations with initial value I converge at the basepoint. The same conclusions hold when the finitely many coefficients of the family depend on a and converge together with their first two parameter derivatives. No rate that is uniform over growing families is asserted.*

The constants in (1) and (2) depend only on d, U_0, U_1, and the margins of the input charts, on R_2, L, α, T_0, t_*, T, and on the chart and the margins of the continuations. The bounds for the based holonomy matrices in (2) hold for every mesh $a = L/n$, $n \geq 4$. The assertions about logarithmic representatives and their damping gauge transformations hold for $a \leq a_*$; finitely many additional meshes can be included when the corresponding representatives remain in the fixed smaller chart. The constants in (3) may also depend on the fixed family. The derivatives are real derivatives of the Wilson flow; neither a complex continuation of the flow nor a derivative of a Borel selection is involved.

We outline the proof. On the early interval, where the flow data are singular, we differentiate the fixed-point equation for the remainder $r = A - x - y$ of Theorem 24.5 twice in the parameters. The second derivative of the quadratic term contains products of two differentiated linear heat evolutions, whose singularity $v_a^{-\alpha-1/2}$ is not integrable. These products cancel against the corresponding products in the definition of r, and the remaining terms have the integrable singularity $v_a^{-3\alpha/2}$. We control the parameter derivatives of the damping gauge transformation by unitary variation of constants. After a positive time, the solutions are smooth uniformly in the mesh, and we continue them by comparison with finitely many selected smooth DeTurck solutions, as in Lemma 25.9. Along this continuation, Lemma 25.12 controls the parameter derivatives. Finally we return to the gauge of the initial configuration by conjugating with the composed gauge transformation at the basepoint, and differentiate this conjugation as well. For a fixed smooth family, the consistency results of Sections 25.2 and 25.3, differentiated twice in the parameters, identify the limit.

Proof. Step 0: setup. We work first in one of the finitely many input charts. Since changes between these charts are gauge transformations equal to the identity at the basepoint, they do not change the gauge in which the matrices are expressed. We choose an intermediate parameter domain V with $\overline{U}_0 \subset V \Subset U_1$. We take all difference quotients inside U_1 and first establish all bounds on V; the minimal parameter margin and the constants of the charts and of the conversion of Euclidean norms enter the final constant. In formulas involving directions, v, w have Euclidean norm at most one. Set

$$h_0 = T_{R_2}, \qquad p = \tfrac{3}{2}\alpha < 1,$$

and recall $\beta = \alpha - 1/2$, $\kappa = 1 - 3\alpha/2 = 1 - p$, and $v_a(t) = t + a^2$. Using the contraction proof of Theorem 24.5, we may decrease the local existence time while restricting the horizon of the flow data. All weighted norms and all the gains of the contraction then only decrease, and none of the bounds on the early remainder becomes larger. We choose h_0 small enough for the contractions below, and take $a^2 \le h_0$ and $a \le 1$. All heat integrals in the early argument have physical horizon h_0.

Step 1: the differentiated equation on the early interval. We write $x = x_a(u)$, $y = y_a(u)$, and $A = x + y + r$, and let

$$(\mathcal{T}_a f)(t) = \int_0^t P^a_{t-s} f(s)\, ds, \qquad F_a((x,y),r) = \mathcal{T}_a\big\{\mathcal{N}_a(A,A) - \mathcal{N}_a(x,x) + \mathscr{C}_a(A)\big\}.$$

The remainder satisfies the fixed-point equation $r = F_a((x,y),r)$ exactly, with no term of the vector field truncated. By Theorem 24.5, r lies in a ball of fixed radius $D = D(R_2)$ in the norm R_a. Using the estimates of the local contraction on a slightly larger fixed ball, we obtain

$$\|A(t)\|_\infty \le C_{R_2,D} v_a(t)^{-\alpha/2}, \qquad \|D_a A(t)\|_\infty \le C_{R_2,D} v_a(t)^{-(\alpha+1)/2}. \tag{25.27}$$

Indeed, the exponents β, α of y are smaller than the corresponding exponents $\alpha/2, (\alpha+1)/2$ of x, the remainder has exponents $\kappa, \kappa - 1/2$, and $v_a \le 2$. The derivative in the remainder variable is

$$\mathsf{L}_a \rho = D_r F_a((x,y),r)\rho = \mathcal{T}_a\{\mathscr{B}_a(A)\rho\}.$$

If $\|\rho\|_{\mathsf{R}_a} \le 1$, its source is bounded by

$$C_{R_2,D}\big\{v_a^{\kappa-(\alpha+1)/2} + v_a^{\kappa-\alpha}\big\};$$

the first term comes from the two ordered quadratic products and the second from $D\mathscr{C}_a(A)\rho$. Both exponents exceed -1. Bounding the value of the convolution and one difference of the heat semigroup, and then applying (25.1), we obtain

$$\|\mathsf{L}_a\|_{\mathsf{R}_a \to \mathsf{R}_a} \le C_{R_2,D}\big\{(h_0 + a^2)^{(1-\alpha)/2} + (h_0 + a^2)^{1-\alpha}\big\} \le \tfrac{1}{2}, \qquad \|(I - \mathsf{L}_a)^{-1}\| \le 2. \tag{25.28}$$

We choose h_0, and then the restriction $a \le a_*$ on the mesh, so that this holds on the slightly larger ball. The inverse is given by the norm-convergent Neumann series, and it acts on the whole Volterra integral.

For a direction (ξ, η) in the flow data, the derivative of the source with r fixed is

$$\begin{aligned} J_a(\xi,\eta) &= \mathcal{N}_a(x,\eta) + \mathcal{N}_a(\eta,x) \\ &\quad + \mathcal{N}_a(y+r,\xi+\eta) + \mathcal{N}_a(\xi+\eta,y+r) + D\mathscr{C}_a(A)(\xi+\eta); \end{aligned} \tag{25.29}$$

the products $\mathcal{N}_a(x,\xi)$ and $\mathcal{N}_a(\xi,x)$ cancel against the derivative of $\mathcal{N}_a(x,x)$. If $b = \|\xi\|_{\mathsf{X}^a_\alpha} + \|\eta\|_{\mathsf{Y}^a_\alpha}$, then

$$\|J_a(\xi,\eta)(t)\|_\infty \le C_{R_2,D}\, b\, v_a(t)^{-p}, \qquad \|\mathcal{T}_a J_a(\xi,\eta)\|_{\mathsf{R}_a} \le C_{R_2,D}\, b. \tag{25.30}$$

To verify the time exponents, recall that $\|\mathcal{N}_a(u,v)\|_\infty \le C\|u\|_\infty \|D_a v\|_\infty$. The products of one factor x or ξ with one factor y or η have worst exponents $-\alpha/2 - \alpha = -p$ and $-\beta - (\alpha+1)/2 = -p$. Two factors of the type y, η give the exponent $1/2 - 2\alpha$. A remainder factor against a factor of type x, ξ gives the same exponent $1/2 - 2\alpha$, and against a factor of type y, η the exponent $\kappa - \alpha$. All of these are at least $-p$ for $\alpha < 2/3$. Finally, (25.11) bounds the last term by $C\|A\|_\infty^2 \|\xi+\eta\|_\infty$, again with exponent $-p$. Since $\kappa = 1 - p$, the convolutions have exactly the powers v_a^κ and $v_a^{\kappa-1/2}$ of the norm R_a.

For fixed a, the initial value $A_0(u) = x_a(u,0)$ is twice continuously differentiable in u. The differential equation in the chart, or difference quotients of its contracting integral equation, allow us to differentiate $r = F_a((x,y),r)$ twice. To justify the second route, we subtract two fixed-point identities and integrate the derivative in the field along the segment joining them. The difference of the remainders is then obtained by applying an inverse of norm at most two to the difference in the flow data. By Taylor's integral remainder and (25.30), the first difference quotient converges. Repeating this with the first differentiated equation, and using the second field derivatives of the analytic vector field, we obtain the convergence of the second difference quotient. This justifies the differentiation before we derive the uniform bounds below.

We write $\xi_v = \partial_v x$, $\eta_v = \partial_v y$, $\rho_v = \partial_v r$, and $Z_v = \partial_v A$. The first derivative satisfies

$$(I - \mathsf{L}_a)\rho_v = \mathcal{T}_a J_a(\xi_v, \eta_v), \qquad Z_v = \xi_v + \eta_v + \rho_v. \tag{25.31}$$

By hypothesis, $b \le R_2$ here, and (25.28) and (25.30) imply that $\|\rho_v\|_{\mathsf{R}_a} \le C_{R_2}$. The second derivative satisfies, with all inhomogeneous terms,

$$\begin{aligned} (I - \mathsf{L}_a)\rho_{vw} &= \mathcal{T}_a\{J_a(\xi_{vw},\eta_{vw}) + K_{vw}\}, \\ K_{vw} &= \mathcal{N}_a(Z_v,Z_w) + \mathcal{N}_a(Z_w,Z_v) - \mathcal{N}_a(\xi_v,\xi_w) - \mathcal{N}_a(\xi_w,\xi_v) \\ &\quad + D^2\mathscr{C}_a(A)[Z_v,Z_w]. \end{aligned} \tag{25.32}$$

The two subtracted products of differentiated linear heat evolutions must be kept: bounding the two unsubtracted products separately would produce the exponent $-\alpha - 1/2$,

which is not integrable for $\alpha > 1/2$. We write $Z_v = \xi_v + \delta_v$ with $\delta_v = \eta_v + \rho_v$. Each ordered quadratic difference in K_{vw} then contains at least one factor δ; for instance,

$$\mathcal{N}_a(Z_v, Z_w) - \mathcal{N}_a(\xi_v, \xi_w) = \mathcal{N}_a(\xi_v, \delta_w) + \mathcal{N}_a(\delta_v, \xi_w) + \mathcal{N}_a(\delta_v, \delta_w).$$

The part η of δ has the exponents of the quadratic Picard term, and the part ρ has the exponents of the remainder, which were bounded above. By the exponent calculation for (25.30), the sum of these terms is bounded by $C_{R_2} v_a^{-p}$. For the last term we use $\|D^2\mathscr{C}_a(A)[Z_v, Z_w]\|_\infty \le C\|A\|_\infty \|Z_v\|_\infty \|Z_w\|_\infty$; each factor has the value bound $C v_a^{-\alpha/2}$, which again gives the exponent $-p$. In total, the second forcing has, before inversion, R_a norm at most C_{R_2}, and by (25.28) we have $\|\rho_{vw}\|_{\mathsf{R}_a} \le C_{R_2}$. These directional estimates give the asserted bounds on both parameter derivatives in Euclidean operator norm, with all directions and all first physical differences included.

Adding the differentiated flow data to these two estimates for the remainder, we find, for $r = 1, 2$,

$$\|D_u^r D_a A(u,t)\|_\infty \le C_{R_2}\big\{ v_a(t)^{-(\alpha+1)/2} + v_a(t)^{-\alpha} + v_a(t)^{\kappa-1/2} \big\}. \tag{25.33}$$

The same bound, with a possibly larger C_{R_2}, holds for $r = 0$. All three negative exponents are smaller than one in absolute value. In particular, the integrals of the right side over $[0, \epsilon]$ are at most

$$C_{R_2}\, \omega(\epsilon), \qquad \omega(\epsilon) = \epsilon^{(1-\alpha)/2} + \epsilon^{1-\alpha} + \epsilon^{\kappa+1/2}, \tag{25.34}$$

uniformly in a, for $0 < \epsilon \le h_0$. Finally, the representatives remain in the chart because

$$a \sup_{t \le h_0} \|A(t)\|_\infty \le C_{R_2}\big\{ a^{1-\alpha} + a^{2-2\alpha} + a(h_0 + a^2)^\kappa \big\} < r_*;$$

in the last term we used the maximum of the remainder over the interval, which is attained at the end and not at time zero. The differentiated mild solution is therefore, for every parameter, the damped representative of the Wilson flow.

Step 2: the damping gauge transformation on the early interval. The generator in physical units is linear in the potential:

$$\lambda_a = a^{-2}\phi(aA) = -\sum_i D_{a,i}^- A_i, \qquad \partial_t k_a = \lambda_a k_a, \qquad k_a(0) = I. \tag{25.35}$$

It is anti-Hermitian. Its parameter derivatives of order zero, one, and two are bounded in $L^1([0,h_0]; \ell^\infty)$ by (25.33), and their integrals over $[0,\epsilon]$ are bounded by (25.34). At any vertex write $l_v = \partial_v k_a$ and $m_{vw} = \partial_v \partial_w k_a$. Direct differentiation gives

$$\begin{aligned} \partial_t l_v &= \lambda_a l_v + (\partial_v \lambda_a) k_a, \qquad l_v(0) = 0, \\ \partial_t m_{vw} &= \lambda_a m_{vw} + (\partial_v \lambda_a) l_w + (\partial_w \lambda_a) l_v + (\partial_{vw} \lambda_a) k_a, \qquad m_{vw}(0) = 0. \end{aligned} \tag{25.36}$$

The homogeneous propagator is unitary. If $B_j = \int_0^{h_0} \|D_u^j \lambda_a\|_\infty \, dt$ for $j = 1, 2$, variation of constants gives

$$\sup_t \|l_v(t)\|_\infty \le B_1, \qquad \sup_t \|m_{vw}(t)\|_\infty \le B_2 + 2B_1^2.$$

These bounds hold at every vertex, uniformly in the mesh, with no exponential of the size of λ_a, and they include the two products of first derivatives in the second equation. Differentiating $k_a^{-1} k_a = I$, we also bound both derivatives of k_a^{-1}. This completes the proof of (1).

Step 3: bounds on later intervals. Fix $0 < s < \min(h_0/2, t_*/2)$, which leaves room for a positive waiting time before s. By the early estimates we have uniform C_a^1 bounds on A, Z_v, and Z_{vw} on $[s/2, h_0]$. We apply Theorem 25.7 to A, and then Lemma 25.12 on intervals after positive waiting times inside the early interval. At time s these give bounds on every given fixed order of differences of the three fields, with constants depending on that order, on L, R_2, s, and on the parameter data.

Next, we justify the use of finitely many selected smooth DeTurck solutions, although we have not assumed that the flow data converge as the mesh varies. Let $\mathscr{K}$ be the set of smooth connections whose derivatives of every order satisfy the bounds just obtained for $A_a(s, u)$; it depends only on L, R_2, s. By Lemma 25.6, it is compact in C^3, it contains every limit of a sequence $A_{a_j}(s, u_j)$ with $a_j \to 0$, and

$$\sup_u \inf_{b \in \mathscr{K}} \|A_a(s, u) - S_a b\|_{C_a^1} \longrightarrow 0 \qquad (a \to 0). \tag{25.37}$$

Only the spatial bounds at time s are needed here.

We apply part (4) of Lemma 25.5 to $\mathscr{K}$ with horizon $T - s$. It provides $\eta_{\mathscr{K}} > 0$ and finitely many continuations, built from the DeTurck solutions of Theorem 24.10 with $r = 3$, whose needed C^5 norms are finite. It also provides one restriction $a \le a_{\mathscr{K}}$ and one C_a^1 bound for all comparisons with lattice fields within $\eta_{\mathscr{K}}$ of the sample of an element of $\mathscr{K}$. Then (25.37) implies that for every sufficiently small mesh and every u there exists $b \in \mathscr{K}$ with $\|A_a(s, u) - S_a b\|_{C_a^1} \le \eta_{\mathscr{K}}/4$. By the early bound on the first parameter derivative, we have

$$\|A_a(s, u') - A_a(s, u)\|_{C_a^1} \le C_{R_2, s} |u' - u|$$

on every segment in V. Hence, for $|u' - u|$ smaller than the input margin and smaller than $\eta_{\mathscr{K}} / (4 C_{R_2, s})$, the field $A_a(s, u')$ lies within $\eta_{\mathscr{K}}/2$ of the same $S_a b$. Then all parameters in this neighborhood of u can use the same continuation, with the same fixed sampled gauge transformations. Then the individual estimate (25.14) gives the C_a^1 bound for the representatives through time T. This estimate applies to an incoming small discrepancy in C_a^1; it does not require a link error of order a^2.

The two initial parameter derivatives at time s already have uniform C_a^1 bounds. Applying (25.24) and (25.26) along this finite continuation, we obtain one uniform C_a^1

bound for the first and second parameter derivatives on every time interval, including its endpoints. Only after the C^1_a bound for the representative has been obtained in this way do we apply the last part of Theorem 25.7. Together with the last part of Lemma 25.12, it gives further spatial orders at every given positive waiting time.

Step 4: composed gauge transformations and matrices. On a later time interval I_j, let $g_j(t)$ be the damping gauge transformation with initial value I at the start of I_j. By (25.35) and the C^1_a bounds just proved, its generator and the first two parameter derivatives of the generator are bounded. Then the equations (25.36) bound the first two parameter derivatives of g_j on I_j. We keep track of the whole gauge transformation at every vertex, and not only of its value modulo a conjugation at the basepoint. If Q_j is the composed gauge transformation at the start of I_j, then

$$Q(t) = g_j(t)Q_j, \qquad Q_{j+1} = k_j\, g_j(h_j)Q_j, \qquad Q_0 = k_a(s), \tag{25.38}$$

where h_j is the length of I_j and k_j is the fixed sampled gauge transformation applied at its end. The order of these products follows from $(U^k)^l = U^{lk}$. Since all factors are unitary, the k_j do not depend on the parameter, and there are finitely many of them, the first and second product rules bound $D_u Q$ and $D_u^2 Q$ at every vertex. This includes the early damping gauge transformation with its initial value I.

Let $H^{\mathrm{rep}}_a(t,u)$ be the holonomy of one of the coordinate cycles in the current damped representative. If the cycle has N links and $aN \le \ell$, differentiating a single exponential gives

$$\|\partial_v e^{aA_e}\|_{\mathrm{op}} \le Ca\|Z_v\|_\infty, \qquad \|\partial_{vw} e^{aA_e}\|_{\mathrm{op}} \le Ca\|Z_{vw}\|_\infty + Ca^2\|Z_v\|_\infty\|Z_w\|_\infty;$$

these follow by integrating the derivative of the exponential once and twice along its unitary factors. An inverse factor satisfies bounds of the same type, by differentiating the identity for the inverse. The product rule over the links of the cycle gives

$$\begin{aligned} \|\partial_v H^{\mathrm{rep}}_a\|_{\mathrm{op}} &\le C\ell\|Z_v\|_\infty, \\ \|\partial_{vw} H^{\mathrm{rep}}_a\|_{\mathrm{op}} &\le C\ell\|Z_{vw}\|_\infty + C(\ell a + \ell^2)\|Z_v\|_\infty\|Z_w\|_\infty. \end{aligned} \tag{25.39}$$

The term ℓa counts the N second derivatives of a single factor, and the term ℓ^2 counts the at most $N(N-1)$ products of two first derivatives. Since every observation time is later than s, the fields in these estimates are uniformly bounded by Step 3. At the basepoint x_0, the holonomy matrix of the Wilson flow in the gauge of the initial configuration is

$$H_a(t,u) = Q(t,x_0)^{-1} H^{\mathrm{rep}}_a(t,u)\, Q(t,x_0). \tag{25.40}$$

Its two derivatives include the derivatives of both factors $Q(t,x_0)^{\pm 1}$. By the bounds for Q and Q^{-1} and (25.39), all these terms are bounded uniformly. At a restart time both representations describe the same holonomy matrix of the Wilson flow, so their parameter

derivatives agree there. The choice of a reference neighborhood was used only to prove a bound for the map $u \mapsto H_a(t,u)$, which is defined independently of this choice. The choice is constant on the parameter neighborhood where the derivatives were computed, and we take no derivative of it. Taking the maximum over the finitely many possible continuations, we obtain the uniform bounds on the first and second derivatives on U_0. On a smaller convex chart, the fundamental theorem of calculus along segments and the bound on the second derivative imply that $\|DH_a(u) - DH_a(u')\| \le C|u-u'|$. Together with $\|H_a\|_{\mathrm{op}} = 1$, this is the uniform $C^{1,1}$ bound in (2).

Step 5: smooth families, consistency of the fields. Let $f(u)$ be a fixed compact family as in (3), with its two parameter derivatives on the larger domain. Its spatial derivatives of every fixed order, and its mixed derivatives with up to two parameter derivatives, have uniform finite bounds. The same holds if its finitely many coefficients depend on a and converge together with their first two parameter derivatives. Lemma 25.2 and Lemma 16.9 apply to f, to its parameter derivatives, and to their ordered products. On meshes that do not refine the fixed input lattices, we use the general smooth-input bounds of Lemma 16.9 in place of its bounds for interpolants. The proof of Lemma 25.2 uses only these bounds and the fixed smooth norms of the inputs, so its conclusions hold on those meshes as well. In particular, the quadratic Picard term satisfies the exact identities

$$\begin{aligned}\partial_v y_a &= \mathcal{Q}_a(\partial_v x_a, x_a) + \mathcal{Q}_a(x_a, \partial_v x_a),\\ \partial_{vw} y_a &= \mathcal{Q}_a(\partial_{vw} x_a, x_a) + \mathcal{Q}_a(x_a, \partial_{vw} x_a) + \mathcal{Q}_a(\partial_v x_a, \partial_w x_a) + \mathcal{Q}_a(\partial_w x_a, \partial_v x_a).\end{aligned}$$

Hence the bounds on the flow data through two parameter derivatives, and the consistency of both components of the flow data, hold for this family, with a constant R_2 depending on the family. All heat comparisons are on the same fixed physical horizon. This also covers coefficients that converge as described.

Theorem 24.10 with $r = 3$ applies to the compact family of smooth initial data, and on each of its continuations the gauge transformations do not depend on u. By the continuum part of Lemma 25.12, the DeTurck solutions $b_j(u)$ on the time intervals have two parameter derivatives, with all the spatial bounds needed below. The bounds of the smooth initial family and the finitely many fixed gauge transformations give these bounds also at the left endpoints of the intervals. This verifies the regularity needed to differentiate the residual of the sampled smooth solution, without deducing it from the Lipschitz statement of Theorem 24.10 alone.

Let B_a be the lattice representative and $b_a = S_a b$ the sample of the selected DeTurck solution on a common time interval. Expanding the vector field, we obtain for $r = 0, 1, 2$

$$\sup_{u,t} \big\| D_u^r \{ \partial_t b_a - \Delta_a b_a - \mathcal{N}_a(b_a, b_a) - \mathscr{C}_a(b_a) \} \big\|_\infty \le C a. \tag{25.41}$$

This follows by differentiating the finite analytic expression and its Taylor remainder with respect to u. The integral remainder is bounded by the corresponding mixed spatial and

parameter derivatives of the fixed smooth family. The linear part is central-difference consistency, the quadratic part is the calculation for $\mathcal{N}_a$ in Lemma 25.2, and the remaining terms form the analytic remainder treated in Lemma 25.3. The first physical difference of the residual is consistent as well, since the smooth spatial derivatives of one more order are bounded.

We now prove stability of the derivatives. For the value we use (25.14). Recall that $\mathscr{B}_a(B)V$ is the linearization, and let $f_a(B;V,W)$ be defined by the last line of (25.25), with V, W as the two first-derivative arguments. On a common bounded set of the norm C^1_a, the displayed products and (25.11) imply

$$\|(\mathscr{B}_a(B) - \mathscr{B}_a(C))V\|_\infty \le C_K \|B - C\|_{C^1_a} \|V\|_{C^1_a},$$

and the difference of f_a at two triples is at most

$$C_K\big(\|B - C\|_{C^1_a}\|V\|_{C^1_a}\|W\|_{C^1_a} + \|V - V'\|_{C^1_a}\|W\|_{C^1_a} + \|V'\|_{C^1_a}\|W - W'\|_{C^1_a}\big)$$

when the remaining fields are bounded by K. For the remainder, this uses the bound on the third derivative in (25.11). We subtract the equations for the first derivatives, keep the linear operator at B_a, and place the difference of the coefficients and the differentiated residual in the forcing. By the Volterra inverse of Lemma 25.5(1), the C^1_a difference of the first derivatives is at most the initial difference plus $C(a + \sup \|B_a - b_a\|_{C^1_a})$. We subtract the equations for the second derivatives in the same way. By the bound for f_a, the additional forcing is at most a constant times the errors of the fields and of the first derivatives already controlled, plus the second differentiated residual. Applying the Volterra inverse again, we obtain the convergence of this difference as well. At a fixed sampled gauge transformation, the consistency error and its first two parameter derivatives are $O(a)$ in C^1_a. To see this, we expand $k(x + ae_i)$ to first order in the formula for $\mathscr{G}_{a,k}$ and differentiate twice in the bounded smooth family. The remainder of second order, before division by a, is $O(a^2)$, and one spatial difference uses one more smooth derivative. Together with (25.26), this propagates the three error bounds across the finite continuation.

For initial values that are exact samples, the three initial errors vanish. For converging finite coefficients they are $O(\delta_a)$ with $\delta_a \to 0$, in all needed fixed spatial norms. The preceding argument then gives, on every common time interval,

$$\sup_{u,t} \|D^r_u(B_a - S_a b)\|_{C^1_a} \le C(a + \delta_a), \qquad r = 0, 1, 2. \tag{25.42}$$

For $r = 0$, the sharper link consistency of Theorem 25.4 is also available, since its hypothesis of an initial link error $O(a^2)$ holds at every restart from an exact sample. The estimate in C^1_a above is used for the parameter derivatives and for the generators.

Step 6: smooth families, generators, gauge transformations, and matrices. We verify the convergence of the generators in L^1 on the early interval directly from the weighted

estimates, without a uniform unweighted estimate at time zero. Let $\lambda = -\sum_i \partial_i b_i$, with the sign fixed by (25.35). On every interval $[\epsilon, h_0]$, by the consistency of the values and first differences, we have

$$\sup_u \|D_u^r \lambda_a - S_a D_u^r \lambda\|_\infty \longrightarrow 0, \qquad r = 0, 1, 2.$$

By (25.34), the integral of each lattice term over $[0, \epsilon]$ is at most $C_{R_2}\omega(\epsilon)$. The limiting continuum bound has the same property, by the limit of the same estimates at positive times or by the stronger smooth bounds of the fixed family. Taking first $a \to 0$ at fixed ϵ and then $\epsilon \downarrow 0$, we obtain

$$\sup_u \int_0^{h_0} \|D_u^r \lambda_a - S_a D_u^r \lambda\|_\infty \, dt \longrightarrow 0, \qquad r = 0, 1, 2. \tag{25.43}$$

On later time intervals the generators and their two parameter derivatives are bounded by the C_a^1 estimates of Step 3, and (25.42) implies the analogous convergence in L^1 on each whole interval.

Let k solve $\partial_t k = \lambda k$ with $k(0) = I$ in the continuum. Then $\partial_t(k^{-1}) = k^{-1} \sum_i \partial_i b_i$, and k^{-1} is the gauge transformation that undoes the damping in Theorem 24.10, with the convention used there. At every vertex, unitary variation of constants gives

$$\sup_{t,u} \|k_a(t,u) - S_a k(t,u)\|_{\mathrm{op}} \le \sup_u \int \|\lambda_a - S_a \lambda\|_\infty \, dt \longrightarrow 0. \tag{25.44}$$

For the first derivative we use its integral formula from (25.36). Its homogeneous propagators $k_a(t)k_a(r)^{-1}$ converge uniformly by (25.44), its source generators converge in L^1 by (25.43), and k_a converges uniformly. Subtracting the two integrals, we bound the difference by the L^1 error of the generators plus a uniform error of the factors times a bounded L^1 norm, which proves the convergence of the first derivative. For the second derivative, the two additional sources are $(\partial_v \lambda_a) l_w$ and $(\partial_w \lambda_a) l_v$. Since the first derivatives just treated converge uniformly and the generators converge in L^1, the same subtraction proves the convergence of the second derivative; the term $(\partial_{vw} \lambda_a) k_a$ is handled by its own L^1 convergence. Since the fixed sampled gauge transformation at a restart has the same value at the basepoint as its continuum counterpart, the finite products (25.38) converge at the basepoint, together with their first two parameter derivatives.

On each of the three coordinate cycles, the physical path is the same coordinate circle, of length L and with the same basepoint, for every mesh. Using the estimate for smooth edge transport in Lemma 24.7 and unitary telescoping, we compare the product of the exponentials of the sampled selected DeTurck solution with its smooth holonomy. To include derivatives, we regard this product as the parallel transport, along the same coordinate circle, for a piecewise constant coefficient. This coefficient and its two parameter derivatives differ from the corresponding smooth coefficients by $O(a)$, using

one smooth spatial derivative. Differentiating the one-dimensional transport equation once and twice, we find the same linear and quadratic forcing structure as in (25.36), now over the fixed interval of arclength L. By unitary variation of constants and subtraction, the products and their two parameter derivatives converge at rate $O(a)$. The errors between the lattice fields and the samples in (25.42) add $O(a+\delta_a)$, by the same transport argument or by (25.39) and its version for differences. Finally we undo the gauge transformations at the basepoint by (25.40). The convergence at the basepoint proved above identifies the holonomy matrices of the Wilson flow with the holonomy matrices of the covariant continuum flow, in the gauge of the initial configuration, uniformly over the compact smooth family. This proves (3).

Step 7: dependence of the constants and coarse meshes. All restrictions on the mesh and all constants in Steps 5 and 6 may depend on the fixed smooth family and on the displayed bounds. All bounds in Steps 1–4 used only R_2, the parameter domains, the waiting times, the horizon, the torus, and the margins of the finitely many continuations. For the finitely many meshes with $a > a_*$, the initial fields and their two parameter derivatives are bounded by the weighted norm at time zero, since these meshes are bounded below. Since the Wilson vector field and its first two derivatives are bounded on the corresponding compact products of copies of $\mathrm{SU}(2)$, the real integral equations for the derivatives give finite uniform bounds on the fixed horizon. This gives the bounds for the based holonomy matrices on these meshes, and we take a maximum over this finite set. For any additional meshes on which the damped representatives remain in the fixed smaller chart, the positive chart margin also gives bounds for their logarithms and for the equations of their gauge transformations. □

25.8 Flows with the modified plaquette potential

We now treat the flows of the plaquette potential $q + cq^2$ with $0 \le c \le C_0$, which are used in Section 29 to show that the limit does not depend on the choice of smoothing within this family. As in Theorem 24.12, let

$$\mathcal{A}_c(U) = \sum_{p \in \mathcal{P}_N} \{ q(U_p) + c\, q(U_p)^2 \}, \qquad \Psi_t^{(N,c)} = \Phi^{\mathcal{A}_c}_{4t/a^2}, \qquad a = L/N,$$

where $\Phi^{\mathcal{A}_c}$ is the flow of the vector field $-\nabla \mathcal{A}_c$ for the product metric; thus $\Psi^{(N,0)} = \Psi^{(N)}$. By Lemma 24.11, the damped representatives of this flow solve

$$\partial_t A = \Delta_a A + \mathcal{N}_a(A, A) + F_a(A) + E_{a,c}(A)$$

in a smaller chart, where $F_a(A) = a^{-3} R_3(aA) = \mathscr{C}_a(A)$ is the cubic-and-higher remainder and $E_{a,c}$ is the additional analytic term coming from cq^2. Since the linear and quadratic parts are the same as for the Wilson flow, the flow data are unchanged. The additional

term satisfies the bounds on field derivatives (24.32), the bounds on differences (24.33), and the stronger bound (24.34), which makes it $O(a^3)$ on bounded sets of the norm C_a^1. Only bounded $c \geq 0$ is considered.

Lemma 25.14. *Fix $L > 0$, $0 \leq C_0 < \infty$, and a smaller chart.*

1. *For flow data bounded by R, the solutions of Theorem 24.12 have bounds on every fixed order of physical differences on every interval after a positive waiting time, uniformly in a and $c \in [0, C_0]$. The same holds on any restarted time interval for which a uniform C_a^1 bound is given, with the dependence stated in Theorem 25.7 and an additional dependence on C_0.*
2. *Let b be a fixed smooth periodic DeTurck solution on $[0, h]$ whose spatial derivatives through order five are bounded by K_b. There are $\eta_b, a_b > 0$ and $K_b' < \infty$, depending only on L, h, K_b, C_0, and the chart, such that, whenever*

$$\|B_a(0) - S_a b(0)\|_{C_a^1} \leq \eta \leq \eta_b, \qquad a \leq a_b,$$

the damped flow for $\mathcal{A}_c$ exists in the chart through time h and

$$\sup_{t \leq h} \|B_a(t) - S_a b(t)\|_{C_a^1} \leq K_b'(\eta + a), \qquad \sup_{t \leq h} \|B_a(t)\|_{C_a^1} \leq K_b'. \tag{25.45}$$

This holds uniformly for $c \in [0, C_0]$, and also on each time interval of a fixed continuation as in Theorem 24.10, with its fixed sampled gauge transformations at the restarts. In particular, every sufficiently small initial discrepancy in C_a^1 is allowed.

The constants are deterministic and do not depend on the mesh below the thresholds.

Proof. Part (1). The local solution of Theorem 24.12 gives the initial C_a^1 bound after a positive waiting time. Suppose that differences through order $m-1$ have been bounded by $K_1, \dots, K_{m-1}$ on a preceding interval. By the product rules (25.2), we have

$$\|D_a^{m-1} \mathcal{N}_a(B, B)\|_\infty \leq P_m(K_1, \dots, K_{m-1}) + C_m K_1 \|D_a^m B\|_\infty,$$

since the only factor of order m occurs when all additional differences fall on the factor that already carries a difference, and its companion is a bounded value of B. By the composition rule of Lemma 24.2 and by (24.33), both analytic terms F_a and $E_{a,c}$ contribute only a bounded function of $K_1, \dots, K_{m-1}$. Indeed, their arguments carry no difference to begin with, and all their powers of the mesh are nonnegative. We start the mild equation at the left endpoint u_0 of the preceding interval, commute $m-1$ differences onto the initial value and onto the source, and place one difference on the heat semigroup. For $Z_m(d) = \sup_{0<v\leq d} \sqrt{v} \|D_a^m B(u_0 + v)\|_\infty$, using the bound for one difference of the heat semigroup, we obtain

$$Z_m(d) \leq C_m K_{m-1} + C_m P_m \, d + C_m K_1 \sqrt{d} \, Z_m(d),$$

where for the highest term we used $\int_0^v (v-r)^{-1/2} r^{-1/2}\, dr = \pi$. At fixed mesh, $Z_m(d)$ is finite before the absorption. We choose d so that the last coefficient is at most $1/2$, and cover the smaller interval by intervals of this length. By induction, every fixed order is bounded, with uniform constants of the stated dependence.

Part (2). Let $b_a = S_a b$, and define

$$e_{a,c} = \partial_t b_a - \Delta_a b_a - \mathcal{N}_a(b_a, b_a) - F_a(b_a) - E_{a,c}(b_a).$$

The residual of Theorem 25.4(1) bounds the residual for the Wilson flow in physical units by $K_{K_b} a$, after dividing the dimensionless residual $O(a^4)$ of the link logarithms by a^3. By (24.34), the additional term is at most $K_{K_b,C_0} a^3$. Hence $\sup_t \|e_{a,c}\|_\infty \le Ka$, and no difference of this residual will be needed. Let $Z = B_a - b_a$, and stop at the first time at which $\|Z\|_{C^1_a} = 1$. Apart from $-e_{a,c}$, the source of order zero in the equation for Z is

$$\mathcal{N}_a(b_a, Z) + \mathcal{N}_a(Z, b_a) + \mathcal{N}_a(Z, Z) + (F_a + E_{a,c})(b_a + Z) - (F_a + E_{a,c})(b_a).$$

By the bound on $\mathcal{N}_a$ and the bounds on the cubic field derivatives, its supremum norm is at most $K_{K_b,C_0} \|Z\|_{C^1_a}$ on this interval. The stopped comparison with the smooth DeTurck solution b and the induction over restarts in the proof of Lemma 25.5 apply with this larger local Lipschitz constant and the residual just bounded. They prove (25.45), remove the stopping condition, and give the assertion for continuations, with the additional dependence on C_0. □

Lemma 25.15. *Fix $L > 0$, $1/2 < \alpha < 2/3$, $0 \le R, C_0 < \infty$, $0 < t_* \le T < \infty$, and $0 \le \ell < \infty$. There is a deterministic function $\omega(a)$ with $\omega(a) \to 0$ as $a \downarrow 0$ with the following property. Let $A_{0,a}$ be a lattice initial potential whose flow data on the common early interval $[0, T_{R,C_0}]$ of Theorem 24.12 have norm at most R, and let $U^c_a(t) = \Psi^{(N,c)}_t(e^{aA_{0,a}})$. Then, for every sufficiently small mesh,*

$$\sup_{0\le c\le C_0} \sup_{t_*\le t\le T} \sup_{\substack{\ell_a \text{ closed path} \\ aN_{\ell_a}\le \ell}} \left| \tfrac{1}{2} \operatorname{tr} \operatorname{Hol}_{\ell_a} U^c_a(t) - \tfrac{1}{2} \operatorname{tr} \operatorname{Hol}_{\ell_a} U^0_a(t) \right| \le \omega(a). \tag{25.46}$$

The same holds for any fixed finite collection of characters of finite-dimensional representations of SU(2). *No approximation or area hypothesis on the closed paths is needed, since paths in the same lattice are compared. The function ω may depend on the displayed data, on the representations, and on the chart; no rate is asserted.*

Proof. Fix $0 < s < \min(t_*, T_{R,C_0})$ such that there is a positive waiting time before s. The early comparison (24.36), evaluated at time s, gives

$$\sup_c \|A^c_a(s) - A^0_a(s)\|_{C^1_a} \longrightarrow 0$$

uniformly over the initial potentials considered. We prove the remaining uniform assertion by contradiction, which avoids the need for a single smooth continuation that is uniform over arbitrary families with bounds of finite order. Suppose that the assertion fails. Then there exist meshes $a_j \downarrow 0$, initial potentials with flow data bounded by R, parameters c_j, closed paths, and times that exhibit a fixed positive discrepancy. On a fixed interval before s, all fixed differences of the Wilson fields $A^0_{a_j}$ are bounded by Theorem 25.7.

By Lemma 25.6, applied at time s, there exist a subsequence and a smooth periodic b_s such that

$$\| A^0_{a_j}(s) - S_{a_j} b_s \|_{C^1_{a_j}} \longrightarrow 0.$$

Only the spatial bounds at time s are needed here. (Since the time derivatives of all differences are bounded by the equation and the bounds on the next two differences, Lemma 25.8 would give convergence on the whole interval before s as well.)

We use the continuation of Theorem 24.10 for the single initial value b_s, with $r \geq 5$, through the horizon $T - s$. Its finitely many DeTurck solutions have finite smooth bounds, and its gauge transformations are fixed and smooth. The endpoints at time s of the Wilson flow and of the flows for $\mathcal{A}_c$ approach the sample of b_s in C^1_a, the latter uniformly in c. We apply Lemma 25.14 on each time interval of the continuation (for $c = 0$ this is also Lemma 25.5). In the gauges of the continuation, both flows approach the sample of the same selected DeTurck solution uniformly in C^1_a on the finite continuation, with error $K(\eta_j + a_j)$, where $\eta_j \to 0$, uniformly over $c \in [0, C_0]$.

For anti-Hermitian X, Y, the integral formula for the derivative of the exponential implies that $\| e^{aX} - e^{aY} \| \leq Ka |X - Y|$. We telescope over the $N_{\ell_a} \leq \ell / a$ unitary factors of a closed path, including the inverse factors. The matrix error is then at most $K\ell \| B_a - S_a b \|_\infty$, where b is the selected DeTurck solution at the given time. Since a conjugation at the basepoint does not change the character, each of the two character values approaches the character of the product of the exponentials $e^{aS_a b}$ along the same path, uniformly in the path and in the time. For a fixed representation, the same calculation in its unitary matrices involves in addition the norm of the corresponding representation of $\mathfrak{su}(2)$ and its dimension. This contradicts the fixed positive discrepancy. The supremum of the bounded left side of (25.46) over the initial potentials considered defines a function of a that tends to zero, which proves the lemma. □

PART VIII

Fluctuation estimates and Wilson-loop convergence

SECTION 26

Concentration of reconstruction fluctuations

This section and the next control the heat evolution of the reconstructed field and its quadratic Picard term under the conditioned Wilson measure. Recall from Section 3.6 that the field on the finest lattice is reconstructed from the coarse field one renormalization group step at a time, from coarse to fine, by adding the normalized fluctuation variables of each step. At the step from mesh a_{j-1} to mesh a_j, the heat evolution x_j of the reconstructed field changes by $d_j = x_j - x_{j-1}$. In Lemma 26.2, we write d_j exactly as a sum of four terms:

- the linear fluctuation s_j, a linear function of the newly integrated fluctuation variables after subtraction of their conditional mean;
- the heat evolution z_j of the conditionally centered nonlinear reconstruction residual;
- an interpolation defect r_j, which compares the linearized reconstruction of the coarser field with the direct interpolation of that field;
- a predictable term u_j, which contains the nonlinear part of the zero-fluctuation reconstruction and the conditional mean correction, that is, the conditional mean of the difference between the reconstructed field and its zero-fluctuation reconstruction.

The quadratic Picard term $y_j = \mathcal{Q}_\delta(x_j, x_j)$ then changes by the two mixed terms $\mathcal{Q}_\delta(x_{j-1}, d_j)$, $\mathcal{Q}_\delta(d_j, x_{j-1})$, and by the sixteen ordered products of the four terms.

This section proves the estimates that involve the newly integrated fluctuation variables. Theorem 26.10 bounds the linear fluctuation s_j and the mixed Duhamel terms of s_j with a predictable background field, in either order; the backgrounds of interest are x_{j-1} and r_j. Theorem 26.11 bounds z_j and its mixed terms with x_{j-1}. Theorem 26.12 bounds the quadratic Duhamel term $\mathcal{Q}_\delta(s_j, s_j)$ and, separately, its conditional mean, which is not zero. The terms built only from r_j and u_j are treated in Section 27. Section 28 assembles the estimates of both sections into bounds on the linear and quadratic flow data of the reconstructed field, and the coefficient bounds proved here are also used in Sections 29 and 34.

At mesh $a = a_j$, the linear fluctuation has size $g_3 a^{\alpha - 1/2}\sqrt{\log(2 + L/a)}$ in the norm X^δ_α, and the heat evolution of the nonlinear reconstruction residual has size $g_3^2 a^\alpha \log(2 + L/a) + g_3^3 a^{1/2} p_j^3$, where p_j is the largest fluctuation cutoff radius of the step. The centered part of $\mathcal{Q}_\delta(s_j, s_j)$ has size $g_3^2 a^{2\alpha - 1}\log(2 + L/a)$ in the norm Y^δ_α, and its conditional mean is at most $C g_3^2 \|\theta_{j-1}\|_\infty$, where θ_{j-1} is the logarithm of the coarser reconstructed field. Since

$1/2 < \alpha < 2/3$ and p_j grows only logarithmically, the first three rates are summable over the geometric sequence of meshes. The mean is summable because the coarser fields are bounded by a summable deterministic sequence; see (26.8).

Heuristics. At times t of order a^2, a linear reconstruction fluctuation is a lattice potential of size $g_j/a = g_3 a^{-1/2}$, where $g_j^2 = g_3^2 a$ is the coupling at mesh a; multiplying by the weight a^α of X_α^δ gives $g_3 a^{\alpha-1/2}$. A quadratic reconstruction fluctuation has the coefficient $g_j^2/a = g_3^2$, and the weight a^η of the corresponding heat norm gives $g_3^2 a^\eta$. The source of the quadratic Duhamel term contains one lattice derivative, and for the linear fluctuation it has size $g_3^2 a^{-2}$. Integration over a time interval of length a^2 and the weight $a^{2\alpha-1}$ of Y_α^δ give $g_3^2 a^{2\alpha-1}$. The maximum over space and time contributes a factor $\sqrt{\log(2+L/a)}$ for linear forms in the fluctuation variables and $\log(2+L/a)$ for quadratic forms. Scaling alone does not give the long-time bounds. They come from the spatial averaging of the heat kernel, and their proof keeps track of the physical volume of each lattice cell.

Inputs and two points that need care. The probabilistic input is the conditional fluctuation kernel of Theorem 13.8: given the coarser field, the normalized fluctuation variables of one renormalization group step have the density $Z^{-1}\mathbf{1}_\Omega e^{-V}$ on a product Ω of three-dimensional balls, with $D_w^2 V \geq I/2$. By the logarithmic Sobolev inequality of Theorem 5.4, linear and quadratic functions of these variables concentrate, with constants independent of the dimension. We also use the bounds on conditional means and covariances of Theorem 13.10, and the reconstruction maps $\widehat{\mathscr{R}}$ of Theorem 15.12, with their disintegration (Lemma 15.10) and uniform bounds on their absolute Taylor coefficients. The deterministic inputs are the cardinal interpolation and the chaining lemma of Lemmas 16.3 and 16.4, the cancellation estimate of Lemma 17.2, the covariance estimate of Theorem 17.4, and the quadratic coefficient of the damped Wilson flow and its Duhamel estimates from Lemmas 24.2 and 24.6 and Definition 24.3.

Two points need care. First, the normalized fluctuation variables are neither Gaussian nor independent, and their conditional mean is not zero when the coarser field is not the identity. We subtract the conditional mean under the conditional fluctuation kernel itself, and we keep the nonzero mean of every quadratic term. Second, all fields are interpolated to the finest lattice, of mesh δ, while their randomness lives at the much coarser mesh a. To obtain the factor $a^{3/2}$ in the operator bounds, and logarithms of L/a rather than of L/δ in the maximal inequalities, we keep the cell volume of each coefficient on its own lattice and cover space and time at the scale a.

We separate the heat evolution of rough initial data from its quadratic Picard term as Cao and Chatterjee do for the Yang–Mills heat flow with random initial data in [42, Definition 2.8 and Theorem 2.10]; their treatment follows the approach of Bourgain [32] and Da Prato and Debussche [63]. The first nonlinear correction of Cao and Chatterjee also contains a cubic term, and their random-data theorem treats a class of initial data

that includes Gaussian free fields; here the estimates are proved from the conditional fluctuation kernels. The concentration inequalities use the convexity methods of Gross [103] and Bakry and Émery [8], in the form proved in Theorem 5.4. The quadratic tail bound is of Hanson–Wright type [108]; for dependent coordinates satisfying a concentration inequality, compare Adamczak [1, Theorem 2.5]. The maximal inequalities use elementary chaining in the sense of Dudley [79] (see also [74]), in the form of Lemma 16.4.

26.1 Setting and the exact decomposition of an increment

The hierarchy. Throughout this section we fix $L > 0$, $\gamma = g_3^2 L > 0$, an odd integer $M \geq 3$, and an integer $J \geq 1$ for which the constructions of Theorems 13.8 and 15.12 apply, and we set $B = M^J$. We fix a coarse side $n \in 4\mathbb{N}$ at least the threshold of Theorem 15.12. For $K \geq 0$ we set $N = nB^K$ and

$$a_j = (L/n)B^{-j}, \qquad g_j = g_3\sqrt{a_j} \qquad (0 \leq j \leq K), \qquad \delta = a_K,$$

so that $g_j^2 = \gamma/(nB^j)$ is the lattice coupling at mesh a_j. The jth renormalization group step from the coarse side maps the lattice of mesh a_j to the lattice of mesh $a_{j-1} = Ba_j$; it consists of J averaging steps, and its intermediate scales have couplings $g_{j,i}$, $0 \leq i \leq J-1$, whose ratios to g_j lie in an interval depending only on M and J. The largest of them is

$$t_j = M^{(J-1)/2} g_j, \qquad t_j^2 = \frac{\gamma}{M m_j}, \qquad m_j = nB^{j-1}.$$

Here $m_j \geq 4$ is the side of the coarser lattice of the step. The zero-fluctuation reconstruction at this step is built from a classical background field whose effective classical action has been obtained by $\mathfrak{d}_j = J(K-j)$ preceding averaging steps, counted from the finest lattice.

The measure and the filtration. We use the conditioned Wilson measure

$$\nu_K = \mu_{N,\gamma}(\,\cdot \mid S_{N,n,\gamma})$$

and the reconstruction maps $\widehat{\mathscr{R}}$ of Theorem 15.12. Let θ_0 be the logarithm of the coarsest configuration in the gauge chosen there, and let w_j be the normalized fluctuation variables of the jth renormalization group step from the coarse side. We write $\theta_j = a_j A_j$ for the link logarithm of the field reconstructed at mesh a_j, so that A_j is the corresponding lattice potential. Let $\mathscr{R}_j(\theta, w)$ be the logarithmic form of the reconstruction map at step j; thus $\theta_j = \mathscr{R}_j(\theta_{j-1}, w_j)$, and $\mathscr{R}_j(\theta, w) = \widehat{\Phi}_{\mathfrak{d}_j,j}(\theta, (g_{j,i} w_i)_i)$ in the notation of Section 17. Let $\mathcal{F}_j$ be the σ-algebra generated by the coarsest configuration and by $w_1, \dots, w_j$. All conditional statements below hold for every value of θ_{j-1} that occurs on the small-field event, and *uniformly in* θ_{j-1} refers to these values.

Each scalar fluctuation coordinate λ of the jth step is attached to a lattice location on one of its intermediate scales. We write a_λ for the mesh of that lattice, $v_\lambda = a_\lambda^3$ for its cell volume, and $g_\lambda = g_3\sqrt{a_\lambda}$ for its coupling. Then $C_J^{-1}a_j^3 \le v_\lambda \le C_J a_j^3$, and the ratios g_λ/g_j are bounded above and below by constants depending only on M and J. The fluctuation cutoff domain of the step is

$$\Omega_j = \prod_{i,e}\{w_{i,e} \in \mathbb{R}^3 : |w_{i,e}| \le p_{j,i}\}, \qquad p_j = \max_i p_{j,i} \ge 1,$$

where the radii follow the logarithmic prescription of Definition 4.4, up to an additive constant depending on M and J that accounts for the intermediate scales: $p_j \le A_{\mathrm{w}} \log(1/t_j) + c_J$.

Common domains. We assume that all integrated couplings lie below the common upper bound g_* of Theorems 13.8, 13.10, and 17.4 and Lemma 15.10; in particular, $t_j \le g_*$ for every j. We also assume that the coarser fields lie in the small-link domain B_r, the target set of Theorem 13.8, and that the reconstruction is evaluated in the larger analytic domain of Theorem 15.12, with the fixed positive distances between its nested domains. These choices are made before K, j, or any sample, and they do not change with K or j.

For a coarser field θ and a number $\mathfrak{d} \ge 0$ of preceding averaging steps, we write $\mu_{\mathfrak{d},\theta}$ for the conditional fluctuation kernel of Theorem 13.8 on Ω_j. For coarser fields in the small-link domain, $\mu_{\mathfrak{d},\theta}(dw) = k(e^\theta, dw)$ in the notation of (4.8), for a step preceded by $\mathfrak{d}$ averaging steps. Let $\mathbb{E}_\theta$, $\mathbb{P}_\theta$, and Cov_θ denote expectation, probability, and covariance under this kernel. We write

$$m_\theta = \mathbb{E}_\theta w_j, \qquad \zeta_j = w_j - m_\theta,$$

and Σ_θ for the conditional fluctuation covariance of w_j. (This Σ_θ is unrelated to the normal covariance of (4.12).)

Norms and adjoints. We fix a finite horizon $T > 0$ for all heat estimates. Coefficient arrays indexed by fluctuation coordinates carry the counting norm, which sums over every scalar coordinate of every intermediate scale; we write $\|l\|_2$ or $\|l\|_{\ell^2(w)}$ for it, and the transpose ^{T} is taken with respect to the counting inner product. Fields on a lattice of mesh b carry the physical norms

$$\|f\|_{L^2_b} = \Big(b^3 \sum_x |f(x)|^2\Big)^{1/2}, \qquad \|f\|_{L^1_b} = b^3 \sum_x |f(x)|,$$

and the adjoint W^* of a map $W : \ell^2(w) \to L^2_\delta$ is taken with respect to L^2_δ, so that matrix products with W^* contain the factor δ^3. The covariance matrix of the linear reconstruction coefficient is the counting matrix

$$\mathsf{Z}_\theta = E_\theta \Sigma_\theta E_\theta^{\mathsf{T}},$$

where E_θ is defined in Lemma 26.2; the corresponding physical operator is $a^3\mathsf{Z}_\theta$. We always use the counting matrix Z_θ between counting rows. The heat semigroup $P_t^\delta = e^{t\Delta_\delta}$, the cardinal interpolation $I_b = I_{b\to\delta}$ from mesh b to mesh δ, the differences D_δ, and the norms X_α^δ, Y_α^δ, H_σ^δ, and V_σ^δ are those of Definition 4.8, with $v_\delta(t) = t + \delta^2$; here D_δ includes every componentwise difference and every translation required by the quadratic coefficient of Lemma 24.2. For $0 < \eta < 3/2$ we also write

$$\mathsf{H}_\eta^\delta(f) = \mathsf{X}_\eta^\delta(P_\cdot^\delta f) = \sup_{0\le t\le T} \big\{ (t+\delta^2)^{\eta/2} \|P_t^\delta f\|_\infty + (t+\delta^2)^{(\eta+1)/2} \|D_\delta P_t^\delta f\|_\infty \big\};$$

for $0 < \eta < 1 - \alpha$ this is the norm of Definition 4.8. Finally,

$$\mathcal{Q}_\delta(u,v)(t) = \int_0^t P_{t-s}^\delta \mathcal{N}_\delta(u(s), v(s))\, ds, \qquad \mathcal{B}_\delta(u,v) = \mathcal{Q}_\delta(u,v) + \mathcal{Q}_\delta(v,u),$$

where $\mathcal{N}_\delta$ is the ordered quadratic coefficient of the damped Wilson flow on the lattice of mesh δ; it is not symmetric, and we always keep the order of its arguments.

Constants. Unless stated otherwise, constants C, C_J, and $C_{J,q}$ depend only on L, T, M, J, the fixed analytic domains and the distances between them, the bounds on the absolute Taylor coefficients of the reconstruction maps, the interpolation function of the cardinal interpolation, the exponents, and the indicated derivative orders. They do not depend on the lattice side, on K, on the number of preceding averaging steps, on the coarser field, on the coupling below g_*, or on the refinement ratio a/δ. The constants of maximal inequalities proved with the fluctuation cutoff (Lemma 26.9) may in addition depend on the fixed γ, n, and the prescription of the cutoff radii; the covering and chaining bounds of Lemmas 26.7 and 26.8 have no such dependence. Among the constants of this section, only the bound C_{CP} on finitely many derivatives of the zero-fluctuation reconstruction (see the proof of Lemma 26.2) is chosen before J; all other bounds are fixed-J bounds. All estimates concern the whole torus.

The conditional law and the Taylor coefficients

The first lemma identifies the conditional law of the fluctuation variables of one step and records the coefficient bounds used in all later estimates. Its proof mostly verifies the hypotheses of earlier results; the new ingredient is the passage from absolute coefficient bounds on a larger domain to derivative bounds, without loss in the volume-normalized column sums.

Lemma 26.1. *Assume the setting of Section 26.1. For every $K \ge 0$ and $1 \le j \le K$, the conditional law of w_j given $\mathcal{F}_{j-1}$ is the normalized density $Z_{j,\theta}^{-1} e^{-V_{j,\theta}(w)}\, dw$ on Ω_j, where $\theta = \theta_{j-1}$, the potential $V_{j,\theta}$ is smooth on a neighborhood of the closed product Ω_j, and*

$$D_w^2 V_{j,\theta} \ge \tfrac{1}{2} I \qquad \text{on } \Omega_j.$$

This density and the normalized fluctuation coordinates are the same before and after the change to the reconstruction maps $\widehat{\mathscr{R}}$ at a fixed coarser field. For each base point $w_* = 0$ or $w_* = m_\theta$, the normalized tensors $g_j^{-1} D_w \mathscr{R}_j(\theta, w_*)$ and $(2g_j^2)^{-1} D_w^2 \mathscr{R}_j(\theta, w_*)$ have uniformly bounded absolute output row sums and volume-normalized input column sums for every choice of fixed input, on common nested domains in the unscaled coarser field and the coupling-scaled fluctuation inputs $q_{j,i} = g_{j,i} w_i$. On a smaller domain these bounds extend to every fixed-order mixed derivative in the unscaled coarser field and the q coordinates, with a constant depending on the order. These assertions are uniform in the lattice side and in the number of preceding averaging steps, at fixed M, J, and domains.

Proof. At step j, the coarser lattice has side $m_j = nB^{j-1} \geq 4$, the number of preceding averaging steps is $\mathfrak{d}_j = J(K - j)$, and $t_j^2 = \gamma/(M m_j)$. By Lemma 15.10, the coarser field lies in the small-link domain B_r. The cutoff radii follow the logarithmic prescription, and the intermediate scales change their maximum by at most an additive constant depending on M and J. The common upper bound g_* includes the smallness conditions of Theorems 13.8 and 13.10. With $p = p_j$ and $t = t_j$, we have in particular

$$Ctp < 1, \qquad \frac{C[tp + t^2(1 + E_*)]}{(1 - Ctp)^3} \leq \frac{1}{2}, \qquad tp^3 \leq c_*. \tag{26.1}$$

Here E_* is the upper bound on the weighted analytic coefficient norm of the effective interaction in Theorem 13.8, and C and c_* are constants of that theorem and of Theorem 13.10. Since $p_{\max}(t) \leq A_{\mathrm{w}} \log(1/t) + c_J$ and $t[\log(1/t) + c_J]^k \to 0$ as $t \to 0$ for each fixed k, we may choose g_* to satisfy (26.1) before K, j, or any sample is chosen. The domain conditions on the product Ω_j, and the positive distances from the analytic images to the boundaries of their domains, are the common-domain hypotheses preserved in Theorem 15.12.

All hypotheses of Theorem 13.8 hold at this coarser side, number of averaging steps, coarser field, and product Ω_j. That theorem gives the potential, its smooth extension to a neighborhood, and the lower bound $I/2$ on its Hessian; the integration domain is Ω_j itself, not a larger enclosing product domain. By its last clause and Lemma 15.10, this law is the conditional law of w_j under ν_K, since the factors that depend only on the coarser field cancel. By Theorem 15.13, the reconstruction maps preserve, at this coarser field, the normalized fluctuation coordinates, the balls, the action, the Haar disintegration density, the triangular determinant, the input effective interaction produced by the finer-scale integrations, the normalizer, and the conditional fluctuation kernel. Two equal positive normalized densities have potentials that differ by a constant depending only on the coarser field. Fixing that constant, we obtain the same $V_{j,\theta}$, and hence the same Hessian, after the change of representatives. In particular, we never transport a Hessian through a nonlinear change of the fluctuation variables. The auxiliary integral of Theorem 14.6 over larger domains does not enter, because the coarser field lies in B_r.

For the analytic assertion, we use the norm of Theorem 15.12 on the absolute joint Taylor coefficients, including its volume-normalized column sums, rather than a bound on the values of a holomorphic map. The products of coarser fields and coupling-scaled inputs occurring here lie in the inner domain $\mathscr{D}_{\mathrm{in}}$ of that theorem, at a positive distance from its boundary, and the absolute coefficient norm is bounded uniformly on $\mathscr{D}_{\mathrm{in}}$. We choose an evaluation polydisc and a larger polydisc,

$$\mathscr{P}_- \Subset \mathscr{P}_+ \Subset \mathscr{D}_{\mathrm{in}}, \qquad \eta_\lambda = \mathrm{rad}_\lambda(\mathscr{P}_+) - \mathrm{rad}_\lambda(\mathscr{P}_-) > 0.$$

They may be centered at any point of evaluation, with gaps bounded below by fixed fractions of the distance to the boundary of $\mathscr{D}_{\mathrm{in}}$; inscribing coordinate polydiscs in the product balls needs only a fixed change of color coordinates. The nested domains of Theorem 15.12 give these gaps uniformly, and nothing depends on a modulus of convergence or on the size of the lattice. The coupling-scaled images $(g_{j,i}w_i)_i$ of every point of Ω_j, of the point $w = 0$, and of the conditional mean m_θ lie in such an evaluation polydisc, because the mean of a probability measure on a ball lies in that ball.

Differentiating the absolute joint series term by term and evaluating it on $\mathscr{P}_-$ introduces the factorial of the derivative order and inverse powers of the gaps. These operations preserve the column sum with a fixed input, because all other inputs, including the output, are already summed in that column sum. Equivalently, one may apply the Cauchy integral formula on $\mathscr{P}_+$ to the coefficients, in these finite-dimensional row and column norms. We obtain uniform bounds for the first, second, and every fixed higher derivative. A derivative in a fluctuation variable of intermediate scale i introduces the factor $g_{j,i}$, and the ratios $g_{j,i}/g_j$ and the ratios of cell volumes are bounded by constants depending only on M and J. Dividing the first and second derivatives in w by g_j and $2g_j^2$, respectively, we obtain the two normalized tensors of either Taylor expansion in Lemma 26.2, with their volume-normalized column sums. All constants in this argument are fixed-J constants; the constant C_{CP} chosen before J is not enlarged. □

The exact decomposition

Table 26.1 lists the four terms of the increment of the heat evolution; their formulas are in the next lemma.

The classical part uses the zero-fluctuation reconstruction $C_j = a_j^{-1}\mathscr{R}_j(\theta_{j-1}, 0)$, which is a minimizing reconstruction and not a conditional mean. Its linearization P_j maps a lattice potential on the coarser lattice, of mesh $H = a_{j-1}$, to a lattice potential on the lattice of mesh a_j. The interpolation defect compares this linearization, interpolated from mesh a_j, with the coarser field interpolated directly from its own lattice; the two interpolations are applied on their own lattices before they are subtracted. In the notation of Lemma 28.5, $C_j = a_j^{-1}\widehat{P}_j(\theta_{j-1})$ and $\mathsf{P}_j = B\widehat{L}_j$, so the linearized reconstruction is $H^{-1}\mathsf{P}_j\theta_{j-1} = a_j^{-1}\widehat{L}_j\theta_{j-1}$.

Lemma 26.2. *Assume the setting of Section 26.1, and fix $K \geq 0$.*

Term	Field before heat evolution $P_\cdot^\delta$	Conditional mean	Treated in
s_j	$I_{a_j}(g_j/a_j)E_\theta\zeta_j$, linear in ζ_j	zero	Theorem 26.10
z_j	$I_{a_j}Z_j$, nonlinear in ζ_j	zero	Theorem 26.11
r_j	$H^{-1}(I_{a_j}\mathsf{P}_j - I_H\mathsf{E}_H)\theta_{j-1}$	predictable	Lemma 27.1
u_j	$I_{a_j}U_j^0$, nonlinear classical part plus mean	predictable	Theorem 27.7

Table 26.1. The four terms of the increment $d_j = x_j - x_{j-1}$ in Lemma 26.2.

1. *For every $1 \le j \le K$, conditional on $\mathcal{F}_{j-1}$, the law of w_j is the conditional fluctuation kernel $\mu_{\mathfrak{d}_j,\theta_{j-1}}$ on the product Ω_j, with $\mathfrak{d}_j = J(K-j)$, including all Haar disintegration densities, determinants, input effective interactions, and indicators. For this fixed coupling and coarse side, $p_j \le C_\gamma(1+j)$. Every estimate below for a single kernel holds uniformly for any number $\mathfrak{d} \ge 0$ of preceding averaging steps, on the same domains; the conditioned Wilson measure uses $\mathfrak{d} = \mathfrak{d}_j$.*
2. *Write the Taylor expansion of the reconstruction at the conditional mean as*

$$\mathscr{R}_j(\theta, m_\theta + \zeta) = \mathscr{R}_j(\theta, m_\theta) + g_j E_\theta\zeta + g_j^2 \mathsf{B}_\theta(\zeta,\zeta) + R_\theta(\zeta), \tag{26.2}$$

where the ratios of the intermediate couplings to g_j are included in E_θ and B_θ. Let $C_j = a_j^{-1}\mathscr{R}_j(\theta_{j-1}, 0)$ and $m_j^{\mathrm{ph}} = \mathbb{E}(A_j - C_j \mid \mathcal{F}_{j-1})$. With $H = a_{j-1} = Ba_j$, the zero-fluctuation reconstruction has the exact expansion

$$C_j(\theta) = H^{-1}\big\{\mathsf{P}_j\theta + \overline{\mathsf{Q}}_j(\theta,\theta) + \overline{\mathsf{R}}_j(\theta)\big\}, \tag{26.3}$$

where P_j is linear, $\overline{\mathsf{Q}}_j$ is quadratic, and $\overline{\mathsf{R}}_j$ is the remainder. Let E_H be the identity map of arrays on the lattice of mesh H, and set

$$\begin{aligned}
x_j &= P_\cdot^\delta I_{a_j} A_j, \qquad d_j = x_j - x_{j-1},\\
s_j &= (g_j/a_j) P_\cdot^\delta I_{a_j} E_\theta\zeta_j,\\
Z_j &= A_j - \mathbb{E}(A_j \mid \mathcal{F}_{j-1}) - (g_j/a_j)E_\theta\zeta_j, \qquad z_j = P_\cdot^\delta I_{a_j} Z_j,\\
r_j &= H^{-1}P_\cdot^\delta(I_{a_j}\mathsf{P}_j - I_H\mathsf{E}_H)\theta_{j-1},\\
U_j^0 &= H^{-1}\big\{\overline{\mathsf{Q}}_j(\theta_{j-1},\theta_{j-1}) + \overline{\mathsf{R}}_j(\theta_{j-1})\big\} + m_j^{\mathrm{ph}}, \qquad u_j = P_\cdot^\delta I_{a_j} U_j^0,
\end{aligned} \tag{26.4}$$

with $\theta = \theta_{j-1}$ in E_θ. Then

$$d_j = s_j + z_j + r_j + u_j. \tag{26.5}$$

The terms s_j and z_j have conditional mean zero given $\mathcal{F}_{j-1}$, while r_j and u_j are $\mathcal{F}_{j-1}$-measurable; neither of the latter is recentered. With $y_j = \mathcal{Q}_\delta(x_j, x_j)$, for every $1 \le k \le l \le K$,

$$y_l - y_{k-1} = \sum_{j=k}^{l}\big\{\mathcal{B}_\delta(x_{j-1}, d_j) + \mathcal{Q}_\delta(d_j, d_j)\big\}. \tag{26.6}$$

Inserting (26.5) *expresses the right side through the four mixed terms* $\mathcal{B}_\delta(x_{j-1}, v)$, $v \in \{s_j, z_j, r_j, u_j\}$, *and the sixteen ordered products* $\mathcal{Q}_\delta(v, v')$, $v, v' \in \{s_j, z_j, r_j, u_j\}$; *equivalently, through the nine ordered products of* s_j, z_j, *and* $r_j + u_j$. *All these identities are finite and exact, uniformly in* K, $\mathfrak{d}_j$, *and* θ_{j-1}.

3. *There is also an expansion at* $w = 0$. *Set*

$$E_\theta^{(0)} = g_j^{-1} D_w \mathscr{R}_j(\theta, 0), \qquad \mathsf{B}_\theta^{(0)} = (2g_j^2)^{-1} D_w^2 \mathscr{R}_j(\theta, 0),$$

define $s_j^{(0)}$ *as* s_j *with* E_θ *replaced by* $E_\theta^{(0)}$, *and define* $Z_j^{(0)}$ *and* $z_j^{(0)}$ *by the same centered subtraction. Then* (26.5) *and* (26.6) *hold with* $s_j^{(0)}$, $z_j^{(0)}$ *in place of* s_j, z_j, *and with* r_j, u_j *unchanged. Define* $\widetilde{R}_\theta$ *by*

$$\mathscr{R}_j(\theta, m_\theta + \zeta) - \mathscr{R}_j(\theta, m_\theta) = g_j E_\theta^{(0)} \zeta + g_j^2 \mathsf{B}_\theta^{(0)}(\zeta, \zeta) + \widetilde{R}_\theta(\zeta). \tag{26.7}$$

Then $\|\widetilde{R}_\theta\|_\infty \le C_J g_j^3 p_j^3$ *on* Ω_j. *Theorems 26.10 to 26.12 hold for either expansion, with* E_θ, B_θ, R_θ *replaced consistently by* $E_\theta^{(0)}$, $\mathsf{B}_\theta^{(0)}$, $\widetilde{R}_\theta$ *in the second. This is a second decomposition of the same sample, under the same law.*

Proof. The proof consists of exact computations, apart from two estimates: the deterministic bound on the coarser fields in Step 2, which is used throughout the section, and the bound on $\widetilde{R}_\theta$ in Step 7.

Step 1: the conditional law. The disintegration of Lemma 15.10 applies with coarse mesh L/n, total number K of renormalization group steps, and the reconstruction maps $\widehat{\mathscr{R}}$, whose gauge transformations depend only on the coarser field. Every restriction imposed by the small-field event at coarser scales is measurable with respect to the coarser field and therefore cancels in the normalized conditional law of the finer variables. This proves the assertion about the law of w_j given $\mathcal{F}_{j-1}$, which is a statement about the joint law of all variables under ν_K. Each cutoff radius is a fixed multiple of $\log(1/t_j)$, up to the ratios between intermediate scales. Since $t_j = M^{(J-1)/2} g_3 \sqrt{L/n}\, B^{-j/2}$, their maximum satisfies $p_j \le C_{\gamma,n,M,J}(1 + j)$.

Step 2: a deterministic bound on the coarser fields. Let $C_{\mathrm{rec},J}$ be the fixed-J bound on the absolute row sums of the derivative of one reconstruction step in the coupling-scaled inputs. By the bound on the reconstruction in Lemma 15.10, we have

$$\|\theta_j\|_\infty \le a_{\mathrm{cap}} \|\theta_{j-1}\|_\infty + C_{\mathrm{rec},J} t_j p_j, \qquad a_{\mathrm{cap}} = C_{\mathrm{CP}}/B, \qquad a_{\mathrm{cap}} \sqrt{B} < 1.$$

Here C_{CP} bounds finitely many derivatives of the zero-fluctuation reconstruction and is chosen before J. We iterate this recursion, using $p_i \le p_j$ for $i \le j$ and $t_i = M^{(J-1)/2} g_3 \sqrt{a_j}\, B^{(j-i)/2}$, and obtain

$$\|\theta_j\|_\infty \le r a_{\mathrm{cap}}^j + M^{(J-1)/2} C_{\mathrm{rec},J} g_3 \sqrt{a_j}\, p_j \sum_{h=0}^{j-1} (a_{\mathrm{cap}} \sqrt{B})^h \le r a_{\mathrm{cap}}^j + C_{\mathrm{cap},J} g_3 \sqrt{a_j}\, p_j, \quad (26.8)$$

where r is the radius of B_r and $C_{\mathrm{cap},J} \ge M^{(J-1)/2} C_{\mathrm{rec},J} / (1 - a_{\mathrm{cap}} \sqrt{B})$ is a separate constant. A constant C_J in a deterministic bound on the coarser fields below may include $C_{\mathrm{cap},J}$; it is never used to enlarge C_{CP} or to change J. The conditional fluctuation kernel and the coefficient bounds used in the Taylor expansions below are verified in Lemma 26.1.

Step 3: the expansion at the conditional mean. By convexity, the product of balls contains the coordinatewise mean m_θ and the segment $m_\theta + v\zeta$, $0 \le v \le 1$. We apply Theorem 13.10 to the reconstruction on the domain of Lemma 26.1, including the ratios between intermediate scales. With

$$E_\theta = g_j^{-1} D_w \mathscr{R}_j(\theta, m_\theta), \qquad \mathsf{B}_\theta = (2 g_j^2)^{-1} D_w^2 \mathscr{R}_j(\theta, m_\theta),$$

Taylor's formula gives (26.2) exactly, with

$$R_\theta(\zeta) = \frac{1}{2} \int_0^1 (1-v)^2 D_w^3 \mathscr{R}_j(\theta, m_\theta + v\zeta)[\zeta, \zeta, \zeta]\, dv, \qquad \|R_\theta\|_\infty \le C_J g_j^3 p_j^3. \quad (26.9)$$

The derivatives here are taken in the normalized fluctuation variables. Writing an increment of the coupling-scaled input $q_{j,i}$ as $g_{j,i} w_i$ contributes its own factor $g_{j,i}$ at each input, and all ratios $g_{j,i}/g_j$ lie in an interval depending only on M and J. This accounts for the normalization of both tensors.

Step 4: the expansion of the zero-fluctuation reconstruction. We define $\overline{\mathsf{A}}_j(\theta) = B \mathscr{R}_j(\theta, 0)$, $\mathsf{P}_j = D\overline{\mathsf{A}}_j(0)$, and $\overline{\mathsf{Q}}_j = D^2 \overline{\mathsf{A}}_j(0)/2$, and let $\overline{\mathsf{R}}_j$ be what remains after subtracting these two terms from $\overline{\mathsf{A}}_j$. We have $\overline{\mathsf{A}}_j(0) = 0$, because the zero-fluctuation reconstruction of the identity is the identity. Since $B a_j = H$, we have $a_j^{-1} \mathscr{R}_j(\theta, 0) = H^{-1} \overline{\mathsf{A}}_j(\theta)$, which is (26.3).

Step 5: the four terms. By the definitions of C_j, m_j^{ph}, and Z_j,

$$A_j = C_j + m_j^{\mathrm{ph}} + (g_j/a_j) E_\theta \zeta_j + Z_j.$$

We apply I_{a_j} to this identity, subtract $I_H A_{j-1} = H^{-1} I_H \mathsf{E}_H \theta_{j-1}$, and apply P_t^δ. By (26.3), the linear part of C_j and the coarser field combine to $H^{-1} P_t^\delta (I_{a_j} \mathsf{P}_j - I_H \mathsf{E}_H) \theta_{j-1} = r_j(t)$. The remaining predictable terms are u_j, which proves (26.5). Since $\mathbb{E}_\theta \zeta_j = 0$, the definitions imply that $\mathbb{E}_\theta s_j = \mathbb{E}_\theta z_j = 0$, while r_j and u_j depend only on θ_{j-1}. The conditional mean correction m_j^{ph}, which is in general not zero, has not been removed.

Step 6: the quadratic telescope. For any bilinear map $\mathcal{Q}$ and any x, d,

$$\mathcal{Q}(x+d,x+d)-\mathcal{Q}(x,x)=\mathcal{Q}(x,d)+\mathcal{Q}(d,x)+\mathcal{Q}(d,d).$$

We apply this identity to $\mathcal{Q}_\delta$ on the lattice of mesh δ, with $x=x_{j-1}$ and $d=d_j$, and sum from $j=k$ to $j=l$. This is (26.6). Inserting $d_j=\sum_{v\in\{s_j,z_j,r_j,u_j\}}v$, we obtain $\mathcal{B}_\delta(x_{j-1},d_j)=\sum_v\mathcal{B}_\delta(x_{j-1},v)$ and $\mathcal{Q}_\delta(d_j,d_j)=\sum_{v,v'}\mathcal{Q}_\delta(v,v')$, which are the four mixed terms and the sixteen ordered products. Combining r_j+u_j gives the nine ordered products.

Step 7: the expansion at zero. We derive the second expansion from an exact Taylor computation; we do not assume that $m_\theta=0$. At $w=0$ we have

$$\mathscr{R}_j(\theta,v)=\mathscr{R}_j(\theta,0)+g_jE_\theta^{(0)}v+g_j^2\mathsf{B}_\theta^{(0)}(v,v)+R_\theta^{(0)}(v).$$

By Lemma 26.1, the third directional derivative is bounded, and we obtain $\|R_\theta^{(0)}(v)\|_\infty\le C_Jg_j^3\|v\|_\infty^3$. One may also obtain this bound directly from the one-variable Cauchy formula for the bounded reconstruction along the line through 0 and v, written in the coupling-scaled inputs $(g_{j,i}v_i)_i$; the radius available on that line is the distance to the boundary of the domain of these inputs divided by the supremum norm of the direction. By convexity, the segments from 0 to the points used here lie in the product. We subtract the expansions at $v=m_\theta+\zeta$ and at $v=m_\theta$ and obtain

$$\widetilde{R}_\theta(\zeta)=g_j^2\{\mathsf{B}_\theta^{(0)}(m_\theta,\zeta)+\mathsf{B}_\theta^{(0)}(\zeta,m_\theta)\}+R_\theta^{(0)}(m_\theta+\zeta)-R_\theta^{(0)}(m_\theta).$$

The bilinear form $\mathsf{B}_\theta^{(0)}$ is bounded in the supremum norm, by polarization of the same directional Taylor formula. Together with the bound $\|m_\theta\|_\infty\le C_Jt_j\|\theta\|_\infty$ of Theorem 13.10, this bounds the first term by $C_Jg_j^2t_j\|\theta\|_\infty p_j$. Since θ lies in a fixed ball, t_j/g_j is fixed, and $p_j\ge1$, this is at most $C_Jg_j^3p_j^3$. The two remainders $R_\theta^{(0)}$ obey the same bound. We define $z_j^{(0)}$ by the centered subtraction; the algebra of Steps 5 and 6 then applies with r_j and u_j unchanged. The row and column bounds and the Cauchy argument below are made on the common coefficient domain of Lemma 26.1, so they apply at either base point $w=m_\theta$ or $w=0$. This completes the proof. □

Remark 26.3. In this section s_j and z_j always denote the terms of the expansion (26.2) at the conditional mean, whose linear coefficient is $E_\theta=g_j^{-1}D_w\mathscr{R}_j(\theta,m_\theta)$; the terms of the expansion at $w=0$, with linear coefficient $E_\theta^{(0)}=g_j^{-1}D_w\mathscr{R}_j(\theta,0)$, are written $s_j^{(0)}$ and $z_j^{(0)}$. Both pairs use the same centered vector $\zeta_j=w_j-m_\theta$, and

$$s_j+z_j=s_j^{(0)}+z_j^{(0)}=P_\cdot^\delta I_{a_j}\big(A_j-\mathbb{E}(A_j\mid\mathcal{F}_{j-1})\big),$$

so the decomposition (26.5) and the terms r_j and u_j are the same in both conventions. Section 28 uses the expansion at $w = 0$: its terms s_j and z_j are the terms $s_j^{(0)}$ and $z_j^{(0)}$ of this section. By part (3) of Lemma 26.2, Theorems 26.10 to 26.12 hold for these terms as stated.

26.2 Deterministic estimates for heat kernels and coefficients

Standing conventions. In this section and the next, $a = a_j$ for some $1 \le j \le K$, $H = Ba = a_{j-1}$, and $\delta = a_K$. Then $0 < \delta \le a \le L/4$, and $a/\delta = B^{K-j}$ and $H/\delta = B^{K-j+1}$ are integers. We fix $1/2 < \alpha < 2/3$ and set

$$\beta = \alpha - 1/2, \qquad p_\alpha = (\alpha+1)/2, \qquad \Lambda_a = \log(2 + L/a),$$

where Λ_a is the logarithmic lattice-size factor, written $\Lambda_{a_j} = \ell_j$ in Section 17; it is unrelated to the normalization constant Λ. For $q > 0$ and $0 \le t \le T$, we also set

$$I_q^a(t) = \int_0^t (s + a^2)^{-p_\alpha} (t - s + a^2)^{-q}\, ds. \tag{26.10}$$

For a heat path $B(t) = P_t^\delta b$ on the lattice of mesh δ we write

$$\mathsf{R}_a(B) = \sup_{0 \le t \le T} \big\{ (t+a^2)^{\alpha/2} \|B(t)\|_\infty + (t+a^2)^{(\alpha+1)/2} \|D_\delta B(t)\|_\infty \big\} \tag{26.11}$$

for its radius at scale a; it is the norm $\mathsf{X}_\alpha^\delta(B)$ with δ^2 replaced by a^2 in the weights.

Let $f(t,x)$ be a field on $[0,T] \times \Lambda_N$ whose components are linear functions of a vector of counting inputs, with deterministic coefficients. Its *value row* at (t,x) is the coefficient vector of a scalar component of $f(t,x)$, and its *first-difference rows* are those of the components of $D_\delta f(t,x)$. For a field whose components are quadratic forms, rows are replaced by the symmetric coefficient matrices, measured in Hilbert–Schmidt and operator norm. Given exponents (κ_0, κ_1), the *weighted coefficient bound* of f is

$$\sup_{0 \le t \le T} \sup_x \max\big\{ (t+\delta^2)^{\kappa_0} \|\text{value row}\|,\ (t+\delta^2)^{\kappa_1} \|\text{first-difference row}\| \big\}.$$

We use $(\kappa_0, \kappa_1) = (\eta/2, (\eta+1)/2)$ for the norms X_η^δ and H_η^δ, and $(\kappa_0, \kappa_1) = (\beta, \alpha)$ for the norm Y_α^δ. A bound by S for the weighted coefficient bound means that every scalar component of the weighted value and first difference, evaluated at a fixed point (t,x), is a linear (or quadratic) form in the inputs with coefficient norm at most S.

The periodic heat kernel

We write $P_t^\delta f(x) = \delta^3 \sum_y p_t^\delta(x,y) f(y)$, so that $p_t^\delta(x,\cdot)$ is the heat kernel relative to the physical measure $\delta^3 \sum_y$, and we let $\|\cdot\|_1$, $\|\cdot\|_2$ be the norms of L_δ^1 and L_δ^2.

Lemma 26.4. *For every fixed integer $q \geq 0$ and $0 \leq t \leq T$,*

$$\|D_\delta^q p_t^\delta(x,\cdot)\|_1 \leq C_q (t+\delta^2)^{-q/2},$$
$$\|D_\delta^q p_t^\delta(x,\cdot)\|_2 \leq C_q (t+\delta^2)^{-3/4-q/2},$$
$$\|D_\delta^q p_t^\delta(x,\cdot)\|_\infty \leq C_q (t+\delta^2)^{-(3+q)/2}.$$

The kernel is nonnegative and has physical mass one. Fixed translations and adjoint differences obey the same estimates, with the same dependence of the constants.

Proof. We write $\Delta_\delta = \delta^{-2}\sum_i (T_i + T_i^{-1} - 2)$, where T_i is the translation by δe_i. The exponential series of the positive part $\delta^{-2}\sum_i (T_i + T_i^{-1})$, multiplied by e^{-6t/δ^2}, is a convolution with nonnegative coefficients whose sum is one. At $t = 0$ its density is $\delta^{-3}\mathbf{1}_{x=y}$. For $t \leq \delta^2$, contraction and the finite difference stencil give the three bounds, since $(t+\delta^2) \asymp \delta^2$ there.

We give the details for the L^1 bound on differences at longer times. On $\mathbb{Z}$, at dimensionless time $v = t/\delta^2 \geq 1$, the Fourier multiplier of the qth unscaled forward difference of the random walk kernel is

$$f_{v,q}(\xi) = (e^{i\xi} - 1)^q e^{-4v\sin^2(\xi/2)}, \qquad -\pi \leq \xi \leq \pi.$$

Backward differences change only a factor of modulus one. Since $\sin^2(\xi/2) \geq c\xi^2$ on this interval, bounding each derivative of a factor and substituting $z = \sqrt{v}\,\xi$, we find

$$\int |f_{v,q}|^2 \, d\xi \leq C_q v^{-q-1/2}, \qquad \int |\partial_\xi f_{v,q}|^2 \, d\xi \leq C_q v^{-q+1/2}.$$

For $q = 0$ only the derivative of the exponential occurs in the second integral, and its size is $Cv|\xi|e^{-cv\xi^2}$; for $q \geq 1$ the other term is $C_q|\xi|^{q-1}e^{-cv\xi^2}$, and both integrals have the displayed powers. By Parseval's identity, the difference kernel $h_{v,q}(m)$ satisfies

$$\sum_m (1 + m^2/v)|h_{v,q}(m)|^2 \leq C_q v^{-q-1/2}.$$

Using the Cauchy–Schwarz inequality with weights $1 + m^2/v$, together with $\sum_m (1 + m^2/v)^{-1} \leq C\sqrt{v}$, we obtain $\sum_m |h_{v,q}(m)| \leq C_q v^{-q/2}$. Taking products over the three coordinates, we obtain this bound for every difference in several directions on $\mathbb{Z}^3$. Periodization does not increase the absolute sum, and rescaling each difference by δ^{-1} gives the physical L^1 estimate.

The remaining estimates on the finite torus follow from the finite Fourier sum. Frequencies k in the principal cube satisfy $\omega_\delta(k) = 4\delta^{-2}\sum_i \sin^2(\pi\delta k_i/L) \geq c|k|^2/L^2$, and the multiplier of a difference of order q is bounded by $C_q(|k|/L)^q$. Grouping the integer frequencies in unit shells $m \leq |k| < m+1$, each of which contains at most $C(m+1)^2$ points,

and comparing the decreasing Gaussian tails with integrals after splitting at $m = L/\sqrt{t}$, we obtain

$$L^{-3}\sum_{k}(|k|/L)^{q}e^{-ct|k|^{2}/L^{2}} \le C_{q}t^{-(3+q)/2} + \mathbf{1}_{q=0}L^{-3}.$$

This bounds the absolute Fourier sum, and hence the L^{∞} norm. Parseval's identity with order $2q$ and time $2t$ gives the square of the L^{2} bound. When $q = 0$, the constant Fourier mode contributes L^{-3} to that square; since $t \le T$, it is absorbed into the stated estimate with a constant depending on T/L^{2}. Differences annihilate the constant mode when $q > 0$. □

Coefficient tensors

Lemma 26.5. *Suppose a tensor $b_{y;\lambda\mu}$, with y on the lattice of mesh a and λ, μ fluctuation coordinates of cell volumes v_{λ}, v_{μ}, satisfies*

$$\sup_{y}\sum_{\lambda,\mu}|b_{y;\lambda\mu}| \le C_{J}, \qquad \sup_{\lambda}\frac{a^{3}}{v_{\lambda}}\sum_{y,\mu}|b_{y;\lambda\mu}| \le C_{J}, \qquad v_{\lambda}/a^{3} \le C_{J},$$

and the same column estimate with the roles of the two inputs interchanged. Set $F_{t} = P_{t}^{\delta}I_{a}b$, regarding the ordered pair (λ, μ) as one counting input. Then, for every fixed integer $q \ge 0$,

$$\|D_{\delta}^{q}F_{t}\|_{\ell^{2}(\lambda,\mu)\to L^{2}_{\delta}} \le C_{J,q}a^{3/2}(t + a^{2})^{-q/2},$$
$$\sup_{x}\|D_{\delta}^{q}F_{t}(x,\cdot,\cdot)\|_{2} \le C_{J,q}a^{3/2}(t + a^{2})^{-3/4-q/2}.$$

Symmetrizing a scalar coefficient matrix increases neither its Hilbert–Schmidt norm nor the displayed bound for its operator norm. The same heat argument, for one input, applies to E_{θ}.

Proof. By the column hypothesis and $v_{\lambda}/a^{3} \le C_{J}$, we have

$$\sup_{\lambda,\mu}\sum_{y}|b_{y;\lambda\mu}| \le \sup_{\lambda}\sum_{y,\mu'}|b_{y;\lambda\mu'}| \le C_{J}.$$

In other words, the column of a pair is bounded, because the column sum with one input fixed already sums over the other input. For any array h indexed by pairs, the Cauchy–Schwarz inequality with weights $|b_{y;\lambda\mu}|$ implies that

$$\sum_{y}\Big|\sum_{\lambda,\mu}b_{y;\lambda\mu}h_{\lambda\mu}\Big|^{2} \le \Big(\sup_{y}\sum_{\lambda,\mu}|b_{y;\lambda\mu}|\Big)\Big(\sup_{\lambda,\mu}\sum_{y}|b_{y;\lambda\mu}|\Big)\sum_{\lambda,\mu}|h_{\lambda\mu}|^{2}.$$

Multiplying by a^{3}, we obtain the physical operator factor $a^{3/2}$. By Lemma 16.3, the cardinal weights are nonnegative, their row sums are one, and their column sums, weighted by the output cell volume, are a^{3}. By Jensen's inequality, $I_{a} : L^{2}_{a} \to L^{2}_{\delta}$ has norm

at most one. The absolute rows and columns of its differences are bounded by $C_q a^{-q}$ times those of I_a, because each column is a smooth bump at scale a.

For $t \le a^2$, we commute the differences through the heat semigroup. The absolute row is then $C_{J,q} a^{-q}$, the absolute column, weighted by the output cell volume, is $C_{J,q} a^{3-q}$, and the heat semigroup preserves these bounds. By the Schur test, we have the operator bound. The counting ℓ^2 norm of a row is at most its absolute row sum, which gives the pointwise bound in this range. For $t \ge a^2$, we put all differences on the heat kernel. Its L^1 estimate in Lemma 26.4 and the Schur test imply the operator bound, and its physical L^2 row, composed with the undifferentiated operator, gives the pointwise bound. The bounds of the two ranges agree at $t = a^2$ up to fixed constants. This proves the estimates for all orders, with no factor counting output sites.

For scalar coefficients, the counting norm of the vector indexed by ordered pairs is the Hilbert–Schmidt norm of the corresponding matrix. The orthogonal projection $A \mapsto (A + A^{\mathsf{T}})/2$ does not increase that norm, and the operator norm is at most the Hilbert–Schmidt norm. This proves the last assertion. □

Mixed Duhamel terms with a background field

The next lemma bounds the coefficients of the mixed Duhamel terms $\mathcal{Q}_\delta(B, F)$ and $\mathcal{Q}_\delta(F, B)$, where B is a background heat path, fixed after conditioning, and F is linear in the counting inputs. Both orders are treated, and for each the proof must decide where to put the difference contained in $\mathcal{N}_\delta$. Table 26.2 summarizes the choice, with $u = t - s$. Two differences of the background suffice for these row bounds; the four differences assumed in the lemma are used only for the covering bounds of Lemma 26.7.

Range	Source difference on	Placement
$u \ge a^2$	B	keep it on B; use the L^2_δ row of the outer heat kernel
$u \ge a^2$, $s \le u$	F_s	move it to the outer heat kernel by summation by parts
$s \ge u \ge a^2$	F_s	keep it on F_s
$u < a^2$	either	put all output differences on the source; contract by the heat semigroup

Table 26.2. Placement of differences in the proof of Lemma 26.6.

Lemma 26.6. *Assume the standing conventions of Section 26.2, and put $S = s + a^2$ and $U = t - s + a^2$. Suppose a coefficient map F_s, from a space of counting inputs to fields on the lattice of mesh δ, satisfies*

$$\|D^q_\delta F_s\|_{2 \to L^2_\delta} \le C_q h S^{-q/2}, \qquad \sup_x \|D^q_\delta F_s(x, \cdot)\|_2 \le C_q h S^{-3/4 - q/2}$$

for all fixed orders q required below, and that $B(s) = P_s^\delta b^\delta$ satisfies

$$\|D_\delta^q B(s)\|_\infty \le C_q R (s + a^2)^{-(\alpha+q)/2}, \qquad 0 \le q \le 4. \tag{26.12}$$

The constants C_q are fixed, and B is fixed after conditioning. The hypothesis (26.12) *holds for $B(s) = P_s^\delta I_H b$ with $R = \mathsf{R}_a(B)$ and C_q depending only on q, M, J, α, T/L^2, and the interpolation function. For either order $\mathcal{Q}_\delta(B, F)$ or $\mathcal{Q}_\delta(F, B)$, the coefficient rows of the mixed Duhamel term after $r = 0, 1$ output differences are bounded by*

$$C_J R h \, I^a_{3/4+r/2}(t),$$

and its weighted coefficient bound for Y_α^δ is at most $C_J R h \, a^{\alpha-3/2}$. These assertions hold with an ordered pair as the counting input, as well as with a single input.

Proof. Steps 3 and 4 are summarized in Table 26.2.

Step 1: backgrounds interpolated from mesh H. We first verify (26.12) for $B(s) = P_s^\delta I_H b$ and $R = \mathsf{R}_a(B)$; the radius then controls all higher differences. At $s = 0$, since I_H reproduces the values of b at the sites of the lattice of mesh H, we have $\|b\|_\infty \le \|I_H b\|_\infty \le R a^{-\alpha}$. For $s \le a^2$, by the bound on differences of the cardinal interpolation and heat contraction, we have $\|D_\delta^q B(s)\|_\infty \le C_q R H^{-q} a^{-\alpha} \le C_{q,B} R (s + a^2)^{-(\alpha+q)/2}$. For $s \ge a^2$, we write $B(s) = P_{s/2}^\delta B(s/2)$ and apply the L^1 bound of Lemma 26.4 to the differences of $P_{s/2}^\delta$, using $\|B(s/2)\|_\infty \le R(s/2 + a^2)^{-\alpha/2}$. This proves the same bound for every fixed q. The constant depends on $B = H/a$ and q, but not on b or R. For a general background, the bounds (26.12) are hypotheses. The row estimates below use only $0 \le q \le 2$.

Step 2: the quadratic coefficient. We use the expression of the quadratic coefficient in Lemma 24.2, on the periodic lattice of side $L/\delta = nB^K \ge 4$ and with physical difference scale δ. That lemma writes the quadratic coefficient of the damped Wilson flow as a fixed finite sum of terms $c[T_1 u_i, T_2 D_\delta^\pm v_j]$, with fixed translations T_1, T_2. We keep this order, these coefficients, and these translations in every Duhamel term of this section, including those in the estimates for the residual, for the square, and for the mean. Since this coefficient is a quadratic polynomial, no bound on the amplitude of the fields is needed to evaluate it. Subtracting $[f, g]$ from $[Tf, Tg]$ and dividing by δ gives the product rule

$$D^+[f, g] = [D^+ f, Tg] + [f, D^+ g],$$

and the backward rule follows by replacing T by T^{-1}. By this rule, a difference on F can be moved onto the whole bracket and onto B, with the translated arguments kept. Summation by parts moves a difference of the whole bracket to the outer heat kernel. All translations are isometries of L^2_δ and of the supremum norm.

Step 3: the range $u = t - s \geq a^2$. A source term whose difference falls on B has coefficient row at most

$$C_J R h \, S^{-p_\alpha} u^{-3/4-r/2},$$

by the L^2_δ bound of Lemma 26.4 on the differentiated outer heat kernel and the operator bound on F_s. If the difference of the source falls on F_s and $s \leq u$, summation by parts gives a term of this form and a term bounded by

$$C_J R h \, S^{-\alpha/2} u^{-5/4-r/2} \leq C_J R h \, S^{-p_\alpha} U^{-3/4-r/2},$$

since $S \leq U$ and $u \asymp U$. If $s \geq u \geq a^2$, we leave the difference on F_s; its operator bound gives the factor $S^{-1/2}$, and the same bound follows. For the order $\mathcal{Q}_\delta(F, B)$ the difference of the source falls on B, and the first case applies; for the order $\mathcal{Q}_\delta(B, F)$ the second and third cases apply.

Step 4: the range $u < a^2$. We put every output difference on the source and contract by the heat semigroup. At output order one, the products have the distributions of differences BD^2F, $(DB)DF$, and $(D^2B)F$, with their fixed translations; at output order zero the total order is one. Each coefficient row is bounded by

$$C_J R h \, S^{-p_\alpha - 3/4 - r/2} \leq C_J R h \, S^{-p_\alpha} U^{-3/4-r/2},$$

because $U \leq 2a^2 \leq 2S$. The color brackets contribute a constant factor. Integrating the rows of Steps 3 and 4 in s, we obtain the bounds by $C_J R h \, I^a_{3/4+r/2}(t)$.

Step 5: the convolution integrals. Set $e = a^2$ and $p = p_\alpha < 1$. For $t \leq e$, direct integration bounds $I^a_q(t)$ by te^{-p-q}. For $t \geq e$ we split at $t/2$. On the early half, $t - s + e \asymp t + e$ and $\int_0^{t/2} (s+e)^{-p} \, ds \leq C_p (t+e)^{1-p}$. On the late half, $s + e \asymp t + e$, and integrating the other factor yields $C(t+e)^{1/4}$ for $q = 3/4$ and $Ca^{-1/2}$ for $q = 5/4$. In both regimes we obtain

$$I^a_{3/4}(t) \leq C_\alpha (t + a^2)^{1/4 - p_\alpha}, \qquad I^a_{5/4}(t) \leq C_\alpha a^{-1/2} (t + a^2)^{-p_\alpha}. \tag{26.13}$$

Multiplying by $(t + \delta^2)^\beta$ and $(t + \delta^2)^\alpha$, respectively, gives at most the same expressions with δ^2 replaced by a^2. The remaining powers of $t + a^2$ are $\alpha/2 - 3/4$ and $(\alpha - 1)/2$, which are both negative. Evaluating at $t + a^2 = a^2$ bounds both weighted rows by $C_\alpha a^{\alpha - 3/2}$. This proves the final assertion, with all input factors contained in h. □

Covering numbers of coefficient rows

Lemma 26.7. *Assume the standing conventions of Section 26.2. Let $B(t) = P^\delta_t b^\delta$ be $\mathcal{F}_{j-1}$-measurable and satisfy*

$$\| D^q_\delta B(t) \|_\infty \leq C_q R (t + a^2)^{-(\alpha+q)/2}, \qquad 0 \leq q \leq 4,$$

where R is $\mathcal{F}_{j-1}$-measurable and the C_q are fixed constants. Put $F_t = (g_j/a)P_t^\delta I_a E_\theta$, for either expansion of Lemma 26.2. For either order of the mixed Duhamel term of B and F, let $l_r(t,x)$ be a scalar coefficient row after r output differences, $r = 0, 1$. Set

$$S = g_3 R a^\beta, \qquad A_r(t,x) = S^{-1}(t+\delta^2)^{\kappa_r} l_r(t,x), \qquad \kappa_0 = \beta, \quad \kappa_1 = \alpha.$$

If $R = 0$, all these rows vanish, and we define their normalized versions to be zero. Otherwise the distance

$$d((r,t,x),(r',s,y)) = \|A_r(t,x) - A_{r'}(s,y)\|_2,$$

on the index set that includes the finite list of scalar components and differences, has diameter bounded by a fixed constant, and its covering numbers satisfy

$$N(v) \le C(1 + L/a)^P v^{-Q}, \qquad 0 < v \le 1. \tag{26.14}$$

The same holds for the rows normalized pointwise, $l_r(t,x)/(g_3 R a\, I^a_{3/4+r/2}(t))$, extended continuously to $t = 0$. The constants depend only on the deterministic data and on $C_0, \dots, C_4$; they do not depend on the fluctuation cutoff, the coupling, the coarser field, the number of preceding averaging steps, or a/δ.

Proof. After conditioning, all rows are deterministic. By Lemmas 26.1 and 16.3, for every fixed order needed,

$$\sup_x \|D_\delta^q F_t(x,\cdot)\|_2 \le C_{J,q} g_3 a (t + a^2)^{-3/4 - q/2} \le C_{J,q} g_3 a^{-1/2-q}.$$

Each of the two ordered sources, denoted G_t, is the quadratic coefficient applied to $B(t)$ and F_t in that order. By the product rule of Lemma 24.2 and the four assumed differences of the background, we have

$$\sup_x \|D_\delta^q G_t(x,\cdot)\|_2 \le C_J R g_3 a^{-\alpha - 3/2 - q}, \qquad 0 \le q \le 3. \tag{26.15}$$

Order four suffices, because at most $q+1$ differences fall on either argument. The heat equations for B and F imply that, for $r = 0, 1$,

$$\sup_x \|D_\delta^r \partial_t G_t(x,\cdot)\|_2 \le C_J R g_3 a^{-\alpha - 7/2 - r}.$$

Indeed, a time derivative replaces one factor by a sum of its second differences; together with the difference of the source and the r output differences, the largest order on the background is $r + 3 \le 4$.

For $l_r(t) = \int_0^t P_{t-s}^\delta D_\delta^r G_s \, ds$, positivity and contraction of the heat semigroup also hold for rows in counting ℓ^2, by the triangle inequality. Thus

$$\sup_{t,x} \|D_\delta^h l_r(t,x)\|_2 \le C_J T R g_3 a^{-\alpha - 3/2 - r - h} \quad (h = 0, 1), \qquad \partial_t l_r(t) = D_\delta^r G_t + \Delta_\delta l_r(t).$$

Commuting the Laplacian onto G_s in the last integral bounds the time derivative by $C_J R g_3 [a^{-\alpha-3/2-r} + T a^{-\alpha-7/2-r}]$; the largest order of the source here is $r+2 \le 3$, which is covered by (26.15).

Let $\ell_* = 1 + L + \sqrt{T}$ and $\epsilon = a/\ell_* < 1$. Since $a \le L/4$, every power of a in these polynomial estimates may be replaced by the same power of ϵ, with a constant factor depending only on L and T. After division by $S = R g_3 a^{\alpha-1/2}$, the unweighted row, one spatial difference, and one time derivative are bounded by $C\epsilon^{-4}$, $C\epsilon^{-5}$, and $C\epsilon^{-6}$, respectively. For example, the spatial exponent is $2\alpha + 2 + r < 5$, and the time exponent is $2\alpha + 3 + r < 6$. By Lemma 26.6, the weighted row itself is bounded uniformly.

The weights have powers less than one. For $0 < k < 1$ and $h \ge 0$ we have $(z+h)^k - z^k \le h^k$ for $z \ge 0$, since the left side decreases in z. This gives $|(t+\delta^2)^k - (s+\delta^2)^k| \le |t-s|^k$, with no constant depending on δ. Applying this with $k = \beta$ and $k = \alpha$, and using a shortest lattice path on the torus for the spatial difference, we obtain

$$\|A_r(t,x) - A_r(s,y)\|_2 \le C\epsilon^{-8}\{\operatorname{dist}(x,y) + |t-s|^\beta\}. \tag{26.16}$$

Here $|t-s|$ and $|t-s|^\alpha$ are bounded by fixed multiples, depending on T, of $|t-s|^\beta$, and the exponent eight is a common bound for the preceding exponents. The triangle inequality and $\sup \|A_r\|_2 \le C$ bound the diameter, also between different members of the finite list of components.

We also check the second normalization, which avoids a division by t at the initial time. We write

$$l_r(t) = t U_r(t), \qquad U_r(t) = \int_0^1 P^\delta_{(1-v)t} D^r_\delta G_{vt}\, dv,$$

and $I^a_q(t) = t J_q(t)$ with

$$J_q(t) = \int_0^1 (vt + a^2)^{-p_\alpha} ((1-v)t + a^2)^{-q}\, dv.$$

This positive function has a lower bound depending only on L, T, α, and q, because $t + a^2 \le T + (L/4)^2$. Differentiating its integrand shows that $|J_q'(t)| \le C_\alpha a^{-2} J_q(t)$. By the formula for U_r and the heat equations, $\partial_t U_r$ is the integral over $v \in [0,1]$ of

$$(1-v) P^\delta_{(1-v)t} \Delta_\delta D^r_\delta G_{vt} + v P^\delta_{(1-v)t} D^r_\delta \partial_s G_s|_{s=vt}.$$

The bounds on the source control it by $CRg_3 a^{-\alpha-7/2-r}$, and one spatial difference of U_r is bounded by $CRg_3 a^{-\alpha-5/2-r}$. By the row bounds of Lemma 26.6, $U_r/(g_3 R a J_{3/4+r/2})$ is bounded uniformly. By the quotient rule, its moduli in time and space are bounded by fixed multiples of ϵ^{-8}. For example, the largest factor in the time derivative of the numerator is $a^{-\alpha-9/2-r}$, with exponent below seven, and the derivative of J_q contributes only a^{-2} times the already bounded quotient. The formula defines the continuous value at $t = 0$, and the pointwise normalized rows obey the modulus (26.16) as well.

For $0 < v \le 1$ we choose the spatial step $cv\epsilon^8$ and the time step $(cv\epsilon^8)^{1/\beta}$, where $c > 0$ depends only on the constant in the modulus. We choose nearest lattice sites when the spatial step is at least δ, and all lattice sites otherwise. Their number is at most $C(1 + L/(v\epsilon^8))^3$, and the time net has at most $C(1 + T/(v\epsilon^8)^{1/\beta})$ points. Both nets are deterministic, independent of the fluctuation variables and of the amplitude of the background. Multiplying these counts by each other and by the number of components and orders proves (26.14), for example with $P = \lceil 24 + 8/\beta \rceil$ and $Q = \lceil 3 + 1/\beta \rceil$. All constants have the stated independence, because only coefficient norms have been used and neither a sample nor the cutoff radius entered. □

26.3 Concentration and maximal inequalities

We now combine the deterministic estimates with concentration under the conditional fluctuation kernel. We control a supremum over space and time in two ways. The first uses the covering bound of Lemma 26.7 and chaining; its constants do not depend on the fluctuation cutoff or on the coupling, and it applies to mixed Duhamel terms with general backgrounds (Lemma 26.8). The second uses the fluctuation cutoff to bound moduli of continuity of the realized fields, followed by a union bound over a finite net at scale a (Lemma 26.9); its constants may depend on the fixed coupling and coarse side.

Lemma 26.8. *Assume the standing conventions of Section 26.2, and fix $\theta = \theta_{j-1}$ and $\mathfrak{d} \ge 0$. Let $(X_i)_{i \in \mathcal{T}}$ be a family of linear evaluations $X_i = l_i\zeta$, where $\zeta = w - \mathbb{E}_\theta w$ under $\mu_{\mathfrak{d},\theta}$, indexed by a finite list of components, the output sites, and the times in $[0, T]$, with coefficients continuous in time at each site. Suppose that $\sup_i \|l_i\|_2 \le C_0 S$, and that the distance $\|l_i - l_{i'}\|_2/S$ on $\mathcal{T}$ satisfies the covering bound* (26.14)*. Then, for every $u \ge 0$ and $1 \le p < \infty$,*

$$\mathbb{P}_\theta\Big\{\sup_i |X_i| > CS\sqrt{\Lambda_a + u}\Big\} \le Ce^{-u}, \qquad \Big\|\sup_i |X_i|\Big\|_{L^p(\mu_{\mathfrak{d},\theta})} \le CS(\sqrt{\Lambda_a} + \sqrt{p}).$$

The constants depend only on the lower bound $1/2$ for the Hessian and on the constants C_0, C, P, Q in the covering bound; in particular, they do not depend on the fluctuation cutoff.

Proof. By Lemma 26.1 and Theorem 5.4, for each coefficient row l, we have $\log \mathbb{E}_\theta e^{zl\zeta} \le z^2\|l\|_2^2$ for $z \in \mathbb{R}$, and the exponential Markov inequality shows that $l\zeta$ satisfies $\mathbb{P}_\theta\{|l\zeta| > 2\|l\|_2\sqrt{u}\} \le 2e^{-u}$; the same holds for every difference of two rows. We apply Lemma 16.4 with the distance $\|l_i - l_{i'}\|_2/S$, $s = CS$, $b = 0$, diameter at most $2C_0$, $A = C(1 + L/a)^P$, and entropy exponent Q. At a fixed reference index, the evaluation has coefficient norm at most $C_0 S$. By the Cauchy–Schwarz inequality in the finite-dimensional space of ζ, limits of rows in this distance correspond to limits of the evaluations. Because the coefficients are continuous in time and the lattice is finite, the supremum is determined by a countable dense set. Since $\log(2A) + Q \le C\Lambda_a$, the tail and moment bounds of Lemma 16.4 imply the assertions, with the explicit factor $\sqrt{p}$. If $S = 0$, all rows vanish. □

Lemma 26.9. *Assume the standing conventions of Section 26.2. Fix $\theta = \theta_{j-1}$ and the conditional fluctuation kernel of Lemma 26.1, and let $\zeta = w_j - m_\theta$.*

1. *A linear evaluation $l\zeta$ with $\|l\|_2 \le S$ satisfies $\mathbb{P}_\theta\{|l\zeta| > CS\sqrt{v}\} \le 2e^{-v}$ for $v > 0$.*
2. *A quadratic evaluation $\zeta^{\mathsf{T}} A\zeta - \mathbb{E}_\theta \zeta^{\mathsf{T}} A\zeta$, with A symmetric and $\|A\|_{\mathrm{HS}} \vee \|A\|_{\mathrm{op}} \le S$, satisfies*

$$\mathbb{P}_\theta\big\{|\zeta^{\mathsf{T}} A\zeta - \mathbb{E}_\theta \zeta^{\mathsf{T}} A\zeta| > C(\|A\|_{\mathrm{HS}}\sqrt{v} + \|A\|_{\mathrm{op}} v)\big\} \le 2e^{-v}, \qquad v > 0;$$

   in particular, the threshold $CS(1+v)$ suffices.
3. *Consider the following fields, all centered under $\mu_{\mathfrak{d}_j,\theta}$: the heat fields $P_\cdot^\delta I_a f$ of arrays f on the lattice of mesh a whose entries are linear or quadratic in ζ, measured in H_η^δ for some $0 < \eta < 3/2$; the mixed Duhamel terms of s_j, or of the quadratic part of z_j, with a background $P_\cdot^\delta I_H b$ fixed after conditioning, measured in Y_α^δ; and the quadratic Duhamel term $\mathcal{Q}_\delta(s_j, s_j) - \mathbb{E}_\theta \mathcal{Q}_\delta(s_j, s_j)$, measured in Y_α^δ. Suppose S bounds the weighted coefficient bound of the field and, for heat fields, also a^η times the coefficient norms of the entries of f. For a mixed Duhamel term let $R \ge \mathsf{R}_a(P_\cdot^\delta I_H b)$. In the mixed linear, mixed quadratic, and self-quadratic Duhamel cases, respectively, also require $S \ge Rg_3 a^{\alpha-1/2}$, $S \ge Rg_3^2 a^\alpha$, and $S \ge g_3^2 a^{2\alpha-1}$. These additional lower bounds are not imposed on heat fields. Then the norm of the field exceeds $CS\sqrt{\Lambda_a + u}$ in the linear case, and $CS(\Lambda_a + u)$ in the quadratic case, with probability at most Ce^{-u}, for every $u \ge 0$; the corresponding moment bounds hold for every $1 \le p < \infty$.*

The constants in (1) and (2) depend only on the lower bound $1/2$ for the Hessian. The constants in (3) may in addition depend on the fixed γ, n, and the prescription of the cutoff radii, as stated in Section 26.1.

Proof. The proof of (3) uses the fluctuation cutoff to bound the moduli of continuity of the realized fields. The short times $t \le a^2$, for heat fields, and $t \le \min(a^2, a^8)$, for Duhamel terms, are treated without a time net. On the remaining times, crude bounds by a fixed power of a^{-1} suffice, because the net then has polynomially many points in $1/a$ and only the logarithm of its size enters.

Step 1: pointwise tails. By Lemma 26.1, the potential is smooth on a neighborhood of the closed product Ω_j and $D_w^2 V \ge m_* I$ with $m_* = 1/2$. The domain is a finite product of Euclidean balls, with the reflecting boundary condition. These are the hypotheses of Theorem 5.4, applied to the potential itself, including its determinant and Haar disintegration terms. For a linear row l, that theorem implies that $\log \mathbb{E}_\theta e^{zl\zeta} \le z^2\|l\|_2^2/(2m_*)$, and optimizing Markov's inequality in z, we obtain the two-sided sub-Gaussian tail (1). For a symmetric matrix A, we write $a_2 = \|A\|_{\mathrm{HS}}$ and $a_\infty = \|A\|_{\mathrm{op}}$. By the same theorem, we have $\log \mathbb{E}_\theta e^{z(\zeta^{\mathsf{T}} A\zeta - \mathbb{E}_\theta \zeta^{\mathsf{T}} A\zeta)} \le 8z^2 a_2^2/m_*^2$ for $|z| \le m_*/(4a_\infty)$. Chernoff's inequality, applied with both signs and $z = \min(c_1\sqrt{v}/a_2, c_2/a_\infty)$, gives (2). Vanishing norms are

treated by continuity. Throughout, ζ is centered at the conditional mean m_θ under the same kernel.

Step 2: consequences of the cutoff. We now prove (3) by a finite net, including the endpoints of the time interval; this avoids any entropy at the scale δ. On Ω_j we have $\|\zeta\|_\infty \le C_J p_j$, and, at fixed γ and n, $p_j \le C_{\gamma,n}[1+\log(2+L/a)]$. In particular, $p_j^k \le C_{\gamma,n,k} a^{-1}$ for every fixed k when $a \le \min(1, \sqrt{T})$. The bounded remaining range of a is absorbed by enlarging the constants, which then depend on L, T, γ, and n.

Step 3: continuous extensions. We estimate the deterministic moduli through continuous extensions in space, starting from the smooth periodic cardinal interpolant on the torus. The exponential of the positive shift part defining P_t^δ acts on its translates for every real x, not only at lattice sites; this defines a smooth function whose restriction to the lattice is the discrete heat evolution. Continuous spatial derivatives commute with this convolution. Further,

$$\|\Delta_\delta f\|_{C^q} \le C \|f\|_{C^{q+2}},$$

by the second-order Taylor formula with integral remainder for each symmetric difference. Thus a time derivative costs two derivatives of the smooth data, never a factor δ^{-2}. The same extension applies to translated brackets and to their Duhamel integrals.

Step 4: unweighted bounds on the cutoff. Let the background $P_\cdot^\delta I_H b$ have radius at most R, and fix an order q of continuous spatial derivatives and an order k of time derivatives. On Ω_j, the supremum of $D^q \partial_t^k$ of each field or source satisfies the following bounds:

field or source	bound
$(g_j/a) P_t^\delta I_a E_\theta \zeta$	$C_{J,q,k} g_3 p_j a^{-1/2-q-2k}$
$P_t^\delta I_a \mathsf{B}_\theta(\zeta,\zeta)$	$C_{J,q,k} p_j^2 a^{-q-2k}$
$\mathcal{N}_\delta(B, s_j)$, $\mathcal{N}_\delta(s_j, B)$	$C_{J,q,k} R g_3 p_j a^{-\alpha-3/2-q-2k}$
$\mathcal{N}_\delta(B, g_3^2 P^\delta I_a \mathsf{B}_\theta(\zeta,\zeta))$, and the reversed order	$C_{J,q,k} R g_3^2 p_j^2 a^{-\alpha-1-q-2k}$
$\mathcal{N}_\delta(s_j, s_j)$	$C_{J,q,k} g_3^2 p_j^2 a^{-2-q-2k}$

To verify these entries, note that the absolute row bounds give $C_J p_j$ for $E_\theta \zeta$ and $C_J p_j^2$ for $\mathsf{B}_\theta(\zeta,\zeta)$. A spatial derivative of their cardinal interpolants costs $C_q a^{-q}$, and the heat semigroup contracts every continuous derivative. By its initial value and the heat equation, the background is bounded by $C_{J,q,k} R a^{-\alpha-q-2k}$. Using the quadratic coefficient of Lemma 24.2, we multiply the two factors in each bracket and distribute its difference; this gives the last three entries. By the product rule for differences, the same bounds hold for differences of these smooth extensions. A time derivative is the sum of the terms with one factor differentiated, and it satisfies the listed bound. Centering at the conditional mean doubles these bounds. For a Duhamel field, spatial derivatives are bounded by T

times the corresponding bound on the source, and its first time derivative is the source plus Δ_δ of the Duhamel field.

Step 5: heat fields. For a heat field measured with exponent $0 < \eta < 3/2$, we treat the times $0 \le t \le a^2$ without a time net. By heat contraction and the bound on differences of the cardinal interpolation, we have

$$\sup_{t \le a^2} \left\{ (t+\delta^2)^{\eta/2} \|P_t^\delta I_a f\|_\infty + (t+\delta^2)^{(\eta+1)/2} \|D_\delta P_t^\delta I_a f\|_\infty \right\} \le C_\eta a^\eta \max_y |f(y)|.$$

The maximum on the right is over at most $C_J (L/a)^3$ scalar entries, and we take a union bound over the tails of (1) or (2) at these entries. For $t \ge a^2$, the weights and their first time derivatives are bounded by fixed powers of a^{-1}. The following coefficient argument treats arbitrary admissible S, including for the special heat fields listed in the table. Let d_w be the number of scalar fluctuation coordinates of the step. Since there are J intermediate scales with fixed ratios of meshes, $d_w \le C_J (L/a)^3$. On the cutoff domain, we have $\|\zeta\|_2 \le C_J p_j \sqrt{d_w}$, and the assumed bounds on the coefficients of the entries of f give

$$\max_y |f_y| \le C_J S a^{-\eta} \times \begin{cases} p_j \sqrt{d_w} & \text{for centered linear forms,} \\ p_j^2 d_w & \text{for centered quadratic forms;} \end{cases}$$

in the quadratic case we apply the bound on the operator norm both to the value of the form and to its expectation. By the bounds on the cardinal interpolation, heat contraction, and the continuous extension of Step 3, we have

$$\|D^q \partial_t^k P_t^\delta I_a f\|_\infty \le C_{J,q,k} a^{-q-2k} \max_y |f_y|.$$

For $t \ge a^2$, the weighted value and first-difference components and their first spatial and time derivatives are bounded, after division by S, by a fixed power of a^{-1}, independently of a/δ. By the bounds of Step 2 on p_j, and since $d_w \le C a^{-3}$, the exponent 30 suffices. If $S = 0$, the coefficients of the entries of f vanish, and so does the field.

Step 6: Duhamel fields. For a Duhamel term, we set $t_0 = \min(T, a^2, a^8)$. If $t \le t_0 \le a^2$, its weighted value and first difference, divided by S, are bounded by $C p_j^k t/a^2$, with $k = 1$ for a mixed linear term and $k = 2$ for a quadratic term. Indeed, the last three source bounds of the table, multiplied by $t a^{2\alpha-1}$ and $t a^{2\alpha}$ at output orders zero and one, respectively, give this ratio for the natural scales $R g_3 a^{\alpha-1/2}$, $R g_3^2 a^\alpha$, and $g_3^2 a^{2\alpha-1}$, respectively. The additional lower bounds on S make the same bounds valid after division by S. If $R = 0$, each mixed field vanishes. Since $p_j^k t_0/a^2 \le p_j^k \min(1, a^6)$ is bounded at fixed coupling, using Step 2 also on the bounded coarse-mesh range, this is a deterministic contribution CS. If $t_0 < T$, then $t_0^{-1} = \max(a^{-2}, a^{-8}) \le \max\{1, (L/4)^6\} a^{-8}$. Thus on $t \ge t_0$ a differentiated weight costs at most $C a^{-8}$, with the allowed dependence on L. The table and the formula for

the time derivative of a Duhamel term again bound the first moduli in space and time by CSa^{-30}. The largest unweighted exponent of a source, after division by its scale, is less than 6; together with the factor a^{-8} from the weight and the growth of the cutoff, the total exponent stays below 30. If $t_0 = T$, the deterministic bound covers the whole interval.

Step 7: the net. We choose spatial and time steps ca^{30}, with c small depending on the constant in the modulus. A net of the torus and of the time interval then has at most

$$C(1 + La^{-30})^3(1 + Ta^{-30})$$

points, and the error in each normalized weighted component is at most one. When a step of the spatial net exceeds δ, we choose nearest lattice sites, and otherwise all lattice sites; the displayed count bounds either choice. The continuous extension is used only to bound the modulus between these sites, and all probability estimates are evaluated on the lattice. The logarithm of this count, and of the count of the short-time entries in Step 5, is at most $C\Lambda_a$, independently of a/δ. We apply the finite-family clause of Lemma 16.4 with $s = CS$ and $b = 0$ for a linear field, and with $s = CS$ and $b = CS$ for a quadratic field, using the tails of Step 1. The deterministic error from interpolation and from short times is $e \le CS$, and the logarithmic count is $C\Lambda_a$, with the dependence on the fixed γ and n stated above. This proves the maximal tails and all their moments. □

26.4 The linear fluctuation and the mixed Duhamel terms

We now prove the estimates for the linear fluctuation s_j and its mixed Duhamel terms with a predictable background. The background x_{j-1}, the heat evolution of the coarser field interpolated from mesh H, is covered by part (3) of the next theorem. The interpolation defect r_j, a predictable heat path on the finest lattice, is covered by parts (4) and (5). For the general class of part (4), we assume bounds on four differences of the background at scale a. These are needed for the covering bound of Lemma 26.7, and a bound on the value and the first difference alone does not give them uniformly at small times.

Theorem 26.10. *Assume the setting of Section 26.1 and the standing conventions of Section 26.2, and put $W_\theta(t) = P_t^\delta I_a E_\theta$, with $\theta = \theta_{j-1}$.*

1. *For every fixed integer $r \ge 0$, the coefficient rows and the operator of W_θ satisfy*

$$\sup_x \|D_\delta^r W_\theta(t,x,\cdot)\|_{\ell^2(w)} \le C_{J,r} a^{3/2}(t + a^2)^{-3/4-r/2},$$
$$\|D_\delta^r W_\theta(t)\|_{\ell^2(w)\to L^2_\delta} \le C_{J,r} a^{3/2}(t + a^2)^{-r/2}.$$

Each fluctuation coordinate enters with its own cell volume v_λ, which is comparable to a^3 up to a factor depending only on M and J. For the same scalar output component, times

$s, t \in [0, T]$ with $\tau = \min(s, t)$, and output sites x, y, the difference of the coefficient rows at (t, x) and at (s, y) is bounded in $\ell^2(w)$ by

$$C_{J,r} a^{3/2} (\tau + a^2)^{-3/4 - r/2} \min\Big\{1, \frac{\operatorname{dist}(x, y)}{\sqrt{\tau + a^2}} + \frac{|t - s|}{\tau + a^2}\Big\}.$$

2. *For every $1 \le p < \infty$, uniformly in θ_{j-1},*

$$\big\| \mathsf{X}^{\delta}_{\alpha}(s_j) \big\|_{L^p(\mu_{\mathfrak{d}_j, \theta})} \le C_J g_3 a^{\beta} (\sqrt{\Lambda_a} + \sqrt{p}),$$

with C_J independent of p.

3. *Let $B_j(t) = P^{\delta}_t I_H b$ be an $\mathcal{F}_{j-1}$-measurable heat evolution of an array b interpolated from the lattice of mesh H, and let $\mathsf{R}_j(B_j) = \mathsf{R}_a(B_j)$ be its radius* (26.11)*. For each fixed $r \ge 2$,*

$$\| D^r_{\delta} B_j(t) \|_{\infty} \le C_{r,B}\, \mathsf{R}_j(B_j) (t + a^2)^{-(\alpha + r)/2},$$

where $C_{r,B}$ depends only on r, M, J, α, T/L^2, and the interpolation function, and not on b or its radius. For each of the two orders $\mathcal{M}_j = \mathcal{Q}_{\delta}(B_j, s_j)$ and $\mathcal{M}_j = \mathcal{Q}_{\delta}(s_j, B_j)$, the value rows and first-difference rows of the coefficients are bounded by

$$C_J g_3 \mathsf{R}_j(B_j) a\, I^a_{3/4}(t) \qquad \text{and} \qquad C_J g_3 \mathsf{R}_j(B_j) a\, I^a_{5/4}(t),$$

respectively. Each order has conditional mean zero given $\mathcal{F}_{j-1}$. For every $u \ge 0$, on the event $\{\mathsf{R}_j(B_j) \le R\}$,

$$\mathbb{P}\Big\{ \mathsf{Y}^{\delta}_{\alpha}(\mathcal{M}_j) > C_J g_3 R a^{\beta} \sqrt{\Lambda_a + u} \;\Big|\; \mathcal{F}_{j-1} \Big\} \le C e^{-u}.$$

The sum $\mathcal{B}_{\delta}(B_j, s_j)$ of the two orders satisfies the same estimate with a larger C_J.

4. *The two mixed-term coefficient row bounds, conditional mean-zero assertions, and conditional maximal inequalities of (3) also hold for an $\mathcal{F}_{j-1}$-measurable heat path $B_j(t) = P^{\delta}_t b^{\delta}_j$ on the lattice of mesh δ, provided an $\mathcal{F}_{j-1}$-measurable radius $R^{\sharp}_j$ satisfies*

$$\| D^q_{\delta} B_j(t) \|_{\infty} \le C_q R^{\sharp}_j (t + a^2)^{-(\alpha + q)/2} \qquad (0 \le t \le T,\ 0 \le q \le 4),$$

with fixed constants $C_0, \dots, C_4$; the heat equation then supplies the increments in time. For this class we replace $\mathsf{R}_j(B_j)$ by $R^{\sharp}_j$ in both row bounds and in the conditional tail. The normalized coefficient distances of Lemma 26.7 have diameter bounded by a fixed constant and covering numbers $N(v) \le C(1 + L/a)^P v^{-Q}$, $0 < v \le 1$, with P, Q, C independent of a/δ, the lattice side, the number of averaging steps, θ_{j-1}, and the coupling. The covering is at scale a; no maximum over all sites of the finest lattice is used.

5. *The interpolation defect*

$$B_j(t) = H^{-1} P_t^{\delta}(I_a \mathsf{P}_j - I_H \mathsf{E}_H)\theta_{j-1} = r_j(t)$$

belongs to the class of (4), with $R_j^{\sharp} = C_J \|\theta_{j-1}\|_{\infty} H^{\alpha-1}$. *If* $\|\theta_{j-1}\|_{\infty} \le \bar{b}_{j-1}$ *on the small-field event, for a deterministic* $\bar{b}_{j-1}$, *then for every* $1 \le p < \infty$,

$$\big\|\mathsf{Y}_{\alpha}^{\delta}(\mathcal{Q}_{\delta}(s_j, r_j))\big\|_{L^p(\nu_K)} + \big\|\mathsf{Y}_{\alpha}^{\delta}(\mathcal{Q}_{\delta}(r_j, s_j))\big\|_{L^p(\nu_K)} \le C_{J,p} g_3 a^{\beta} (\sqrt{\Lambda_a} + \sqrt{p})\, \bar{b}_{j-1} H^{\alpha-1}.$$

All assertions hold for either expansion of Lemma 26.2, with the conditionally centered vector ζ_j *in both. The constants in the coefficient bounds depend only on* L, T, M, J, *the analytic domains, the column bounds,* α, *and* r; *they do not depend on* K, j, $\mathfrak{d}_j$, a/δ, *the dimension, the coupling, or* θ_{j-1}. *The constants in the conditional maximal inequalities may in addition depend on the fixed coupling, the coarse side, and the prescription of the cutoff radii. No bound on the expectation of a background radius is assumed or proved.*

Proof. We first prove the deterministic assertions, then the probability estimates, and then the application to r_j.

Step 1: coefficient rows. By Theorem 13.10, the first reconstruction tensor has bounded absolute rows and volume-normalized column sums. Each fluctuation coordinate has the volume $v_\lambda = a_\lambda^3$ of the lattice of its intermediate scale, and the finite ratios between intermediate scales imply that $C_J^{-1} a^3 \le v_\lambda \le C_J a^3$; there is no comparison with δ^3. This verifies the hypotheses of Lemma 16.3 with input mesh a and output mesh δ, and that lemma yields the two bounds of (1) for every fixed order r.

Step 2: increments of the rows. Fix r. A shortest coordinate path on the torus from x to y and the bound on rows of order $r+1$ bound the spatial increment by $C_{J,r}\,\mathrm{dist}(x,y) a^{3/2}(t + a^2)^{-5/4-r/2}$; the triangle inequality gives twice the bound of order r instead. For the time increment, we integrate $\partial_t D_\delta^r W_\theta = \Delta_\delta D_\delta^r W_\theta$ from $\min(s,t)$ to $\max(s,t)$ and use the bound of order $r+2$. Combining these linear increment bounds with twice the bound on values, we obtain the stated minimum. The coordinate path has length at most $\sqrt{3}$ times the distance on the torus, which is absorbed into $C_{J,r}$.

Step 3: the linear fluctuation. Since $g_j/a = g_3 a^{-1/2}$ and $\delta \le a$, the weighted coefficient bound of s_j for X_α^δ is at most the supremum over t of

$$(t+\delta^2)^{\alpha/2} g_3 a^{-1/2} a^{3/2} (t+a^2)^{-3/4} \quad \text{and} \quad (t+\delta^2)^{(\alpha+1)/2} g_3 a^{-1/2} a^{3/2} (t+a^2)^{-5/4}.$$

Both are bounded by $C_J g_3 a (t+a^2)^{\alpha/2-3/4} \le C_J g_3 a^{\alpha-1/2}$, because $\alpha < 3/2$. At a fixed coarser field, these evaluations are linear in ζ_j, and their conditional mean is zero. The entries of the initial array $(g_j/a) E_\theta \zeta_j$ have coefficient norms at most $C_J g_3 a^{-1/2}$, and a^α

times these norms is at most $C_J g_3 a^\beta$. The conditional fluctuation kernel and its Hessian bound $1/2$ are verified in Lemma 26.1. By Lemma 26.9, with $S = C_J g_3 a^\beta$, we have

$$\mathbb{P}_\theta\{\mathsf{X}_\alpha^\delta(s_j) > C_J g_3 a^\beta \sqrt{\Lambda_a + u}\} \le Ce^{-u}.$$

Integrating this tail, we obtain the moment bound of (2). In detail, $\sqrt{\Lambda_a + u} \le \sqrt{\Lambda_a} + \sqrt{u}$, and the positive part of the normalized norm beyond $\sqrt{\Lambda_a}$ has a tail bounded by Ce^{-cv^2} at level v. Its pth moment is at most $(C\sqrt{p})^p$: in the integral $p\int_0^\infty v^{p-1}e^{-cv^2}\,dv$, we bound $v^{p-1}e^{-cv^2/2}$ by its maximum and integrate $e^{-cv^2/2}$. The constants of Lemma 26.9 do not depend on p, so C_J does not depend on p.

Step 4: rows of the mixed terms. The bound on higher differences of $B_j = P_\cdot^\delta I_H b$ was proved in Step 1 of the proof of Lemma 26.6, from the values of the interpolation at the sites of the lattice of mesh H at time zero and from the splitting of the heat semigroup at later times. Its constant $C_{r,B}$ depends only on r, M, J, α, T/L^2, and the interpolation function, and not on the array b or its radius. We apply Lemma 26.6 with $F_s = (g_j/a)W_\theta(s)$ and $h = (g_j/a)a^{3/2} = g_3 a$; by (1), F_s satisfies its hypotheses. For each order separately, we obtain the value rows $C_J g_3 \mathsf{R}_j(B_j) a\, I^a_{3/4}(t)$ and the first-difference rows $C_J g_3 \mathsf{R}_j(B_j) a\, I^a_{5/4}(t)$. The two orders are linear functions of ζ_j with $\mathcal{F}_{j-1}$-measurable coefficients. Each therefore has conditional mean zero as a field in space and time, and no covariance needs to be computed.

Step 5: conditional maxima of the mixed terms. By Lemma 26.6, the weighted coefficient bound of each order is $C_J g_3 \mathsf{R}_j(B_j) a^\beta$. We fix a coarser field in the measurable event $\{\mathsf{R}_j(B_j) \le R\}$. The four differences of the background were just proved, and Lemmas 26.7 and 26.8 yield the conditional tail of (3) for each order. A union bound for the two tails and the triangle inequality for the sum give the assertion for $\mathcal{B}_\delta(B_j, s_j)$; the factor two is absorbed into C_J and C. If $R = 0$, then on this event $\mathsf{R}_j(B_j) = 0$ and $I_H b = B_j(0) = 0$; since the interpolation reproduces b at the sites of the lattice of mesh H, we have $b = 0$, and both terms vanish identically.

Step 6: general backgrounds. For the class of (4), we condition on $\mathcal{F}_{j-1}$ and use the radius $R_j^\sharp$ and the four assumed difference bounds. These are the hypotheses of Lemmas 26.6 and 26.7. The former implies both row bounds and the common weighted bound $C_J g_3 R_j^\sharp a^\beta$; its proof treats the difference in either argument. The latter implies the bounded diameter and the covering bound (26.14), independently of the cutoff and of the coupling; the heat equation gives the increments in time used there, with at most four differences of the background. Each term is linear in the conditionally centered ζ_j and has conditional mean zero. On $\{R_j^\sharp \le R\}$, Lemma 26.8 implies the conditional maximum and its moments. If the radius vanishes, the bound on the background of order zero shows that both terms vanish. Every conditional event is measurable: the reconstruction

and its coefficients are Borel, the lattice is finite, and suprema over continuous time are determined by rational times.

Step 7: the interpolation defect. We verify that r_j belongs to the class of (4), keeping the two lattices on which it is defined. Here $a = a_j$, $H = Ba$, and $\delta = a_K$, so

$$\delta = a/m, \qquad m = B^{K-j} \in \mathbb{N}, \qquad H/\delta = B^{K-j+1} \in \mathbb{N}.$$

We apply Lemma 17.2 with coarse mesh H, fine mesh a, $\mathfrak{d}_j$ preceding averaging steps, horizon T, and the integer refinements just displayed. By the expansion (26.3), its fine reconstruction of a lattice potential v on the coarser lattice is $\mathsf{P}_j v$, and its coarse embedding is $\mathsf{E}_H v$. It follows that its difference operator is $I_a \mathsf{P}_j - I_H \mathsf{E}_H$, and with $v = \theta_{j-1}/H$ its heat evolution is r_j. By that lemma, for every fixed integer q, we have

$$\|D_\delta^q r_j(t)\|_\infty \le C_{J,q} \frac{\|\theta_{j-1}\|_\infty}{H} (t + H^2)^{-q/2} \frac{H}{\sqrt{t + H^2}}.$$

For $z = t/H^2$, $0 < \alpha < 1$, and $B \ge 1$ we have

$$(z + B^{-2})^{(\alpha+q)/2} (1 + z)^{-(q+1)/2} \le (1 + z)^{(\alpha-1)/2} \le 1.$$

Multiplying the bound on $\|D_\delta^q r_j(t)\|_\infty$ by $(t + a^2)^{(\alpha+q)/2} = H^{\alpha+q}(z + B^{-2})^{(\alpha+q)/2}$, we obtain

$$(t + a^2)^{(\alpha+q)/2} \|D_\delta^q r_j(t)\|_\infty \le C_{J,q} \|\theta_{j-1}\|_\infty H^{\alpha-1}.$$

Choosing C_J large enough for $q = 0, 1, 2, 3, 4$, we obtain the radius $R_j^\sharp = C_J \|\theta_{j-1}\|_\infty H^{\alpha-1}$.

Step 8: moments under the conditioned Wilson measure. For either order separately, the conditional moment bound of (4) implies that

$$\Big(\mathbb{E}\big[\mathsf{Y}_\alpha^\delta(\mathcal{Q}_\delta(s_j, r_j))^p \mid \mathcal{F}_{j-1} \big] \Big)^{1/p} \le C_J g_3 a^\beta (\sqrt{\Lambda_a} + \sqrt{p}) \|\theta_{j-1}\|_\infty H^{\alpha-1},$$

and the same inequality holds with the two arguments interchanged, by the separate row computation for that order. We replace $\|\theta_{j-1}\|_\infty$ by $\bar{b}_{j-1}$, raise to the power p, and integrate over the law of θ_{j-1} under ν_K. By the tower property, we obtain both $L^p(\nu_K)$ bounds, and adding them gives (5) after changing $C_{J,p}$.

Step 9: the expansion at zero. By Lemma 26.1, we have the same rows and columns for $E_\theta^{(0)}$. Replacing E_θ by $E_\theta^{(0)}$ in the Schur, mixed-term, covering, and concentration arguments proves all assertions for the second expansion. The centered vector ζ_j, its domain, and its law are the same in both cases. □

26.5 The conditionally centered nonlinear residual

The conditionally centered nonlinear reconstruction residual Z_j is the reconstructed field after subtraction of its conditional mean and of the linear term; it is not a quadratic approximation. Its quadratic part is a centered quadratic form in ζ_j, to which the quadratic concentration of Lemma 26.9 applies, and the rest is bounded deterministically on the cutoff domain.

Theorem 26.11. *Assume the setting of Section 26.1 and the standing conventions of Section 26.2, and put $a = a_j$, $\theta = \theta_{j-1}$, and $\zeta = w_j - m_\theta$. Let $p_j \geq 1$ bound the cutoff radii of this step, so that $\|\zeta\|_\infty \leq 2C_J p_j$.*

1. *The initial residual is*

$$Z_j = g_3^2\big\{\mathsf{B}_\theta(\zeta,\zeta) - \mathbb{E}_\theta \mathsf{B}_\theta(\zeta,\zeta)\big\} + a^{-1}\big\{R_\theta(\zeta) - \mathbb{E}_\theta R_\theta(\zeta)\big\},$$

   and $\|a^{-1}(R_\theta - \mathbb{E}_\theta R_\theta)\|_\infty \leq C_J g_3^3 a^{1/2} p_j^3$.

2. *The coefficients $b_{y;\lambda\mu}$ of B_θ satisfy*

$$\sup_y \sum_{\lambda,\mu} |b_{y;\lambda\mu}| \leq C_J, \qquad \sup_\lambda \frac{a^3}{v_\lambda} \sum_{y,\mu} |b_{y;\lambda\mu}| \leq C_J$$

   for either fixed input, where v_λ is the cell volume of the coordinate λ and $v_\lambda / a^3 \leq C_J$. Consequently

$$\|\mathsf{B}_\theta\|_{\ell^2(\text{ordered pairs}) \to L^2_a} \leq C_J a^{3/2}.$$

   For each scalar component and every fixed $r \geq 0$, the symmetric coefficient matrix $\mathsf{A}^{(r)}_{t,x}$ of $D^r_\delta P^\delta_t I_a \mathsf{B}_\theta(\zeta,\zeta)$ at x satisfies

$$\|\mathsf{A}^{(r)}_{t,x}\|_{\mathrm{HS}} \vee \|\mathsf{A}^{(r)}_{t,x}\|_{\mathrm{op}} \leq C_{J,r} a^{3/2} (t + a^2)^{-3/4 - r/2}.$$

   Centering changes only the constant term of the quadratic form, not this matrix.

3. *For $0 < \sigma < 1 - \alpha$ and every $u \geq 0$,*

$$\mathbb{P}_\theta\Big\{\mathsf{H}^\delta_\sigma\big(I_a[\mathsf{B}_\theta(\zeta,\zeta) - \mathbb{E}_\theta \mathsf{B}_\theta(\zeta,\zeta)]\big) > C_J a^\sigma (\Lambda_a + u)\Big\} \leq C e^{-u},$$

   and the same bound holds for $\mathsf{H}^\delta_\alpha = \mathsf{X}^\delta_\alpha(P^\delta_\cdot\, \cdot\,)$ with a^α in place of a^σ. In particular, for every fixed $1 \leq p < \infty$, both conditionally at every θ_{j-1} and under ν_K,

$$\|\mathsf{H}^\delta_\sigma(I_a Z_j)\|_p \leq C_{p,J}\big\{g_3^2 a^\sigma (1+j) + g_3^3 a^{1/2} p_j^3\big\},$$
$$\|\mathsf{X}^\delta_\alpha(z_j)\|_p \leq C_{p,J}\big\{g_3^2 a^\alpha (1+j) + g_3^3 a^{1/2} p_j^3\big\}.$$

4. *Let $B_j = x_{j-1}$, with radius $\mathsf{R}_j = \mathsf{R}_a(x_{j-1})$ as in Theorem 26.10. Each of $\mathcal{Q}_\delta(B_j, z_j)$ and $\mathcal{Q}_\delta(z_j, B_j)$ has conditional mean zero given $\mathcal{F}_{j-1}$. Its part that is quadratic in ζ has weighted coefficient bound, in Hilbert–Schmidt and operator norm for Y^δ_α, at most $C_J \mathsf{R}_j g_3^2 a^\alpha$, and its remaining centered part has Y^δ_α norm at most $C_J \mathsf{R}_j g_3^3 a^{1/2} p_j^3$. In particular, on $\{\mathsf{R}_j \le R\}$, each order and their sum satisfy*

$$\mathbb{P}\Big\{ \mathsf{Y}^\delta_\alpha(\mathcal{B}_\delta(B_j, z_j)) > C_J R\big[g_3^2 a^\alpha (\Lambda_a + u) + g_3^3 a^{1/2} p_j^3 \big] \;\Big|\; \mathcal{F}_{j-1} \Big\} \le C e^{-u}.$$

The constants in the coefficient bounds have the dependence stated in Theorem 26.10; the constants in the maximal and L^p bounds may in addition depend on the fixed γ, n, p, and σ. All constants are uniform in $K \ge j$, in the number of preceding averaging steps, in θ_{j-1}, in the dimension, and in a/δ. Here $p_j \le C_\gamma(1+j)$, and the factor $1+j$ absorbs Λ_a at the fixed coarse side n; this does not give uniformity as $n \to \infty$. All norms include the first-difference component at short times. Both expansions of Lemma 26.2 are allowed.

Proof. The proof has five steps: the exact form of Z_j, the coefficient bounds, the maximal inequality for the quadratic part, the remainder and the moments, and the two mixed terms.

Step 1: the exact residual. We take the conditional expectation of the Taylor expansion (26.2); its linear term has expectation zero. Subtracting this conditional expectation, then the linear term, and dividing by a, we obtain

$$Z_j = \frac{g_j^2}{a}\big(\mathsf{B}_\theta(\zeta,\zeta) - \mathbb{E}_\theta \mathsf{B}_\theta(\zeta,\zeta)\big) + \frac{1}{a}\big(R_\theta(\zeta) - \mathbb{E}_\theta R_\theta(\zeta)\big).$$

Since $g_j^2/a = g_3^2$, this is the identity of (1). By (26.9) and $\|\zeta\|_\infty \le 2C_J p_j$, the centered remainder is at most $2C_J g_j^3 p_j^3/a = C_J g_3^3 a^{1/2} p_j^3$.

Step 2: coefficient bounds. We apply the row and column bounds of Theorem 13.10 to the scalar coefficients of B_θ. A fluctuation coordinate on its intermediate lattice contributes its own volume v_λ, and converting the output volume to a^3, we obtain the two bounds of (2); the same holds with μ as the fixed input. The normalization by g_j^2 introduces only the fixed ratios of intermediate couplings, and the coefficients do not depend on the realized value of w_j. Lemma 26.5 now implies the operator bound for pairs and the bounds on the matrices $\mathsf{A}^{(r)}_{t,x}$. The symmetric coefficient matrix represents the same quadratic polynomial, and subtracting the conditional mean changes only its constant term.

Step 3: the maximal inequality for the quadratic part. Let $f_y = \mathsf{B}_\theta(\zeta,\zeta)_y - \mathbb{E}_\theta \mathsf{B}_\theta(\zeta,\zeta)_y$. We first treat short times explicitly, including the first difference. For every $0 < \eta < 3/2$,

by heat contraction and the bound on differences of the cardinal interpolation, we have

$$\sup_{0\le t\le a^2}(t+\delta^2)^{\eta/2}\|P_t^\delta I_a f\|_\infty \le C_\eta a^\eta \max_y |f_y|,$$
$$\sup_{0\le t\le a^2}(t+\delta^2)^{(\eta+1)/2}\|D_\delta P_t^\delta I_a f\|_\infty \le C_\eta a^\eta \max_y |f_y|.$$

In the second line, we commute D_δ with the heat semigroup and use $\|D_\delta I_a f\|_\infty \le Ca^{-1}\max_y|f_y|$. There are only $C(L/a)^3$ scalar entries on the right, and the matrix of each entry has Hilbert–Schmidt and operator norm at most C_J, by its absolute row. For $t \ge a^2$, by (2), the weighted coefficient matrices have norms at most

$$C_{J,q}a^{3/2}(t+a^2)^{(\eta-3/2)/2} \le C_{J,q}a^\eta, \qquad q=0,1,$$

where the weight is $(t+\delta^2)^{\eta/2}$ for the value and $(t+\delta^2)^{(\eta+1)/2}$ for the difference. This proves the bound $C_J a^\eta$ for the weighted coefficient bound, including its first-difference component. By the Hessian bound verified in Lemma 26.1, the quadratic part of Lemma 26.9 applies; taking its union over short-time entries and its net at scale a, we obtain

$$\mathbb{P}_\theta\{\mathsf{H}_\eta^\delta(I_a f) > C_J a^\eta(\Lambda_a + u)\} \le Ce^{-u}.$$

We take $\eta = \sigma$ for the first bound of (3), and $\eta = \alpha$ for the second; in the latter case $\mathsf{H}_\alpha^\delta(I_a f)$ is the same heat expression $\mathsf{X}_\alpha^\delta(P_\cdot^\delta I_a f)$. No restriction on η coming from products is needed for this heat estimate; only the later products require $\alpha+\sigma<1$.

Step 4: the remainder and the moments. Let $e = a^{-1}(R_\theta - \mathbb{E}_\theta R_\theta)$ and $\epsilon_j = C_J g_3^3 a^{1/2} p_j^3$. By the bounds on the cardinal interpolation and on the heat kernel, we have

$$\|P_t^\delta I_a e\|_\infty \le \epsilon_j, \qquad \|D_\delta P_t^\delta I_a e\|_\infty \le C_J \epsilon_j (t+a^2)^{-1/2}.$$

In particular, both $\mathsf{H}_\sigma^\delta(I_a e)$ and $\mathsf{H}_\alpha^\delta(I_a e)$ are at most $C_{J,T,L,\alpha,\sigma}\epsilon_j$. For example, the difference component is bounded by $C\epsilon_j(t+a^2)^{\eta/2}$ after multiplication by its weight, for either $\eta=\sigma$ or $\eta=\alpha$, and the horizon and $a \le L/4$ bound the last factor. Integrating the quadratic tail of Step 3, we obtain the conditional moment bound $C_{p,J}a^\eta(\Lambda_a+p+1)$. Since $\Lambda_{a_j} \le C_{n,B}(1+j)$, combining this with the deterministic bound on the remainder, we find the two conditional L^p bounds of (3). For fixed p, we raise these conditional bounds to the power p and integrate over the law of $\mathcal{F}_{j-1}$ under ν_K; the tower property gives the same bounds under ν_K. This changes neither the law of the coarsest configuration nor the conditional kernels of the finer variables.

Step 5: the mixed terms. We first treat the quadratic part. Let $V_s = P_s^\delta I_a \mathsf{B}_\theta(\zeta,\zeta)$, regarded as a coefficient map from ordered pairs of fluctuation coordinates; its rows and operator norm are bounded by Lemma 26.5. We apply Lemma 26.6 with $F_s = g_3^2 V_s$ and $h = g_3^2 a^{3/2}$;

the background $x_{j-1} = P_\cdot^\delta I_H A_{j-1}$ satisfies its hypotheses with $R = \mathsf{R}_j$. The unweighted value rows and first-difference rows of either order are

$$C_J \mathsf{R}_j g_3^2 a^{3/2} I^a_{3/4}(t) \qquad \text{and} \qquad C_J \mathsf{R}_j g_3^2 a^{3/2} I^a_{5/4}(t),$$

respectively, and after weighting they are at most $C_J \mathsf{R}_j g_3^2 a^\alpha$. Rows indexed by pairs have the Hilbert–Schmidt norms of the corresponding matrices, and symmetrization gives the same bound for the operator norm. Centering the quadratic polynomial at its conditional expectation centers the Duhamel term, because, with the background fixed, the term is a fixed linear function of its initial input.

We prove the bound for the remaining part directly. Let $V_s^e = P_s^\delta I_a e$. By the bounds of Step 4 and the radius of the background, we have, in either order,

$$\|\mathcal{N}_\delta(B_j(s), V_s^e)\|_\infty + \|\mathcal{N}_\delta(V_s^e, B_j(s))\|_\infty \le C_J \mathsf{R}_j \epsilon_j (s + a^2)^{-p_\alpha}.$$

For the value of a Duhamel term, contraction and integration give $C\mathsf{R}_j\epsilon_j(t+\delta^2)^{1-p_\alpha}$. For its first difference, we put the difference on the outer heat kernel and use Lemma 26.4; this gives the bound

$$C_J \mathsf{R}_j \epsilon_j \int_0^t (t - s + \delta^2)^{-1/2} (s + a^2)^{-p_\alpha}\, ds \le C_J \mathsf{R}_j \epsilon_j (t + \delta^2)^{1/2 - p_\alpha}.$$

To check the last inequality, we replace $s + a^2$ by $s + \delta^2$ and split the integral at $t/2$; both exponents are below one, and for $t \le \delta^2$ the length of the interval suffices. The weights of Y_α^δ for the value and the difference leave the same nonnegative power $(t+\delta^2)^{\alpha/2}$. This proves the bound $C_J \mathsf{R}_j \epsilon_j$ for the Y_α^δ norm. The same bound follows from Lemma 24.6 applied on the lattice of mesh $\delta = L/(nB^K)$, with first argument the heat path B_j, bounded in X_α^δ, and second argument the heat evolution of $I_a e$, bounded in H_σ^δ: there $\mathsf{X}_\alpha^\delta(B_j) \le \mathsf{R}_j$, $\mathsf{H}_\sigma^\delta(I_a e) \le C\epsilon_j$ by Step 4, $\alpha + \sigma < 1$, and T is fixed. No hypothesis $\delta \le 1$ is needed there: when $\delta > 1$, the clause of that lemma for coarse meshes applies to the finitely many integers $4 \le nB^K < L$ at this fixed L, and the maximum of its constants over these meshes is an allowed constant.

Conditional on $\mathcal{F}_{j-1}$, the map from Z_j to either Duhamel term is linear, and $\mathbb{E}(Z_j \mid \mathcal{F}_{j-1}) = 0$. Hence the term, including the remaining part, has conditional mean zero. On $\{\mathsf{R}_j \le R\}$, the quadratic part of Lemma 26.9 implies the threshold $R g_3^2 a^\alpha (\Lambda_a + u)$, and the deterministic bound just proved yields the threshold $R g_3^3 a^{1/2} p_j^3$. A union bound over the two orders gives the estimate for each order and for their sum.

Finally, for the expansion at zero, Lemma 26.1 provides the second tensor $\mathsf{B}_\theta^{(0)}$ with the same column bounds, and the remainder $\widetilde{R}_\theta$ of Lemma 26.2 has, after centering, the same deterministic bound. The Schur and mixed-term arguments then apply to this second decomposition. □

26.6 The quadratic Duhamel term of the linear fluctuation

The last estimate of this section concerns $\mathcal{Q}_\delta(s_j, s_j)$. Its centered part is a quadratic form in ζ_j, and its conditional mean is in general not zero. The mean vanishes when the coarser field is the identity, by the invariance of the conditional law under global color rotations; at a nonzero coarser field we bound it by comparing the covariance of the linear reconstruction term with its value at the identity.

Theorem 26.12. *Assume the setting of Section 26.1 and the standing conventions of Section 26.2, and put $a = a_j$ and $r_\theta = \|\theta_{j-1}\|_\infty$. Either expansion of Lemma 26.2 may be used.*

1. *For each translated bracket in the quadratic coefficient $\mathcal{N}_\delta$, and for their sum, the matrix $\mathsf{C}^{(r)}_{s,x}$ of the quadratic form $D^r_\delta \mathcal{N}_\delta(s_j(s), s_j(s))(x)$ in ζ_j satisfies*

$$\|\mathsf{C}^{(r)}_{s,x}\|_{\mathrm{HS}} \vee \|\mathsf{C}^{(r)}_{s,x}\|_{\mathrm{op}} \le C_J g_3^2 a^2 (s + a^2)^{-2-r/2}, \qquad r = 0, 1.$$

   The corresponding matrices $\mathsf{A}^{(r)}_{t,x}$ of $D^r_\delta \mathcal{Q}_\delta(s_j, s_j)(t, x)$ satisfy

$$\|\mathsf{A}^{(r)}_{t,x}\|_{\mathrm{HS}} \vee \|\mathsf{A}^{(r)}_{t,x}\|_{\mathrm{op}} \le C_J g_3^2 \frac{t}{t + a^2}\, a^{3/2} (t + a^2)^{-3/4-r/2}, \qquad r = 0, 1,$$

   and hence the weighted coefficient bound of $\mathcal{Q}_\delta(s_j, s_j)$ for Y^δ_α is $C_J g_3^2 a^{2\alpha-1}$. These coefficients keep the physical factor δ^3 of the heat semigroup and the meshes of the input coordinates; no factor $(a/\delta)^{3/2}$ is lost. Every further fixed difference in space or time needed for the covering at scale a is bounded by a fixed power of a^{-1}, with a constant depending on its order, and with the same factor g_3^2.
2. *Regard the normalized first derivative of the reconstruction as a jointly analytic function of the unscaled coarser field and the coupling-scaled fluctuation inputs $q_{j,i} = g_{j,i} w_i$, before its base point in these inputs is evaluated at the conditional mean. Choose an inner polydisc whose gaps from the fixed larger polydisc are $\eta_\lambda > 0$ in each coordinate, and evaluate the bounds of (1) on the larger polydisc. For every finite multi-index $\mathbf{k}$, the bounds of (1) for the source and Duhamel coefficients hold for the derivatives $\partial^{\mathbf{k}}$, with the additional factor $\mathbf{k}! \prod_\lambda \eta_\lambda^{-k_\lambda}$. If an input coordinate on mesh a_λ is written instead as a lattice potential, or as a normalized fluctuation variable of coupling g_λ, it contributes the factor $a_\lambda^{k_\lambda}$, or $g_\lambda^{k_\lambda}$, respectively, and each difference at the location of that input may cost $2/a_\lambda$. Coordinates of the coarser field use the mesh H, the q coordinates use the mesh of their intermediate scale, and none uses δ. These derivatives are taken with the conditional centering held fixed; they are not derivatives of m_θ or of the conditional law.*
3. *Let Σ_θ be the conditional fluctuation covariance of w_j and $\mathsf{Z}_\theta = E_\theta \Sigma_\theta E_\theta^{\mathsf{T}}$. Then $\|\mathsf{Z}_\theta - \mathsf{Z}_0\|_{\mathrm{op}} \le C_J r_\theta$, and Z_0 is proportional to the identity in the color indices. The conditional*

mean of the Duhamel term satisfies

$$\begin{aligned}\|\mathbb{E}_\theta \mathcal{Q}_\delta(s_j,s_j)(t)\|_\infty &\le C_J g_3^2 r_\theta \frac{t}{t+a^2},\\ \|D_\delta \mathbb{E}_\theta \mathcal{Q}_\delta(s_j,s_j)(t)\|_\infty &\le C_J g_3^2 r_\theta (t+a^2)^{-1/2}\min(1,t/a^2),\\ \mathsf{Y}_\alpha^\delta(\mathbb{E}_\theta \mathcal{Q}_\delta(s_j,s_j)) &\le C_{J,T,\alpha} g_3^2 r_\theta.\end{aligned}$$

These means vanish when the coarser field is the identity, and they are kept when it is not.

4. *For every $u \ge 0$,*

$$\mathbb{P}_\theta\Big\{\mathsf{Y}_\alpha^\delta\big(\mathcal{Q}_\delta(s_j,s_j)-\mathbb{E}_\theta\mathcal{Q}_\delta(s_j,s_j)\big) > C_J g_3^2 a^{2\alpha-1}[\log(2+L/a)+u]\Big\} \le Ce^{-u}.$$

5. *Let $b_0=\rho_0$ and $b_i=\rho_0 a_{\mathrm{cap}}^i + C_J g_3\sqrt{a_i}\,p_i$ for $i\ge 1$ be the deterministic bounds on $\|\theta_i\|_\infty$ on the small-field event, as in Theorem 17.4, with $a_{\mathrm{cap}}\sqrt{B}<1$. Then*

$$\sup_{K\ge j}\mathbb{E}_{\nu_K}\mathsf{Y}_\alpha^\delta(\mathcal{Q}_\delta(s_j,s_j)) \le C_J g_3^2\big\{a_j^{2\alpha-1}(1+j)+b_{j-1}\big\}.$$

The right sides are summable over j, with tails that vanish uniformly in K, and each fixed higher moment satisfies the analogous bound.

The constants in the coefficient and mean bounds depend only on L, T, M, J, α, and the fixed analytic, covariance, and column bounds; they do not depend on the coupling, θ_{j-1}, K, j, the number of preceding averaging steps, or a/δ. The constants in the maximal inequalities may in addition depend on the fixed coupling, the coarse side, and the prescription of the cutoff radii.

The long-time bound in (1) is the main analytic point. Integrating the bound on the source alone would lose the averaging of the outer heat kernel over the cells of the input lattice. Instead, for $u = t-s \ge a^2$, we factor the coefficient matrix through physical space,

$$\ell^2(w) \xrightarrow{D_\delta W_s} L^2_\delta \xrightarrow{M_{D_\delta^r p_u^\delta(x,\cdot)}} L^2_\delta \xrightarrow{W_s^*} \ell^2(w),$$

where M_k denotes multiplication by k and W_s^* is the adjoint with respect to L^2_δ. In the computation of the mean, on the other hand, the covariance enters as the counting matrix Z_θ between counting rows.

Proof. The proof has eight steps: the source matrices, the Duhamel matrices for long and short times, their weighted bounds, higher differences, derivatives in unscaled coordinates, the conditional mean, and the maximal and summability claims.

Step 1: the source matrices. We use the quadratic coefficient of Lemma 24.2 on the same periodic lattice of side $nB^K \geq 4$ and mesh δ as in Lemma 26.6. Set $\lambda = g_j/a = g_3 a^{-1/2}$ and $W_s = P_s^\delta I_a E_\theta$. For one scalar color component of one translated bracket of the ordered source, the coefficient matrix is a fixed finite sum of rank-one matrices

$$\lambda^2 \, l_s \otimes m_s,$$

where l_s is a translated value row of W_s and m_s is a translated first-difference row of W_s. The color coefficients are the structure constants of $\mathfrak{su}(2)$, which correspond to the cross product on $\mathbb{R}^3$. The counting Hilbert–Schmidt norm of $l \otimes m$ is $\|l\|_2 \|m\|_2$. At output order $r = 0, 1$, the product rule distributes a total of $r+1$ differences over the two rows. By Theorem 26.10(1), at each (s, x),

$$\|\mathsf{C}_{s,x}^{(r)}\|_{\mathrm{HS}} \leq C_J \lambda^2 a^3 (s+a^2)^{-3/2-(r+1)/2} = C_J g_3^2 a^2 (s+a^2)^{-2-r/2}.$$

Symmetrization gives the same quadratic polynomial and does not increase this bound, and the operator norm is at most the Hilbert–Schmidt norm. This proves the first bound of (1) for each translated bracket and, by the triangle inequality, for the ordered source, which is their finite sum.

Step 2: long times. Let $u = t - s \geq a^2$, and fix one translated scalar summand. After r output differences on the heat kernel, its coefficient for the outer heat semigroup has the form

$$\lambda^2 W_s^* M_{D_\delta^r p_u^\delta(x,\cdot)} D_\delta W_s,$$

with the fixed translations and color projections inserted in their places. For a multiplier k, expanding in an orthonormal basis of $\ell^2(w)$, we find

$$\|M_k D_\delta W_s\|_{\mathrm{HS}}^2 = \delta^3 \sum_y |k(y)|^2 \|D_\delta W_s(y,\cdot)\|_2^2.$$

Translations and color projections change only the constant. The ideal inequality $\|AB\|_{\mathrm{HS}} \leq \|A\|_{\mathrm{op}} \|B\|_{\mathrm{HS}}$, obtained by summing $\|ABe_i\|^2 \leq \|A\|_{\mathrm{op}}^2 \|Be_i\|^2$ over the basis, implies that

$$\begin{aligned} \|\lambda^2 W_s^* M_{D_\delta^r p_u^\delta} D_\delta W_s\|_{\mathrm{HS}} &\leq C_J \lambda^2 a^{3/2} \, a^{3/2} (s+a^2)^{-5/4} u^{-3/4-r/2} \\ &= C_J g_3^2 a^2 (s+a^2)^{-5/4} u^{-3/4-r/2}. \end{aligned}$$

Here we used the operator norm of W_s from Theorem 26.10(1) and the L_δ^2 bound on the heat kernel from Lemma 26.4. The factor δ^3 is part of the identity, and therefore neither a counting norm over the output lattice nor a factor $(a/\delta)^{3/2}$ occurs.

Step 3: short times. For $0 \le u < a^2$, we commute the output differences onto the source and use heat contraction on the matrix-valued field. By the bound of Step 1, we have

$$\|\mathsf{A}^{(r)}_{u,s,x}\|_{\mathrm{HS}} \vee \|\mathsf{A}^{(r)}_{u,s,x}\|_{\mathrm{op}} \le C_J g_3^2 a^2 (s+a^2)^{-2-r/2},$$

where $\mathsf{A}^{(r)}_{u,s,x}$ is the matrix of the integrand at time s. The differences of the smooth cardinal interpolation up to order two justify this bound also at $s = 0$.

Step 4: integration in time and weights. For $t \le 2a^2$, the source bound and contraction give $C_J g_3^2 t a^{-2-r}$, which is at most a fixed multiple of the claimed bound and retains its factor $t/(t+a^2)$. For $t \ge 2a^2$, we split the integral at $s = t/2$. On the early half, $u \ge t/2 \ge a^2$, and

$$a^2 \int_0^{t/2} (s+a^2)^{-5/4} u^{-3/4-r/2}\, ds \le C a^{3/2} t^{-3/4-r/2},$$

because $\int_0^\infty (s+a^2)^{-5/4}\, ds = 4a^{-1/2}$. On the part of the late half with $u \ge a^2$, the bound is

$$C a^2 t^{-5/4} \int_{a^2}^{t/2} u^{-3/4-r/2}\, du.$$

For $r = 0$ this is at most $C a^2 t^{-1}$, which is at most $C a^{3/2} t^{-3/4}$ since $a^2 \le t$; for $r = 1$ the integral is at most $C a^{-1/2}$, and the bound is $C a^{3/2} t^{-5/4}$. The final interval $u < a^2$ contributes at most $C a^4 t^{-2-r/2}$, which is at most $C a^{3/2} t^{-3/4-r/2}$ for the same reason. Multiplying by g_3^2, and noting that $t/(t+a^2)$ lies between $1/2$ and 1 in this range, we obtain the bound of (1) at all times.

For either component of Y^δ_α, replacing the weight $t + \delta^2$ by the larger $t + a^2$ leaves the power $(t+a^2)^{\alpha-5/4}$ in that bound, and this exponent is negative. The supremum is therefore at most $C_J g_3^2 a^{3/2} (a^2)^{\alpha-5/4} = C_J g_3^2 a^{2\alpha-1}$. The factor $t/(t+a^2)$ remains in the unweighted bound; in particular the Duhamel term vanishes at $t = 0$.

Step 5: higher differences. Every further fixed spatial difference follows by distributing differences in the finite translated products and on the rows of the heat-smoothed interpolation kernel. For a polynomial bound, it suffices to put all outer differences on the smooth source. If the total spatial order is q and the time order is k, the source coefficients are bounded in Hilbert–Schmidt norm by $C_{J,q,k} g_3^2 a^{-2-q-2k}$ on $[0, T]$. The Duhamel coefficients are bounded by T times this bound at time order zero, and their time derivative is the source plus the discrete Laplacian of the Duhamel term. This proves the bounds by fixed powers of a^{-1}, with the factor g_3^2.

Step 6: derivatives in the unscaled coordinates. We use the bounds on the absolute joint Taylor coefficients verified in Lemma 26.1, and we choose the evaluation and larger polydiscs there, with the displayed gaps. Before the conditional mean is substituted,

we regard E as a function of the unscaled coarser field and of the base point q in the coupling-scaled fluctuation inputs. The scalar quadratic coefficient matrices above are holomorphic functions of these variables: they use bilinear transposes, and neither complex conjugation nor a conditional covariance. Repeating the absolute row, Schur, and heat arguments with the coefficient bounds valid on the larger polydisc, we find that the bounds of (1) hold there. For a finite multi-index $\mathbf{k}$, we iterate the Cauchy integral formula on circles of radii η_λ about the evaluation point. For a matrix $A(q)$ in finite dimensions, this gives

$$\partial^{\mathbf{k}} A(q) = \frac{\mathbf{k}!}{(2\pi i)^{|\operatorname{supp}\mathbf{k}|}} \int \cdots \int \frac{A(q+z)\prod_{\lambda\in\operatorname{supp}\mathbf{k}} dz_\lambda}{\prod_{\lambda\in\operatorname{supp}\mathbf{k}} z_\lambda^{k_\lambda+1}}.$$

This identity follows by expanding the power series on slightly smaller circles, integrating term by term, and noting that a nonconstant Fourier monomial integrates to zero over a circle; one then increases the circles to the chosen radii. By the triangle inequality in Hilbert–Schmidt or operator norm, the integral is at most the bound on the larger polydisc times $\mathbf{k}!\prod_\lambda \eta_\lambda^{-k_\lambda}$, and the constants of the heat estimates are unaffected. If the input coordinate is $q_\lambda = a_\lambda A_\lambda$ or $q_\lambda = g_\lambda w_\lambda$, the chain rule gives the factor $a_\lambda^{k_\lambda}$ or $g_\lambda^{k_\lambda}$. For an array at an input location on mesh a_λ, the bound $\|D_{a_\lambda} f\| \le 2a_\lambda^{-1}\|f\|$ gives the possible cost of a difference. Coordinates of the coarser field and the q coordinates keep their own meshes. Only after the differentiation do we evaluate at the real base point given by the conditional mean; this base point and the conditional law are held fixed throughout.

Step 7: the conditional mean. We first treat the expansion at the conditional mean. The covariance comparison is applied to the same conditional fluctuation kernel and reconstruction as in Lemma 26.1. By Theorem 13.10,

$$\|\mathsf{Z}_\theta - \mathsf{Z}_0\|_{\mathrm{op}} = \|E_\theta \Sigma_\theta E_\theta^{\mathsf{T}} - E_0 \Sigma_0 E_0^{\mathsf{T}}\|_{\mathrm{op}} \le C_J r_\theta (1 + t_j p_j^3) \le C_J r_\theta,$$

because the common upper bound on the couplings bounds $t_j p_j^3$, by (26.1). The same conclusion is part of Theorem 17.4. The reference Z_0 is built from the conditional law at the zero coarser field. The blocks of its covariance in the color indices are scalar, and so is the linear coefficient at the zero coarser field. Hence Z_0 is proportional to the identity in the color indices, with all its spatial correlations kept.

Here Z_θ is the counting matrix of Section 26.1, and its operator norm is the counting operator norm. The physical operator $a^3\mathsf{Z}_\theta$ is not inserted between counting rows, and the adjoint in the factorization of Step 2 is a different object.

Let $V_s = P_s^\delta I_a$ be the heat evolution of the cardinal interpolation with identity input. For one bracket and one color component, the expected source is the contraction of two rows of V_s against $\lambda^2\mathsf{Z}_\theta$. The contraction against Z_0 vanishes: its two color indices enter

through δ_{bc}, while the bracket coefficient ϵ_{bcd} is antisymmetric in b and c. This holds for every translation and difference in the quadratic coefficient. Equivalently, the expected vector is fixed by every adjoint color rotation, and such a vector is zero. We subtract this vanishing contraction and use the operator norm of $\mathsf{Z}_\theta - \mathsf{Z}_0$ between the rows of V_s. By Lemma 16.3 with identity input, or by the Schur argument of Lemma 26.5,

$$\|\mathbb{E}_\theta D_\delta^r \mathcal{N}_\delta(s_j(s), s_j(s))\|_\infty \le C_J g_3^2 r_\theta a^2 (s + a^2)^{-2-r/2}, \qquad r = 0, 1.$$

For the value, heat contraction and the exact integral

$$a^2 \int_0^t (s + a^2)^{-2}\, ds = \frac{t}{t + a^2}$$

give the first bound of (3). For the first difference at $t \le a^2$, the differentiated source integrates to $C_J g_3^2 r_\theta t a^{-3}$, which is at most $C_J g_3^2 r_\theta (t + a^2)^{-1/2} (t/a^2)$. For $t \ge a^2$, we split at $s = t/2$. On the early half, we put the difference on the outer heat kernel and use its L^1 bound; the contribution is at most

$$C_J g_3^2 r_\theta t^{-1/2} a^2 \int_0^{t/2} (s + a^2)^{-2}\, ds \le C_J g_3^2 r_\theta t^{-1/2}.$$

On the late half, we put the difference on the source and contract by the heat semigroup, which gives $C_J g_3^2 r_\theta a^2 t (t + a^2)^{-5/2} \le C_J g_3^2 r_\theta t^{-1/2}$. This proves the second bound of (3) in both regimes. The weight of the value has the positive exponent β, and the weight of the difference leaves the bounded power $(t + a^2)^{\alpha - 1/2}$; the fixed horizon and $a \le L/4$ then give the bound on Y_α^δ of the mean.

For the expansion at zero, the same covariance comparison follows from Lemma 26.1: we integrate the derivative of $E_\theta^{(0)}$ in the coarser field along the segment to the zero coarser field, and use the bound on $\Sigma_\theta - \Sigma_0$ of Theorem 13.10. At the zero coarser field, $m_0 = 0$, which implies that the reference covariance and the reference linear tensor are the same for both expansions. The contraction above then implies the same bounds on the mean.

Step 8: maxima and summability. At a fixed coarser field, the Duhamel term is a quadratic polynomial in the centered vector ζ_j. Its matrices are bounded in (1), and its conditional mean in (3). By the Hessian bound verified in Lemma 26.1, Lemma 26.9 applies with $S = C_J g_3^2 a^{2\alpha - 1}$; its proof uses the Duhamel factor at very short times and the polynomial bounds of Step 5 afterwards, and it covers both the value and the first-difference components. We obtain the centered tail (4), with $\Lambda_a = \log(2 + L/a)$.

For each fixed $p \ge 1$, integrating this conditional tail and adding the bound on the mean, we obtain

$$\Big(\mathbb{E}_\theta \mathsf{Y}_\alpha^\delta(\mathcal{Q}_\delta(s_j, s_j))^p\Big)^{1/p} \le C_{p,J} g_3^2 \big\{ a_j^{2\alpha - 1} (\Lambda_{a_j} + p + 1) + r_\theta \big\}.$$

The deterministic bound (26.8), from Lemma 15.10, with $C_J \geq C_{\mathrm{cap},J}$ and with the bound on the coarsest field denoted by ρ_0, implies that $r_\theta \leq b_{j-1}$ on the small-field event; this is the bound used in Theorem 17.4. We integrate the conditional bound on the pth moment over the law of θ_{j-1} under ν_K and use $\Lambda_{a_j} \leq C_{n,B}(1+j)$. For $p = 1$, we obtain the bound of (5), and the same computation gives its versions for fixed higher moments.

Finally, if $c > 0$ and $q \geq 0$, then, since $a_{m+h} = a_m B^{-h}$ and $1 + m + h \leq (1+m)(1+h)$,

$$\sum_{j \geq m} a_j^c (1+j)^q \leq a_m^c (1+m)^q \sum_{h \geq 0} B^{-ch} (1+h)^q < \infty.$$

The last series converges because geometric decay eventually dominates the polynomial factor, and the right side tends to zero as $m \to \infty$. We apply this with $c = 2\alpha - 1 > 0$ and $c = 1/2$, and we sum the geometric sequence $\rho_0 a_{\mathrm{cap}}^{j-1}$ separately; the condition $a_{\mathrm{cap}}\sqrt{B} < 1$ implies $a_{\mathrm{cap}} < 1$. Since $p_j \leq C_\gamma(1+j)$, every tail is summable, uniformly in K. The deterministic majorants do not depend on K or on the coarser field, and therefore the convergence over short scales is uniform in the number of steps, at fixed coupling and coarse side. □

Remark 26.13. The mixed terms with one conditionally centered input have conditional mean zero. The centered part of the contribution $\mathcal{Q}_\delta(s_j, s_j)$ to the quadratic Picard term is summable because $2\alpha - 1 > 0$; its mean is summable because $\|\theta_{j-1}\|_\infty \leq b_{j-1}$.

SECTION 27

Conditional means and propagated fluctuations

This section completes the estimates of Section 26 on the heat evolution of the reconstructed field and its quadratic Picard term under the conditioned Wilson measure. Recall the decomposition of Lemma 26.2,

$$x_j - x_{j-1} = s_j + z_j + r_j + u_j,$$

where s_j is the centered linear fluctuation term, z_j the centered nonlinear heat term, r_j the interpolation defect, and u_j the predictable term. The latter is $u_j = P_\cdot^\delta I_{a_j}[U_j^{\mathrm{cl}} + m_j^{\mathrm{ph}}]$, the heat evolution of the sum of the nonlinear part U_j^{cl} of the zero-fluctuation reconstruction and the conditional mean correction m_j^{ph}. Section 26 proved the fluctuation estimates for s_j and z_j; Section 28 combines them with the estimates proved here to bound all ordered products. Here we treat the terms built only from r_j and u_j. For the quadratic Picard term, these are $\mathcal{B}_\delta(x_{j-1}, r_j)$ and $\mathcal{Q}_\delta(r_j, r_j)$. The products involving u_j are handled in Section 28 by the bilinear estimate of Lemma 24.6, once u_j is bounded in the heat norm H_σ^δ of its initial field; we prove that bound here.

Three ordered terms. Let $H = a_{j-1}$ and $a = a_j$. The coarser field enters both x_{j-1} and r_j linearly: with

$$\mathsf{U} = P_\cdot^\delta I_a \mathsf{P}_j / H, \qquad \mathsf{V} = P_\cdot^\delta (I_a \mathsf{P}_j - I_H \mathsf{E}_H)/H,$$

we have $x_{j-1} = (\mathsf{U} - \mathsf{V})\theta_{j-1}$ and $r_j = \mathsf{V}\theta_{j-1}$. For any bilinear map $\mathcal{N}$,

$$\begin{aligned}
\mathcal{N}(U - V, V) + \mathcal{N}(V, U - V) &= \mathcal{N}(U, V) + \mathcal{N}(V, U) - 2\mathcal{N}(V, V),\\
\mathcal{N}(U, U) - \mathcal{N}(U - V, U - V) &= \mathcal{N}(U, V) + \mathcal{N}(V, U) - \mathcal{N}(V, V).
\end{aligned}$$

Applying these identities with $U = \mathsf{U}\theta_{j-1}$ and $V = \mathsf{V}\theta_{j-1}$, we obtain $\mathcal{B}_\delta(x_{j-1}, r_j) = \mathscr{T}^{UV} + \mathscr{T}^{VU} - 2\mathscr{T}^{VV}$ and $\mathcal{Q}_\delta(r_j, r_j) = \mathscr{T}^{VV}$, where $\mathscr{T}^{UV}$, $\mathscr{T}^{VU}$, and $\mathscr{T}^{VV}$ are the quadratic Duhamel terms of the ordered pairs $(\mathsf{U}\theta_{j-1}, \mathsf{V}\theta_{j-1})$, $(\mathsf{V}\theta_{j-1}, \mathsf{U}\theta_{j-1})$, and $(\mathsf{V}\theta_{j-1}, \mathsf{V}\theta_{j-1})$. Since $\mathcal{N}_\delta$ is not symmetric, the three terms are estimated separately; a bound on their sum would not bound the summands.

Propagation through coarser scales. The coarser field θ_{j-1} depends on the fluctuation variables of all coarser steps. We propagate both inputs back through the linearized reconstructions $\mathsf{L}_{i+1}, \dots, \mathsf{L}_{j-1}$ and telescope over the coarser scales i; each step of the

telescope contributes a conditionally centered term $Z_{j,i}^{\omega}$ and a conditional drift $e_{j,i}^{\omega}$ (see (27.30)). Theorem 27.5 bounds the coefficients and the drifts, Theorem 27.6 bounds and sums the centered terms, and Theorem 27.7 controls the predictable term.

The scaling. The maps between lattices are

$$G \xrightarrow{\mathsf{L}_{j-1}\cdots\mathsf{L}_{i+1}} H \xrightarrow{\mathsf{P}_j} a \xrightarrow{I_a} \delta \qquad \text{and} \qquad H \xrightarrow{I_H} \delta,$$

where $G = a_i$ and each arrow is labeled by its map and points to the mesh of its target. The interpolation defect is the difference of the two branches out of H. Each column of this difference with a fixed input on the lattice of mesh H has total mass zero (Lemma 27.1); after heat evolution for time s this gives the factor $d_H(s) = H(s + H^2)^{-1/2}$. The cancellation must be used at the scale H, before the earlier maps are composed: a first moment measured at the scale G would give the wrong length. Each linearization L_i has absolute row sums and volume-normalized column sums at most $a_{\mathrm{cap}} = C_{\mathrm{CP}}/B$. Dividing by the mesh H of the coarser lattice, we obtain the contraction

$$\frac{a_{\mathrm{cap}}^{2(j-1-i)}}{H} = \frac{q_{\mathrm{anc}}^{j-1-i}}{G}, \qquad q_{\mathrm{anc}} = B a_{\mathrm{cap}}^2 < 1,$$

for a quadratic term propagated from scale i. Finally, the Schur bound in counting norms gives a factor $(G/\delta)^{3/2}$, which cancels against the factor $\delta^{3/2}$ of the ℓ^2 row of the heat kernel on the finest lattice.

Inputs and constants. We use the setting and notation of Sections 26.1 and 26.2, including the conditioned Wilson measure ν_K, the filtration $\mathcal{F}_j$, the normalized fluctuation variables w_j, the norms X_α^δ, Y_α^δ, H_σ^δ, and V_σ^δ of Definition 4.8, and the four terms of Lemma 26.2. Throughout, $1/2 < \alpha < 2/3$, $\beta = \alpha - 1/2$, $0 < \sigma < 1 - \alpha$, and the horizon T is fixed. All heat kernels keep their constant mode, and all estimates concern the whole torus. The inputs are the conditional fluctuation kernel and the bounds on conditional means and covariances of Theorems 13.8 and 13.10; the reconstruction maps and the bounds on their absolute Taylor coefficients of Theorems 15.12 and 15.13; the derivatives of the zero-fluctuation reconstruction and the bounds on reconstructions of Lemmas 17.1 and 17.2 and Theorem 17.4; the interpolation and heat estimates of Lemmas 16.1, 16.3, and 16.4; the quadratic coefficient of Lemma 24.2; and the concentration inequalities of Theorem 5.4. The results are used in Section 28, which assembles the bounds on the linear and quadratic flow data, and in Sections 29 and 34.

We summarize the dependence of the constants in Table 27.1. The bounds on coefficients and on conditional means hold uniformly in the coupling below the common upper bound g_*. The maximal inequalities and the summations use the bound $b_i/g_i \le C_\gamma(1+i)$ on the coarser fields, which holds only at fixed positive coupling.

Estimate	Constants may depend on
Unweighted coefficients and derivatives in w (Lemma 27.1; Theorems 27.5 and 27.7, time-dependent rows)	L, T, M, J, the interpolation function, the analytic domains and column bounds, and the orders of differences
Pointwise conditional means and drifts, unweighted (Lemmas 27.3 and 27.4)	the analytic domains and coefficient bounds, M, J, and the common upper bound g_*
Weighted coefficients and drifts in $\mathsf{Y}^{\delta}_{\alpha}$ (Theorem 27.5)	in addition α and the coarse mesh $a_0 = L/n$
Drifts in $\mathsf{V}^{\delta}_{\sigma}$ (Theorem 27.7)	in addition σ; not on a_0
Maximal inequalities, moments, and summations (Theorems 27.6 and 27.7)	in addition the fixed γ, n, ρ_0, the moment, the exponents, and the prescription of the cutoff radii

Table 27.1. Dependence of constants in Section 27. No constant depends on K, on the scale indices i and j, on the number of preceding averaging steps, on a/δ, or on the values of the coarser fields.

The tools are standard: the weighted Schur test, cancellation for convolution with a signed kernel of mass zero, the logarithmic Sobolev inequality (Gross [103]; Bakry and Émery [8]) and the covariance representation of Helffer and Sjöstrand [110] in the forms proved in Theorem 5.4, the derivative formula for normalized expectations, and union bounds over finite nets. As in Section 26, we control a heat evolution together with its quadratic Picard term following Cao and Chatterjee [42, Section 2.1]; here the estimates are proved from the conditional fluctuation kernels.

27.1 Volume-normalized column sums and the interpolation defect

We use the following norms for matrices between arrays on lattices. Each index u of such an array has a location and a cell volume v_u: the cube of the mesh of its lattice. For a matrix A with entries A_{yu} we set

$$\mathsf{R}(\mathsf{A}) = \sup_{y} \sum_{u} |\mathsf{A}_{yu}|, \qquad \mathsf{C}(\mathsf{A}) = \sup_{u} \frac{v_{\mathrm{out}}}{v_{\mathrm{in}}} \sum_{y} |\mathsf{A}_{yu}|,$$

the absolute row sum and the volume-normalized column sum, where v_{in} and v_{out} are the cell volumes of the input and output lattices. All sums include the finitely many direction and color indices.

Lemma 27.1. *Assume the setting of Section 26.1.*

1. *The norms* R *and* C *are submultiplicative under composition. For a block with fixed input and output volumes,*

$$\|\mathsf{A}\|_{\ell^2_{\mathrm{count}} \to \ell^2_{\mathrm{count}}} \le \sqrt{\mathsf{R}(\mathsf{A})\mathsf{C}(\mathsf{A}) v_{\mathrm{in}}/v_{\mathrm{out}}}.$$

For several types of input or output indices, the column ratio in each summand is replaced by $v_{\mathrm{out}}(y)/v_{\mathrm{in}}(u)$. The operator norm from $\ell^2(v_{\mathrm{in}})$ to $\ell^2(v_{\mathrm{out}})$, the ℓ^2 spaces weighted by the cell volumes, is then at most $\sqrt{\mathsf{RC}}$, and counting norms use the corresponding conversions of volumes for each block. The ratios of volumes within one renormalization group step cost only C_J. For a pointwise product $c_{y;u,v} = \mathsf{A}_{yu}\mathsf{B}_{yv}$ of two matrices, the absolute row sum is at most $\mathsf{R}(\mathsf{A})\mathsf{R}(\mathsf{B})$, and the two column sums with a fixed input are at most $\mathsf{C}(\mathsf{A})\mathsf{R}(\mathsf{B})$ and $\mathsf{R}(\mathsf{A})\mathsf{C}(\mathsf{B})$.

2. *Let $a = a_j$, $H = a_{j-1} = Ba$, $\delta = a_K$, and put*

$$\mathsf{D}_j = I_a\mathsf{P}_j - I_H\mathsf{E}_H, \qquad d_H(s) = H(s+H^2)^{-1/2}.$$

Each column of D_j with a fixed input u on the lattice of mesh H has total physical mass zero, separately in every output direction and color, and first absolute moment at most CH^4 about the location of u:

$$\delta^3\sum_y(\mathsf{D}_j)_{yu} = 0, \qquad \delta^3\sum_y \mathrm{dist}(y,u)|(\mathsf{D}_j)_{yu}| \le CH^4.$$

The matrix D_j and the matrix $I_a|\mathsf{P}_j| + I_H|\mathsf{E}_H|$ of absolute values have bounded absolute row sums and volume-normalized column sums. For every $s \in [0,T]$ and $r = 0,1,2$,

$$(\mathsf{R}+\mathsf{C})(D_\delta^r P_s^\delta \mathsf{D}_j) \le C_r(s+H^2)^{-r/2}d_H(s),$$
$$(\mathsf{R}+\mathsf{C})(D_\delta^r P_s^\delta I_a\mathsf{P}_j) \le C_r(s+H^2)^{-r/2}.$$

The cancellation is used for each column with input on the lattice of mesh H, before any earlier linearization is composed.

3. *Let $\mathsf{L}_i = D_\theta\mathscr{R}_i(0,0)$ be the linearization at the zero field of the zero-fluctuation reconstruction of step i, acting on link logarithms, with $\mathsf{R}(\mathsf{L}_i), \mathsf{C}(\mathsf{L}_i) \le a_{\mathrm{cap}} = \mathsf{C}_{\mathrm{CP}}/B$ and $q_{\mathrm{anc}} = Ba_{\mathrm{cap}}^2 < 1$. For $0 \le i \le j-1$ set $m = j-1-i$, $G = a_i = B^m H$, $\mathsf{T}_{ji} = \mathsf{L}_{j-1}\cdots\mathsf{L}_{i+1}$ (the identity if $i = j-1$), and*

$$\mathsf{U}_s = P_s^\delta I_a\mathsf{P}_j\mathsf{T}_{ji}/H, \qquad \mathsf{V}_s = P_s^\delta\mathsf{D}_j\mathsf{T}_{ji}/H, \qquad \mathfrak{A}_{ji} = C_{\mathrm{CP}}^m/G.$$

If $\|\theta_i\|_\infty \le b_i$, then for $r = 0,1,2$,

$$\|D_\delta^r\mathsf{U}_s\theta_i\|_\infty \le C_r\mathfrak{A}_{ji}b_i(s+H^2)^{-r/2}, \qquad \|D_\delta^r\mathsf{V}_s\theta_i\|_\infty \le C_r\mathfrak{A}_{ji}b_i(s+H^2)^{-r/2}d_H(s).$$

For $i \ge 1$, the derivatives in w_i of $\mathsf{U}_s\theta_i$ and $\mathsf{V}_s\theta_i$, where $\theta_i = \mathscr{R}_i(\theta_{i-1}, w_i)$ is differentiated at the given point w_i of Ω_i, have absolute row sums and volume-normalized column sums bounded by the same expressions with b_i replaced by g_i. In bounds on derivatives, b_i may be any deterministic bound on $\|\theta_i(w)\|_\infty$ valid for every $w \in \Omega_i$ at the fixed coarser field θ_{i-1}; a bound sharper than the global one may be used when it holds on that whole set.

A derivative in the dimensionless input θ_i removes a factor b_i; for an input written as a lattice potential, $\theta_i = Gv_i$, the derivative in v_i acquires the factor G; and a derivative in a normalized fluctuation coordinate $w_{i,\lambda}$ acquires its own coupling $g_{i,\lambda}$. These conversions use the mesh of the input, never δ.

4. *Let $\mathscr{S}_s$ be any one of the three ordered sources*

$$\mathcal{N}_\delta(\mathsf{U}_s\theta_i, \mathsf{V}_s\theta_i), \qquad \mathcal{N}_\delta(\mathsf{V}_s\theta_i, \mathsf{U}_s\theta_i), \qquad \mathcal{N}_\delta(\mathsf{V}_s\theta_i, \mathsf{V}_s\theta_i),$$

or their linear combinations with coefficients $1, 1, -1$ or $1, 1, -2$. Then

$$(\mathsf{R}+\mathsf{C})(D_{w_i}D_\delta\mathscr{S}_s) \le C_J C_{\mathrm{CP}}^{2m} g_i b_i G^{-2}(s+H^2)^{-1} d_H(s).$$

The constants depend on L, T, M, J, the interpolation function, the analytic domains and column bounds, and the order of differences; they do not depend on K, j, i, the number of preceding averaging steps, a/δ, the coupling, or the coarser field. These are estimates on the whole torus.

Proof. Constants C_J may absorb the number of coordinate types and their volume ratios within one renormalization group step, but never a ratio between the mesh G of a coarser scale and the finest mesh. The horizon in every heat estimate of this section is the fixed T. The refinement hypotheses of the cardinal interpolation and of Lemma 17.2 hold because

$$\frac{a_j}{\delta} = B^{K-j} \in \mathbb{N}, \qquad \frac{a_{j-1}}{\delta} = B^{K-j+1} \in \mathbb{N}. \tag{27.1}$$

Every order of differences used below is a nonnegative integer. The coarse side $n \ge 4$ and all finer sides nB^l satisfy the hypotheses on lattice sides of the heat and interpolation estimates, including meshes larger than one.

Step 1: the matrix norms. We write v_z for the cell volume of an intermediate index z. By finite summation, we have

$$\sum_u |(\mathsf{AB})_{yu}| \le \sum_z |\mathsf{A}_{yz}| \sum_u |\mathsf{B}_{zu}|,$$

and

$$\frac{1}{v_u}\sum_y v_y |(\mathsf{AB})_{yu}| \le \sum_z \frac{v_z}{v_u}|\mathsf{B}_{zu}| \Big(\frac{1}{v_z}\sum_y v_y |\mathsf{A}_{yz}|\Big).$$

Taking suprema gives both composition inequalities. For an array f, the Cauchy–Schwarz inequality with weights $|\mathsf{A}_{yu}|$ implies that

$$\sum_y v_y |(\mathsf{A}f)_y|^2 \le \mathsf{R}(\mathsf{A}) \sum_u |f_u|^2 \sum_y v_y |\mathsf{A}_{yu}| \le \mathsf{R}(\mathsf{A})\mathsf{C}(\mathsf{A}) \sum_u v_u |f_u|^2.$$

For fixed input and output volumes, replacing both weighted norms by counting norms introduces exactly the factor $(v_{\mathrm{in}}/v_{\mathrm{out}})^{1/2}$. The same computation gives the assertion for

several types of indices. For $c_{y;u,v} = \mathsf{A}_{yu}\mathsf{B}_{yv}$, summing first over u and v gives the row bound. Fixing u and summing first over v, we obtain

$$\sup_u \frac{v_{\mathrm{out}}}{v_{\mathrm{in}}} \sum_{y,v} |\mathsf{A}_{yu}\mathsf{B}_{yv}| \le \mathsf{C}(\mathsf{A})\mathsf{R}(\mathsf{B}),$$

and fixing v gives the other column bound. The same computation applies to two different types of input indices with their volumes. Fixed translations of either output index are permutations of the output indices, so the proof applies to them with the same norms. A color bracket costs only the norm of a fixed bilinear map on $\mathbb{R}^3$.

Step 2: zero mass of the defect. We apply Lemma 17.2 with coarse mesh H and fine mesh $a = H/B$; its linear reconstruction is P_j of Lemma 26.2. The two interpolations are applied on their own lattices. By Lemma 16.3, after interpolation a column with input on the lattice of mesh a has total physical mass a^3, and a column with input on the lattice of mesh H has mass H^3. The identity for the total mass of the columns of P_j in Lemma 17.2 implies that

$$\delta^3 \sum_y (I_a \mathsf{P}_j - I_H \mathsf{E}_H)_{yu} = 0$$

in every output component, without summing over colors or directions. For an index z on the lattice of mesh a, we use the triangle inequality $\operatorname{dist}(y,u) \le \operatorname{dist}(y,z) + \operatorname{dist}(z,u)$ and the first moment of the column of the cardinal interpolation matrix at z to obtain

$$\delta^3 \sum_y \operatorname{dist}(y,u) |(I_a \mathsf{P}_j)_{yu}| \le C \sum_z a^3 \{a + \operatorname{dist}(z,u)\} |(\mathsf{P}_j)_{zu}| \le C H^4.$$

The term $I_H \mathsf{E}_H$ has the same bound, and periodic distances may be used in each triangle inequality. The rows and volume-normalized columns of Lemma 17.2, together with Step 1, also bound $I_a|\mathsf{P}_j| + I_H|\mathsf{E}_H|$.

Step 3: heat evolution of the defect. The estimate on the finest lattice in Lemma 17.2 gives the bound on the absolute rows of $D_\delta^r P_s^\delta \mathsf{D}_j$. We give a separate argument for the columns. For $s \le H^2$ we commute every difference through the heat semigroup and apply it to the smooth columns of the cardinal interpolation matrix. Their rth differences have volume-normalized column sums at most $C_{J,r} H^{-r}$, since $a = H/B$ with B fixed, and the heat semigroup does not increase absolute column sums. For $s \ge H^2$ we subtract the heat kernel at the location of the input u, which is allowed by the zero mass of the column:

$$(D_\delta^r P_s^\delta \mathsf{D}_j)_{yu} = \delta^3 \sum_z \big\{ D_\delta^r p_s^\delta(y,z) - D_\delta^r p_s^\delta(y,u) \big\} (\mathsf{D}_j)_{zu}.$$

Using a shortest coordinate path from z to u, the telescoping identity along it, and Lemma 16.1, we obtain

$$\delta^3 \sum_y |D_\delta^r p_s^\delta(y,z) - D_\delta^r p_s^\delta(y,u)| \le C_r \operatorname{dist}(z,u) (s + \delta^2)^{-(r+1)/2};$$

the coordinate path has length at most $\sqrt{3}\,\mathrm{dist}(z,u)$ on the torus. Dividing the resulting column bound by the input volume H^3 and using the first moment of Step 2, we obtain $C_r H s^{-(r+1)/2}$, which is comparable to $(s+H^2)^{-r/2} d_H(s)$ in this range. For $r=2$ the proof uses at most three differences of the heat kernel.

For $I_a \mathsf{P}_j$ we use differences of the cardinal interpolation for $s \le H^2$, and differences of the heat kernel for $s \ge H^2$, without subtraction; this proves both of its bounds. Thus the cancellation is used at the scale H; a first moment about a location at the scale G would not suffice.

Step 4: derivatives of the reconstruction at an arbitrary point. The coefficient bounds come from Theorem 15.12, not from the heat estimate of Lemma 16.3. We write $\mathscr{D}_{\mathrm{in}} \Subset \mathscr{D}_{\mathrm{mid}} \Subset \mathscr{D}_{\mathrm{out}}$ for its nested analytic domains, with fixed positive gaps between their radii. The products of coarser fields and free coordinates in Lemma 26.2 lie in $\mathscr{D}_{\mathrm{in}}$ at a fixed positive distance from its boundary, uniformly in the side of the coarser lattice and in the number of preceding averaging steps. On that domain the reconstruction has a bounded absolute coefficient norm, including every volume-normalized column sum with a fixed input. Differentiating its majorant series on a smaller domain, we obtain bounds on the first and second derivatives in the free coordinates and on the fixed mixed derivatives used below. Indeed, a derivative of order k of a monomial of degree l multiplies its majorant by at most l^k times a fixed inverse power of the radius. Since the ratio η of the radii is less than one, $\sup_{l \ge k} l^k \eta^{l-k}$ is finite. The same argument with a fixed input gives the column bounds, without summing over a new output volume. These are absolute coefficient bounds, not bounds on values of a holomorphic map.

The coupling-scaled fluctuation inputs are $q_{i,\lambda} = g_{i,\lambda} w_{i,\lambda}$, and the ratios $g_{i,\lambda}/g_i$ lie in a fixed interval determined by M and J. The chain rule supplies one such coupling for every derivative in w. The resulting coefficients satisfy the hypotheses of Lemma 16.3: a fixed number of types of coordinates, bounded rows and volume-normalized columns, and exponential decay in their own units. In particular, for the normalized derivative of the reconstruction,

$$W_i(w) = D_{w_i} \mathscr{R}_i(\theta_{i-1}, w), \qquad \mathsf{R}(W_i) + \mathsf{C}(W_i) \le C_J g_i. \tag{27.2}$$

Here the coarser field is fixed, and the coefficient is evaluated on the whole cutoff domain Ω_i, within the domain of Lemma 26.2, not only at $w=0$. Equivalently, Lemma 16.3 applies to $g_i^{-1} W_i$, with the ratios of intermediate couplings included. Its fixed mixed derivatives satisfy the same bounds, with the coupling factors of their inputs. The same conclusion can be reached from the mean. The segment from the conditional mean $\mathbb{E}w$ to a point w of the product lies in the product by convexity. Along it, Taylor's formula for the first derivative involves the second derivative in w, whose normalized absolute rows and columns are bounded by the same coefficient norm. Since $\|w - \mathbb{E}w\|_\infty \le 2p_i$, its

contribution to either norm is at most $C_J g_i^2 p_i$; the first derivative at the mean has either norm at most $C_J g_i$; and $g_i p_i$ is bounded by the smallness conditions of Lemma 26.1.

Step 5: the zero-fluctuation reconstruction and composition. By the bounds on the derivatives of the zero-fluctuation reconstruction in Lemma 17.2, with the constant C_{CP} chosen before J, we have

$$\begin{aligned} \|\mathscr{R}_i(\phi,0)\|_\infty &\le a_{\mathrm{cap}}\|\phi\|_\infty, \\ \|\mathscr{R}_i(\phi,0) - \mathsf{L}_i\phi\|_\infty &\le C a_{\mathrm{cap}}\|\phi\|_\infty^2. \end{aligned} \tag{27.3}$$

The first line follows by integrating the first derivative along $s\phi$, $0 \le s \le 1$, and the second from Taylor's formula with integral remainder and the second derivative in the coarser field. Both use the constant chosen before J; it is not enlarged after J is fixed.

By composition, we have $\mathsf{R}(\mathsf{T}_{ji}), \mathsf{C}(\mathsf{T}_{ji}) \le a_{\mathrm{cap}}^m$. The division is by the mesh H of the coarser lattice of step j. Thus

$$\frac{a_{\mathrm{cap}}^m}{H} = \frac{C_{\mathrm{CP}}^m}{G} = \mathfrak{A}_{ji}, \qquad \mathfrak{A}_{ji}^2 H = \frac{q_{\mathrm{anc}}^m}{G} = K_{ji}. \tag{27.4}$$

The bounds of (3) follow from those of Step 3. Replacing the rightmost input by W_i, we obtain the bounds on rows and columns of derivatives in w_i. At a fixed coarser field, a smaller bound b_i is allowed only if it bounds $\theta_i(w)$ at every point w of Ω_i. Differentiating in a dimensionless input removes its bound b_i, the substitution $\theta_i = G v_i$ multiplies that derivative by G, and for a fluctuation coordinate the chain rule supplies its own $g_{i,\lambda}$.

Step 6: one more difference of the source. By Lemma 24.2, it suffices to consider one translated summand $[T_\xi f, T_\zeta D_k^\pm h]$, with (f,h) equal to $(\mathsf{U}_s\theta_i, \mathsf{V}_s\theta_i)$, $(\mathsf{V}_s\theta_i, \mathsf{U}_s\theta_i)$, or $(\mathsf{V}_s\theta_i, \mathsf{V}_s\theta_i)$. For a forward difference D_l, the product rule is

$$D_l[T_\xi f, T_\zeta D_k^\pm h] = [T_\xi D_l f, T_{\zeta+\delta e_l} D_k^\pm h] + [T_\xi f, T_\zeta D_l D_k^\pm h].$$

Its derivative in w_i has four terms, obtained by differentiating either argument of either bracket; their orders of differences are $(1,1)$, $(1,1)$, $(0,2)$, and $(0,2)$. A backward difference is a translated forward difference up to sign, so the same four bounds apply to it. In every term one factor is the deterministic defect or the derivative in w_i of the defect. Multiplying the corresponding bounds of (3), we find

$$C_J \mathfrak{A}_{ji}^2 g_i b_i (s + H^2)^{-1} d_H(s).$$

For the row we use the row of the differentiated factor and the supremum of the other factor; for the column we use the volume-normalized column of that factor and the same supremum. For $\mathscr{S}_s = \mathcal{N}_\delta(\mathsf{V}_s\theta_i, \mathsf{V}_s\theta_i)$ there may be two factors $d_H(s)$; since $d_H(s) \le 1$, we may discard one. The two signed combinations cost at most the sum of the absolute values of their coefficients. Summing over the fixed list of summands proves (4), with the stated dependence of the constants. □

27.2 Time-dependent coefficients and conditional drifts

This section bounds the coefficients of the ordered quadratic terms propagated from scale i, and the conditional drifts in the telescope over scales. We first record an elementary summation, then the properties of the conditional fluctuation kernel that we need, with constants uniform in the coupling, and a bound on conditional means of quadratic functions of the reconstructed field. The main estimate is Theorem 27.5.

An elementary summation

We write $\lambda_q = -\log q_{\mathrm{anc}} / \log B > 0$, so that $q_{\mathrm{anc}} = B^{-\lambda_q}$, and recall that $a_i = a_0 B^{-i}$ with $a_0 = L/n$.

Lemma 27.2. *Let $r > 0$ and $d \geq 0$.*

1. *For every $0 < \zeta < \min(r, \lambda_q)$ there exists C, depending only on r, ζ, λ_q, B, and a_0, such that for all $j \geq 1$,*
$$\sum_{i=0}^{j-1} q_{\mathrm{anc}}^{j-1-i} a_i^r \leq C a_{j-1}^{\zeta}.$$
2. *For every $0 < \eta < \min(r, \lambda_q)$ there exists C, depending only on r, d, η, λ_q, B, and a_0, such that for all $k \geq 1$,*
$$\sum_{j \geq k} (1+j)^d \sum_{i=0}^{j-1} q_{\mathrm{anc}}^{j-1-i} a_i^r \leq C a_k^{\eta}.$$
In particular, the left side is finite and tends to zero as $k \to \infty$.

Proof. Let $0 < \zeta < \min(r, \lambda_q)$ and $m = j - 1 - i$. Since $j - 1 = m + i$,

$$q_{\mathrm{anc}}^m a_i^r = a_0^r B^{-\lambda_q m - r i} = a_0^r B^{-\zeta(j-1)} B^{-(\lambda_q - \zeta)m - (r-\zeta)i}.$$

The two remaining exponents are positive, so the sum over $0 \leq i \leq j-1$ of the last factor is at most $\sum_{m,i \geq 0} B^{-(\lambda_q-\zeta)m-(r-\zeta)i} < \infty$. This gives (1), since $B^{-\zeta(j-1)} = (a_{j-1}/a_0)^{\zeta}$. For (2) we choose ζ strictly between η and $\min(r, \lambda_q)$ and apply (1). Since $\zeta - \eta > 0$, the polynomial factor is absorbed: $(1+j)^d B^{-\zeta(j-1)} \leq C_{d,\zeta-\eta} B^{-\eta(j-1)}$, and summing over $j \geq k$ gives at most $C B^{-\eta k} = C(a_k/a_0)^{\eta}$. Polynomial factors in i or m are bounded by $(1+j)^d$, since $i, m \leq j$. □

The conditional fluctuation kernel

The next lemma collects the properties of the conditional law of w_i given $\mathcal{F}_{i-1}$ that we use. In the notation of the lemma, $\mu_{\mathfrak{d}_i,\phi} = k_{\mathfrak{d}_i}(e^{\phi}, dw)$ is the conditional fluctuation kernel of (4.8) after $\mathfrak{d}_i$ preceding averaging steps, and its mean $\mu_\phi = m_\phi$ is the conditional mean of Section 26.1. For the small-field event of Definition 4.4, all cutoff radii of one

renormalization group step are equal, $p_i = A_{\mathrm{w}} \log(1/t_i) \geq 1$. This is the case treated here; it is a special case of the prescription allowed in Section 26.1. The point of the lemma is that its constants do not depend on the coupling below the common upper bound g_*.

Lemma 27.3. *Assume the setting of Section 26.1. Fix $K \geq 1$ and $1 \leq i \leq K$, and let $\phi = \theta_{i-1}$.*

1. *The conditional law of w_i given $\mathcal{F}_{i-1}$ is the conditional fluctuation kernel $\mu_{\mathfrak{d}_i,\phi}$, $\mathfrak{d}_i = J(K-i)$, with density $Z_\phi^{-1} \mathbf{1}_{\Omega_i} e^{-V_{\mathfrak{d}_i,\phi}}$, and, uniformly in K, i, $\mathfrak{d}_i$, ϕ, and the coupling below g_*,*

$$1 - C t_i p_i > 0, \qquad \frac{C[t_i p_i + t_i^2(1+E_*)]}{(1 - C t_i p_i)^3} \leq \frac{1}{2}, \qquad t_i p_i^3 \leq \varepsilon_{\mathrm{sc}}, \tag{27.5}$$

   where E_* is the fixed upper bound on the weighted analytic coefficient norm of the effective interaction in Theorem 13.8, and $\varepsilon_{\mathrm{sc}}$ is fixed by the construction. The same holds at every point $u\phi$, $0 \leq u \leq 1$, of the segment from the zero field to ϕ, with the same product Ω_i.

2. *The potential is C^2 on a neighborhood of the closed product Ω_i, and*

$$D_w^2 V_{\mathfrak{d}_i,\phi} \geq \tfrac{1}{2} I \quad \text{on } \Omega_i. \tag{27.6}$$

   In particular, the conditional fluctuation covariance Σ_ϕ of w_i satisfies $\|\Sigma_\phi\|_{\mathrm{op}} \leq 2$, and every real function F on Ω_i that is Lipschitz for the Euclidean distance satisfies

$$\log \mathbb{E}_\phi e^{z(F - \mathbb{E}_\phi F)} \leq z^2 \operatorname{Lip}(F)^2 \qquad (z \in \mathbb{R}). \tag{27.7}$$

3. *Let $\mu_\phi = \mathbb{E}_\phi w_i$. Then*

$$\|\mu_\phi\|_\infty \leq C_J t_i \|\phi\|_\infty, \qquad \mu_0 = 0, \qquad \|\Sigma_\phi - \Sigma_0\|_{\mathrm{op}} \leq C_J t_i p_i^3 \|\phi\|_\infty, \qquad \|\Sigma_\phi\|_{\mathrm{op}} \leq 2. \tag{27.8}$$

4. *Let $E_\phi = g_i^{-1} D_w \mathscr{R}_i(\phi, \mu_\phi)$ and $\mathsf{Z}_\phi = E_\phi \Sigma_\phi E_\phi^{\mathsf{T}}$. Then*

$$\|E_\phi\|_{\mathrm{op}} + \|E_0\|_{\mathrm{op}} \leq C_J, \qquad \|E_\phi - E_0\|_{\mathrm{op}} \leq C_J \|\phi\|_\infty, \tag{27.9}$$

   and

$$\|\mathsf{Z}_\phi - \mathsf{Z}_0\|_{\mathrm{op}} \leq C_J (1 + t_i p_i^3) \|\phi\|_\infty \leq C_J \|\phi\|_\infty. \tag{27.10}$$

The constants depend only on the fixed analytic domains and coefficient bounds, M, J, and the common upper bound g_*; they do not depend on the coupling below g_*, on the lattice side, on K, i, $\mathfrak{d}_i$, or on ϕ.

Proof. For fixed K and i, Lemma 26.2 identifies the conditional law of w_i given $\mathcal{F}_{i-1}$ with the conditional fluctuation kernel at the coarser field ϕ, with $\mathfrak{d}_i = J(K-i)$ preceding averaging steps. The side of the coarser lattice of the step is $nB^{i-1} \geq 4$, the coarser field lies in B_r, and the coupling-scaled fluctuation inputs $q_{i,\lambda} = g_{i,\lambda} w_{i,\lambda}$ of every point of Ω_i

lie in the common analytic domain, as checked in the proof of Lemma 26.1. The domain conditions there include those on every intermediate classical background field, on the block averaging constraint, and on the Haar disintegration density, and the condition that the reconstruction of every point of the product lies in D_r. These are the common domains of Lemma 26.2, and Theorems 15.12 and 15.13 preserve them. In particular, the change to the reconstruction maps preserves each ball of fluctuation coordinates, the free logarithmic coordinates, the Haar disintegration density, the triangular determinant, the inherited normalization constant, and the normalizer, and hence the normalized kernel.

The hypotheses of Theorem 13.8 hold on this product. Let $t_i = M^{(J-1)/2} g_i$; the radii are $p_i = A_{\mathrm{w}} \log(1/t_i) \geq 1$, and the ratios of intermediate couplings are included in the reconstruction map. The common upper bound g_* of Lemma 26.2 is also the reduced bound of Theorem 13.10. Hence (27.5) holds uniformly in K, i, $\mathfrak{d}_i$, ϕ, and the coupling below g_*. The last condition is uniform in the coupling: since $t[A_{\mathrm{w}} \log(1/t)]^3 \to 0$ as $t \downarrow 0$, the reduced bound controls it on the whole interval of couplings. Every point $u\phi$ of the segment lies in B_r and satisfies the same product and domain conditions, so the theorem on means and covariances also applies along the segment.

We write the density as $Z_\phi^{-1} \mathbf{1}_{\Omega_i} e^{-V_{\mathfrak{d}_i,\phi}}\, dw$. By Theorem 13.8, the potential is smooth on an open neighborhood of the closed product, and (27.6) holds. The restrictions imposed at coarser scales depend only on the coarser field and cancel in this normalized conditional law, by the same theorem. The product is a finite product of convex balls in $\mathbb{R}^3$, the potential is C^2 on its neighborhood, and the Hessian bound holds on the whole product. These are the hypotheses of Theorem 5.4, with $m = 1/2$, and that theorem implies that $\|\Sigma_\phi\|_{\mathrm{op}} \leq 2$ and (27.7). All later uses of conditional concentration in this section are for this kernel, so their constants do not depend on the dimension, the number of averaging steps, or the coupling.

By Theorem 13.10, which applies by the preceding checks and the preservation of the kernel, we have (27.8). To bound the linear coefficient of the reconstruction map, we write the map as a function $\widehat{F}_i(\phi, q)$ of the coupling-scaled fluctuation inputs. Let $S_i = \mathrm{diag}(g_{i,\lambda}/g_i)$ and $q_\phi = (g_{i,\lambda}\mu_{\phi,\lambda})_\lambda$. Then

$$E_\phi = g_i^{-1} D_w \mathscr{R}_i(\phi, \mu_\phi) = D_q \widehat{F}_i(\phi, q_\phi) S_i, \qquad E_0 = D_q \widehat{F}_i(0,0) S_i,$$

and the norm of S_i is bounded by the fixed ratio of intermediate couplings. The inner domain contains these points and the segments joining them: the conditional mean lies in the convex product, and $u\phi$ lies in the ball of coarser fields. The second derivatives in the free coordinates, and the mixed second derivatives in the coarser field and the free coordinates, have bounded absolute row sums and volume-normalized column sums. This follows from Theorem 15.12 and the computation with majorant series in Step 4 of the proof of Lemma 27.1. Integrating these derivatives along the two segments, we obtain

$$(\mathsf{R} + \mathsf{C})(E_\phi - E_0) \leq C_J(\|\phi\|_\infty + \|q_\phi\|_\infty) \leq C_J(1 + t_i^2)\|\phi\|_\infty,$$

where we used $\|q_\phi\|_\infty \le t_i \|\mu_\phi\|_\infty$. Converting the volumes of the fluctuation coordinates to the output volume uses only fixed ratios within one renormalization group step, so the weighted Schur bound of Lemma 27.1(1) implies (27.9). For $\mathsf{Z}_\phi = E_\phi \Sigma_\phi E_\phi^{\mathsf{T}}$ we expand

$$\mathsf{Z}_\phi - \mathsf{Z}_0 = (E_\phi - E_0)\Sigma_\phi E_\phi^{\mathsf{T}} + E_0(\Sigma_\phi - \Sigma_0)E_\phi^{\mathsf{T}} + E_0\Sigma_0(E_\phi^{\mathsf{T}} - E_0^{\mathsf{T}}). \tag{27.11}$$

By (27.8) and (27.9), the three terms are bounded by $C_J\|\phi\|_\infty$, $C_J t_i p_i^3 \|\phi\|_\infty$, and $C_J\|\phi\|_\infty$, respectively, which gives (27.10). Every constant here comes from the common upper bound on the couplings and from the coefficient bounds of the reconstruction maps; none depends on the coupling. The covariance bound of Theorem 17.4, whose constants may depend on the fixed coupling, is not used. □

Conditional means of quadratic functions

The next lemma bounds the conditional mean of a quadratic function of the reconstructed field without using any spatial decay of its coefficients. This allows us to apply it after heat evolution, which spreads the coefficients over the torus. We say that a quadratic form Q on link logarithms, with values in arrays of $\mathfrak{su}(2)$-valued components, is equivariant if $Q(\mathrm{Ad}_h v, \mathrm{Ad}_h v) = \mathrm{Ad}_h Q(v, v)$ for every constant $h \in \mathrm{SU}(2)$ acting on all color indices.

Lemma 27.4. *Assume the setting of Lemma 27.3. Let Q be an equivariant quadratic form on link logarithms on the lattice of mesh a_i, fix one scalar output component of $Q(v, v)$, and let k_Q be the absolute sum of the coefficients of that component over both inputs. Put $r = \|\phi\|_\infty$ and $c = \mathscr{R}_i(\phi, 0)$. Then*

$$|\mathbb{E}_\phi Q(\theta_i, \theta_i) - Q(c, c)| \le C_J k_Q (g_i^2 r + g_i^3 p_i^3), \tag{27.12}$$

$$|Q(c, c) - Q(\mathsf{L}_i\phi, \mathsf{L}_i\phi)| \le C k_Q a_{\mathrm{cap}}^2 r^3. \tag{27.13}$$

The constants depend only on the fixed coefficient bounds, M, J, and the common upper bound g_*; they do not depend on the coupling below g_*, the lattice side, K, i, or the number of preceding averaging steps.

Proof. The matrix C_Q of the fixed scalar component has nuclear norm at most k_Q, since it is a sum of coordinate matrix units, each of nuclear norm one. Thus, for every matrix C,

$$|Q : C| = |\mathrm{tr}(C_Q C)| \le k_Q \|C\|_{\mathrm{op}}. \tag{27.14}$$

This needs no spatial weight on Q.

Let $\mu = \mathbb{E}_\phi w_i$, $\xi = w_i - \mu$, and $v = \mathscr{R}_i(\phi, \mu)$. Using the bound on the mean in (27.8), the expansion (26.2) of Lemma 26.2, and the bounds (27.2) on the derivatives of the reconstruction, we have

$$\begin{aligned} \theta_i &= v + g_i E_\phi \xi + g_i^2 \mathsf{B}_\phi(\xi, \xi) + R_\phi(\xi), \qquad \|R_\phi\|_\infty \le C_J g_i^3 p_i^3, \\ \|v - c\|_\infty &\le C_J g_i \|\mu\|_\infty \le C_J g_i t_i r \le C_J g_i^2 r, \qquad \|v\|_\infty \le C_J r. \end{aligned} \tag{27.15}$$

The normalized coefficients of E_ϕ and of each output component of B_ϕ have bounded absolute rows. By (27.14) and the bound $\|\Sigma_\phi\|_{\mathrm{op}} \le 2$, which follows from the Poincaré inequality, we obtain

$$\|\mathbb{E}_\phi \mathsf{B}_\phi(\xi,\xi)\|_\infty \le 2C_J. \tag{27.16}$$

We do not need the quadratic mean to vanish at a nonzero coarser field.

We insert (27.15) into both arguments of Q. The terms linear in ξ have mean zero, since ξ is centered under the same law. The term with $g_i E_\phi \xi$ in both arguments has mean exactly $g_i^2 Q : (E_\phi \Sigma_\phi E_\phi^{\mathsf{T}})$. By (27.14) and (27.10), it differs from $g_i^2 Q : \mathsf{Z}_0$ by at most $C_J k_Q g_i^2 r$, uniformly in the coupling. The vector-valued contraction $Q : \mathsf{Z}_0$ vanishes. Indeed, Z_0 is scalar in the color indices, so by equivariance the contraction is a vector fixed by all adjoint rotations; such a vector is zero, since a rotation through π about an axis perpendicular to a nonzero vector changes its sign.

The two terms that pair v with $g_i^2 \mathbb{E}_\phi \mathsf{B}_\phi(\xi,\xi)$ are bounded by $C_J k_Q g_i^2 r$, by (27.16). Replacing $Q(v,v)$ by $Q(c,c)$ costs at most $C_J k_Q g_i^2 r$, since the extra factor r is bounded on the fixed chart. Every remaining term contains R_ϕ, or one argument linear and one quadratic in ξ, or two arguments quadratic in ξ. On the cutoff domain $|\xi| \le 2p_i$ coordinatewise, so these terms are bounded by $C_J k_Q g_i^3 p_i^3$, $C_J k_Q g_i^3 p_i^3$, and $C_J k_Q g_i^4 p_i^4$, respectively; the last is absorbed into the first because $g_i p_i$ is bounded by (27.5). The factors v and $g_i p_i$ in products with R_ϕ are bounded on the same domain. This proves (27.12). For the classical error, by (27.3), we have

$$|Q(c,c) - Q(\mathsf{L}_i\phi, \mathsf{L}_i\phi)| \le k_Q(\|c\|_\infty + \|\mathsf{L}_i\phi\|_\infty)\|c - \mathsf{L}_i\phi\|_\infty \le C k_Q a_{\mathrm{cap}}^2 r^3,$$

which is (27.13). The only quantities involving the cutoff that were absorbed into constants are $g_i p_i$, $g_i t_i / g_i^2 = M^{(J-1)/2}$, and $t_i p_i^3$, all bounded by fixed data as checked in Lemma 27.3. □

Coefficients and drifts of the propagated terms

For $\omega \in \{UV, VU, VV\}$ and $0 \le i \le j-1$ we define the bilinear sources

$$S_s^{UV}(v,z) = \mathcal{N}_\delta(\mathsf{U}_s v, \mathsf{V}_s z), \qquad S_s^{VU}(v,z) = \mathcal{N}_\delta(\mathsf{V}_s v, \mathsf{U}_s z), \qquad S_s^{VV}(v,z) = \mathcal{N}_\delta(\mathsf{V}_s v, \mathsf{V}_s z),$$

with U_s, V_s as in Lemma 27.1(3), and the bilinear Duhamel terms

$$\mathscr{T}_{j,i}^{\omega}(v,z)(t) = \int_0^t P_{t-s}^{\delta} S_s^{\omega}(v,z)\, ds.$$

Taking $z = v$ gives the quadratic terms of the introduction; each argument has a fixed place, and no symmetry of $\mathcal{N}_\delta$ is used. Both arguments are propagated through the same linearizations, so $\mathscr{T}_{j,i-1}^{\omega}(v,v) = \mathscr{T}_{j,i}^{\omega}(\mathsf{L}_i v, \mathsf{L}_i v)$. We write $\mathscr{S}_s$ for any of the sources $S_s^{\omega}(\theta_i, \theta_i)$.

Theorem 27.5. *Assume the setting of Section 26.1 and the notation of Lemma 27.1, with $m = j - 1 - i$ and $G = a_i$. Set*

$$K_{ji} = C_{\mathrm{CP}}^{2m} H/G^2 = q_{\mathrm{anc}}^m/G, \qquad \ell_H(t) = 1 + \log(1 + t/H^2),$$
$$J_H(t) = \int_0^t (t-s)^{-1/2}(s + H^2)^{-1}\, ds.$$

1. *For $1 \le i \le j-1$, the derivative $\mathsf{F}_s = D_{w_i}\mathscr{S}_s$ in w_i, at any point of Ω_i, satisfies*

$$(\mathsf{R} + \mathsf{C})(\mathsf{F}_s) \le C_J K_{ji} g_i b_i (s + H^2)^{-1},$$
$$\|\mathsf{F}_s\|_{\ell^2(w_i)\to\ell^2(\delta)} \le C_J K_{ji} g_i b_i (s + H^2)^{-1}(G/\delta)^{3/2},$$

   where both ℓ^2 norms are counting norms. For $s \ge G^2$, the Euclidean norm of its value row improves to $C_J K_{ji} g_i b_i G^{3/2} s^{-7/4}$; no such improvement is asserted for its volume-normalized column sum.

2. *The rows of the derivatives in w_i of the Duhamel terms satisfy, for $0 \le t \le G^2$,*

$$\sup_x \|D_{w_i}\mathscr{T}^{\omega}_{j,i}(t,x)\|_2 \le C_J K_{ji} g_i b_i \log(1 + t/H^2),$$
$$\sup_x \|D_{w_i} D_\delta \mathscr{T}^{\omega}_{j,i}(t,x)\|_2 \le C_J K_{ji} g_i b_i J_H(t),$$

   and, for $t \ge G^2$ and $r = 0, 1$,

$$\sup_x \|D_{w_i} D_\delta^r \mathscr{T}^{\omega}_{j,i}(t,x)\|_2 \le C_J K_{ji} g_i b_i G^{3/2} t^{-3/4 - r/2} \ell_H(T).$$

   At small times the displayed integrals, which vanish at $t = 0$, are kept; in particular $J_H(t) \le C \min\{\sqrt{t}/H^2, (t + H^2)^{-1/2}\ell_H(t)\}$. The bounds on first differences use the outer heat kernel.

3. *For a quadratic coefficient $c_{y;u,v}$, let R_2 be the supremum over outputs of the absolute sum over both inputs, and, for a coefficient with input mesh G and output mesh h,*

$$\mathsf{C}_2(c) = \max\Big\{\sup_u \frac{h^3}{G^3}\sum_{y,v}|c_{y;u,v}|,\ \sup_v \frac{h^3}{G^3}\sum_{y,u}|c_{y;u,v}|\Big\}$$

   the larger of its two volume-normalized column sums with a fixed input. Here $h = \delta$; for $\mathsf{Q}_{j,i}$ in Theorem 27.7, before interpolation, $h = a_j$. For each ω,

$$(\mathsf{R}_2 + \mathsf{C}_2)(\mathscr{T}^{\omega}_{j,i}(t)) \le C K_{ji} \log(1 + t/H^2),$$
$$(\mathsf{R}_2 + \mathsf{C}_2)(D_\delta \mathscr{T}^{\omega}_{j,i}(t)) \le C K_{ji} J_H(t).$$

   With the weights of $\mathsf{Y}^{\delta}_{\alpha}$, that is, after multiplying the first bound by $(t + \delta^2)^{\beta}$ and the second by $(t + \delta^2)^{\alpha}$, the supremum over $t \le T$ of these coefficient norms is therefore at most

$C_{L,T,\alpha,a_0}(1+j)K_{ji}$; *we call this the weighted coefficient bound. On the whole cutoff domain* Ω_i *we also have, for* $r = 0, 1, 2, 3$,

$$\sup_{w_i,x} \|D_{w_i} D_\delta^r \mathscr{T}_{j,i}^\omega(t,x)\|_2 \le C_{J,r} C_{\mathrm{CP}}^{2m} g_i b_i G^{-2}\, t H^{-1-r},$$

and, for $r = 0, 1$,

$$\sup_{w_i,x} \|D_{w_i} \partial_t D_\delta^r \mathscr{T}_{j,i}^\omega(t,x)\|_2 \le C_{J,r} C_{\mathrm{CP}}^{2m} g_i b_i G^{-2}(H^{-1-r} + tH^{-3-r}).$$

These bounds keep the factor $g_i b_i$, *for later use in coverings.*

4. *Define the conditional drift*

$$e_{j,i}^\omega = \mathbb{E}\big[\mathscr{T}_{j,i}^\omega(\theta_i,\theta_i) \;\big|\; \mathcal{F}_{i-1}\big] - \mathscr{T}_{j,i-1}^\omega(\theta_{i-1},\theta_{i-1}).$$

With the deterministic bounds $b_0 = \rho_0$ *and* $b_i = \rho_0 a_{\mathrm{cap}}^i + C_J g_3 \sqrt{a_i}\, p_i$, $i \ge 1$, *on* $\|\theta_i\|_\infty$,

$$\mathsf{Y}_\alpha^\delta(e_{j,i}^\omega) \le C_J(1+j)\frac{q_{\mathrm{anc}}^{j-1-i}}{a_i}\big\{a_{\mathrm{cap}}^2 b_{i-1}^3 + g_i^2 b_{i-1} + g_i^3 p_i^3\big\},$$

and

$$\mathsf{Y}_\alpha^\delta(\mathscr{T}_{j,0}^\omega(\theta_0,\theta_0)) \le C\rho_0^2(1+j)q_{\mathrm{anc}}^{j-1}/a_0.$$

More precisely, for $\phi = \theta_{i-1}$ *and* $\theta_i^{\mathrm{cl}} = \mathscr{R}_i(\phi, 0)$, *write* $e_{j,i}^\omega = e_{j,i}^{\omega,\mathrm{cl}} + e_{j,i}^{\omega,\mathrm{q}}$, *where the linearization error and the fluctuation correction are*

$$\begin{aligned} e_{j,i}^{\omega,\mathrm{cl}} &= \mathscr{T}_{j,i}^\omega(\theta_i^{\mathrm{cl}},\theta_i^{\mathrm{cl}}) - \mathscr{T}_{j,i-1}^\omega(\phi,\phi),\\ e_{j,i}^{\omega,\mathrm{q}} &= \mathbb{E}\big[\mathscr{T}_{j,i}^\omega(\theta_i,\theta_i) \;\big|\; \mathcal{F}_{i-1}\big] - \mathscr{T}_{j,i}^\omega(\theta_i^{\mathrm{cl}},\theta_i^{\mathrm{cl}}). \end{aligned}$$

Then

$$\begin{aligned} \mathsf{Y}_\alpha^\delta(e_{j,i}^{\omega,\mathrm{cl}}) &\le C_J(1+j)K_{ji}a_{\mathrm{cap}}^2\|\phi\|_\infty^3,\\ \mathsf{Y}_\alpha^\delta(e_{j,i}^{\omega,\mathrm{q}}) &\le C_J(1+j)K_{ji}(g_i^2\|\phi\|_\infty + g_i^3 p_i^3). \end{aligned}$$

Both deterministic majorants have summable tails in j, *uniformly in* K. *When the coarser field is the identity, the vector-valued quadratic mean vanishes by the invariance of the conditional law under global color rotations; at a nonzero coarser field, the variation of the covariance, the nonlinear mean, and the classical Taylor error are all kept.*

The constants in the coefficient and mean bounds do not depend on the coupling, K, j, i, *the number of preceding averaging steps, or* a/δ; *they have the dependence of Lemma 27.1, with* α *added. The weighted coefficient bounds and the weighted bounds on drifts may in addition depend on the fixed coarse mesh* $a_0 = L/n$; *this does not apply to the unweighted time-dependent rows. The constants in the summability statements may depend on the fixed* γ, n, ρ_0, *and the prescription of the cutoff radii.*

Proof. We first prove the deterministic estimates on coefficients and on derivatives in w_i, and then the estimates on drifts, which use Lemmas 27.3 and 27.4. Throughout, K_{ji} is the exact value displayed in the statement.

Step 1: sources and late rows. Combining the bound on pointwise products in Lemma 27.1(1) with part (3) of that lemma without a derivative in w_i, and using (27.4), we find that the bilinear coefficient of the source satisfies

$$(\mathsf{R}_2 + \mathsf{C}_2)(S_s^{\omega}) \le C\mathfrak{A}_{ji}^2 (s + H^2)^{-1/2} d_H(s) = \frac{CK_{ji}}{s + H^2}, \tag{27.17}$$

One argument uses a volume-normalized column and the other a row; hence no factor of the output volume occurs. Differentiating the two arguments in w_i instead, we obtain

$$(\mathsf{R} + \mathsf{C})(\mathsf{F}_s) \le \frac{C_J K_{ji} g_i b_i}{s + H^2}. \tag{27.18}$$

The counting Schur bound of Lemma 27.1(1) then implies the operator bound of (1), with the factor $(G/\delta)^{3/2}$. For several types of fluctuation coordinates, the intermediate volumes are their own cell volumes, and replacing them by G^3 costs only C_J.

For $s \ge G^2$ we split the heat semigroup in either argument into two equal halves. The first half, applied to the derivative in w_i, has row and volume-normalized column at most $C_J \mathfrak{A}_{ji} g_i$; in the argument with the defect, both acquire the factor $d_H(s/2) \le \sqrt{2} d_H(s)$. The second half has counting row norm at most $C\delta^{3/2} s^{-3/4-r/2}$ after r differences, by Lemma 16.1. The Schur bound for the first half implies that

$$\begin{aligned} &\sup_x \|D_{w_i} D_\delta^r \mathsf{U}_s \theta_i(x)\|_2 \le C_{J,r} \mathfrak{A}_{ji} g_i G^{3/2} s^{-3/4-r/2}, \\ &\sup_x \|D_{w_i} D_\delta^r \mathsf{V}_s \theta_i(x)\|_2 \le C_{J,r} \mathfrak{A}_{ji} g_i G^{3/2} s^{-3/4-r/2} d_H(s) \qquad (r = 0, 1), \end{aligned} \tag{27.19}$$

where we used $\delta^{3/2}(G/\delta)^{3/2} = G^{3/2}$. In a translated bracket, the derivative in w_i falls either on the argument without a difference or on the argument with the difference. We use, respectively, the bound of (27.19) with $r = 0$ or $r = 1$, and the complementary deterministic bound of Lemma 27.1(3) for the other argument. Every term keeps one factor d_H. Since $d_H(s) \le Hs^{-1/2}$ and $\mathfrak{A}_{ji}^2 H = K_{ji}$, we find

$$\sup_x \|\mathsf{F}_s(x, \cdot)\|_2 \le C_J K_{ji} g_i b_i G^{3/2} s^{-7/4} \qquad (s \ge G^2). \tag{27.20}$$

For the order VV we use $d_H(s)^2 \le d_H(s)$. These bounds also hold on $G^2/2 \le s \le G^2$ after increasing the constant: on that interval the absolute row in (27.18) is bounded by the right side of (27.20). The heat semigroup conserves the mass of columns, so this argument gives no improvement at late times for the absolute column.

Step 2: the outer heat semigroup at small times. Let $\Lambda = C_J K_{ji} g_i b_i$. By heat contraction and (27.18), we have the value row $\Lambda \int_0^t (s + H^2)^{-1}\, ds = \Lambda \log(1 + t/H^2)$ at every t. For the first difference we use the bound on the outer heat kernel

$$\|D_\delta P_r^\delta\|_{\infty\to\infty} \le C(r + \delta^2)^{-1/2} \le C r^{-1/2} \qquad (r > 0),$$

which gives $C\Lambda J_H(t)$, without differentiating the source; the singularity at $s = t$ is integrable. The substitution $z = \sqrt{t - s}$ yields

$$J_H(t) = \frac{2}{\sqrt{t + H^2}} \operatorname{artanh} \sqrt{\frac{t}{t + H^2}}. \tag{27.21}$$

Bounding $(s + H^2)^{-1}$ by H^{-2}, we find $J_H(t) \le 2\sqrt{t}/H^2$ at all t. For $t \ge H^2$, the identity $2 \operatorname{artanh} z = \log((1 + z)/(1 - z))$ gives $J_H(t) \le C(t + H^2)^{-1/2} \ell_H(t)$; for $t \le H^2$ this bound also follows from $\sqrt{t}/H^2 \le C/H$. This proves the stated minimum, including its vanishing at $t = 0$.

Step 3: late times. For $2G^2 \le t \le T$ we split the Duhamel integral at $t/2$. On the early half we use the counting operator bound of (1) for F_s and the counting row of the heat kernel,

$$\|D_\delta^r P_{t-s}^\delta(x, \cdot)\|_2 \le C_r \delta^{3/2} t^{-3/4 - r/2}, \qquad r = 0, 1;$$

the integral is at most $C\Lambda G^{3/2} t^{-3/4 - r/2} \log(1 + t/H^2)$. On the late half we use (27.20) and the ℓ^1 row of $D_\delta^r P_{t-s}^\delta$; the integral is at most

$$C\Lambda G^{3/2} \int_{t/2}^t (t - s)^{-r/2} s^{-7/4}\, ds \le C\Lambda G^{3/2} t^{-3/4 - r/2}.$$

If $G^2 \le t \le 2G^2$, the bounds of Step 2 give the same result, since $t \asymp G^2$ and $J_H(t) \le C t^{-1/2} \ell_H(T)$. Thus the late estimates of (2) hold from $t = G^2$ on. The constants for the fixed horizon may depend on T/L^2.

Step 4: quadratic coefficients and weights. The outer heat kernel has absolute row and volume-normalized column equal to one, and its first difference has both norms at most $C(t - s)^{-1/2}$. Applying these facts to (27.17), we obtain the two coefficient bounds of (3), with the exact integral profiles. If $t \le H^2$, the weighted sum is at most

$$C K_{ji} \{H^{2\beta} t/H^2 + H^{2\alpha} \sqrt{t}/H^2\} \le C K_{ji} H^{2\alpha - 1}.$$

If $t \ge H^2$, it is at most $C_{T,\alpha} K_{ji} \ell_H(T)$, because both powers of the weights are positive and $\delta \le H$. In the first regime we use $H \le a_0$. Since $H = a_0 B^{-(j-1)}$,

$$\begin{aligned} \ell_H(T) &= 1 + \log\bigl(1 + (T/a_0^2) B^{2(j-1)}\bigr) \\ &\le 1 + \log(1 + T/a_0^2) + 2(j - 1) \log B \\ &\le C_{T, a_0, B}(1 + j), \end{aligned} \tag{27.22}$$

where we used $1 + xB^{2(j-1)} \le (1+x)B^{2(j-1)}$ for $x = T/a_0^2$, since $B^{2(j-1)} \ge 1$. The constant in the weighted coefficient bound may therefore depend on the fixed $a_0 = L/n$. The unweighted bounds on time-dependent coefficients and the bounds on rows of derivatives in w_i keep their stated dependence and their logarithmic profiles.

Step 5: crude bounds for coverings. For any fixed integer $r \ge 0$ we commute the differences through the heat semigroup and apply them to the cardinal interpolations on their own lattices before smoothing. The arguments then satisfy

$$\|D_\delta^r \mathsf{U}_s \theta_i\|_\infty + \|D_\delta^r \mathsf{V}_s \theta_i\|_\infty \le C_{J,r} \mathfrak{A}_{ji} b_i H^{-r},$$

and the rows of their derivatives in w_i have the same bound with b_i replaced by g_i. By the finite product rule, we have, for each fixed r,

$$\begin{aligned} \sup_{w_i,s,x} |D_\delta^r \mathscr{S}_s(x)| &\le C_{J,r} \mathfrak{A}_{ji}^2 b_i^2 H^{-1-r}, \\ \sup_{w_i,s,x} \|D_{w_i} D_\delta^r \mathscr{S}_s(x)\|_2 &\le C_{J,r} \mathfrak{A}_{ji}^2 g_i b_i H^{-1-r}. \end{aligned} \tag{27.23}$$

Heat contraction and integration in time give the factor t for the Duhamel term. For the time derivative we use the exact identity $\partial_t \mathscr{T}(t) = \mathscr{S}_t + \Delta_\delta \mathscr{T}(t)$ in finite dimensions. The Laplacian is a sum of three second differences, which are bounded by (27.23) with two more differences. This proves both crude bounds of (3), uniformly on Ω_i, and avoids a bound of size δ^{-2} for the generator.

Step 6: the drifts. We apply Lemma 27.4 to each output component of $\mathscr{T}_{j,i}^\omega(t)$ and of its first difference. Their deterministic coefficients are fixed before conditioning, they are equivariant, and their absolute sums k_Q are bounded by the unweighted bounds of (3). Conditional integration commutes with finite differences of outputs. With $\phi = \theta_{i-1}$ and $\mathscr{T}_{j,i-1}^\omega(\phi,\phi) = \mathscr{T}_{j,i}^\omega(\mathsf{L}_i\phi, \mathsf{L}_i\phi)$, the weighted coefficient bound of Step 4 implies that

$$\begin{aligned} \mathsf{Y}_\alpha^\delta(e_{j,i}^{\omega,\mathrm{cl}}) &\le C_{J,a_0}(1+j) K_{ji} a_{\mathrm{cap}}^2 \|\phi\|_\infty^3, \\ \mathsf{Y}_\alpha^\delta(e_{j,i}^{\omega,\mathrm{q}}) &\le C_{J,a_0}(1+j) K_{ji} (g_i^2 \|\phi\|_\infty + g_i^3 p_i^3). \end{aligned} \tag{27.24}$$

Here C_{J,a_0} has the deterministic dependence already listed, including a_0 from (27.22); it does not depend on the coupling, K, j, i, the number of averaging steps, or a/δ. In the weighted bounds on drifts in the statement, C_J denotes this constant, while the constants of (27.12) and (27.13) are unchanged. Adding the two bounds and using $\|\phi\|_\infty \le b_{i-1}$, we obtain the bound on $e_{j,i}^\omega$.

The identity $\mathscr{T}_{j,i-1}^\omega(v,v) = \mathscr{T}_{j,i}^\omega(\mathsf{L}_i v, \mathsf{L}_i v)$ holds because $\mathsf{T}_{j,i-1} = \mathsf{T}_{ji}\mathsf{L}_i$ in both arguments. Substituting θ_0, whose norm is at most ρ_0, into the weighted coefficient bound, we obtain the bound on the coarsest term, with the same dependence on a_0. When the

coarser field is the identity, the conditional law at the zero field and the reconstruction are equivariant under global color rotations, so the vector-valued quadratic mean itself vanishes, and not only its contribution from the linear covariance.

Step 7: bounds on the coarser fields and summability. Integrating (27.2) from $w = 0$ to w_i along the segment in the convex product, and using (27.3), we obtain

$$\|\theta_i\|_\infty \le a_{\mathrm{cap}}\|\theta_{i-1}\|_\infty + C_J g_i p_i.$$

Iterating, and using $g_{i-l} = B^{l/2} g_i$ and that the cutoff radii do not decrease with i, we obtain

$$\|\theta_i\|_\infty \le \rho_0 a_{\mathrm{cap}}^i + C_J g_i p_i \sum_{l=0}^{i-1} (a_{\mathrm{cap}}\sqrt{B})^l \le \rho_0 a_{\mathrm{cap}}^i + C_J g_3 \sqrt{a_i}\, p_i,$$

where the geometric series is included in the fixed C_J. For fixed γ and n, we obtain

$$b_i \le C_\gamma (1+i)\sqrt{a_i}, \qquad b_i/g_i \le C_\gamma(1+i), \tag{27.25}$$

because $a_{\mathrm{cap}}^i = (a_i/a_0)^{\kappa_{\mathrm{term}}}$ with $\kappa_{\mathrm{term}} = -\log a_{\mathrm{cap}}/\log B > 1/2$. In particular, the three contributions to the drifts, divided by a_i, satisfy

$$\frac{a_{\mathrm{cap}}^2 b_{i-1}^3 + g_i^2 b_{i-1} + g_i^3 p_i^3}{a_i} \le C_\gamma (1+i)^3 a_i^{1/2}. \tag{27.26}$$

For the first term we use $a_{i-1} = B a_i$; the other two are exactly $g_3^2 b_{i-1}$ and $g_3^3\sqrt{a_i}\, p_i^3$. The double series of majorants of the drifts is bounded by

$$C_\gamma \sum_{i\ge 1}\sum_{m\ge 0} (2+i+m)(1+i)^3 q_{\mathrm{anc}}^m a_i^{1/2},$$

and by Lemma 27.2(2), with $r = 1/2$, its tail over $j = i+1+m \ge k$ is at most $C a_k^\eta$ for some $\eta > 0$, and tends to zero; truncation at any K only decreases it. The majorant of the coarsest terms is summable because $\sum_j (1+j) q_{\mathrm{anc}}^{j-1} < \infty$. This proves the summability statement. Only this summation uses the bound (27.25), which holds at fixed coupling; the constants in the coefficient bounds and in the pointwise bounds on means are uniform in the coupling below g_*. □

27.3 Maximal estimates and ultraviolet tails of the ordered terms

We now bound the conditionally centered terms $Z_{j,i}^\omega$ of the telescope, sum the telescope, and obtain the bounds on $\mathcal{Q}_\delta(r_j, r_j)$ and $\mathcal{B}_\delta(x_{j-1}, r_j)$. The maximal inequality uses a finite net in space and time at the scale H, whose size is a fixed power of H^{-1}, independent of δ. It also uses the bound $b_i/g_i \le C_\gamma(1+i)$ of (27.25), so it holds at fixed positive coupling.

Theorem 27.6. *Assume the setting of Section 26.1 and the notation of Theorem 27.5, and fix $\gamma > 0$, L, n, T, M, J, and the domains before any ultraviolet limit is taken. Put*

$$Z^{\omega}_{j,i} = \mathscr{T}^{\omega}_{j,i}(\theta_i, \theta_i) - \mathbb{E}\big[\mathscr{T}^{\omega}_{j,i}(\theta_i, \theta_i) \mid \mathcal{F}_{i-1}\big], \qquad A_{ji} = K_{ji} g_i b_i G^{2\alpha-1} \ell_H(T).$$

1. *There exist $C_\gamma < \infty$ and a fixed finite exponent c such that, for every $u \geq 0$, every $1 \leq i \leq j-1 \leq K-1$, and each ω separately,*

$$\mathbb{P}\Big\{ \mathsf{Y}^{\delta}_{\alpha}(Z^{\omega}_{j,i}) > C_\gamma A_{ji} \sqrt{\log(2 + L/H) + u} \;\Big|\; \mathcal{F}_{i-1} \Big\} \leq C e^{-u}.$$

   It follows that, for every fixed $0 < p < \infty$,

$$\big\| \mathsf{Y}^{\delta}_{\alpha}(Z^{\omega}_{j,i}) \big\|_{L^p(\cdot \mid \mathcal{F}_{i-1})} \leq C_{\gamma,p} (1+j)^c q_{\mathrm{anc}}^{j-1-i} g_i b_i a_i^{2\alpha-2} \big[\sqrt{\log(2 + L/a_i)} + \sqrt{p} \big].$$

   The proof uses a net in physical space and time at the scale H, with at most a fixed power of H^{-1} points, independently of δ/H; a short initial interval of times is controlled by the factor t of the Duhamel term. The proof uses $b_i/g_i \leq C_\gamma(1+i)$, and no constant uniform in the coupling is asserted.

2. *At $i = j-1$ we have $(\mathsf{U} - \mathsf{V})\theta_{j-1} = x_{j-1}$ and $\mathsf{V}\theta_{j-1} = r_j$, and*

$$\mathcal{B}_\delta(x_{j-1}, r_j) = \mathscr{T}^{UV}_{j,j-1} + \mathscr{T}^{VU}_{j,j-1} - 2\mathscr{T}^{VV}_{j,j-1}, \qquad \mathcal{Q}_\delta(r_j, r_j) = \mathscr{T}^{VV}_{j,j-1},$$

   with θ_{j-1} in both arguments of each term on the right. For the full quadratic difference, $\mathcal{Q}_\delta(x_{j-1} + r_j, x_{j-1} + r_j) - \mathcal{Q}_\delta(x_{j-1}, x_{j-1}) = \mathscr{T}^{UV}_{j,j-1} + \mathscr{T}^{VU}_{j,j-1} - \mathscr{T}^{VV}_{j,j-1}$, so the coefficient of $\mathscr{T}^{VV}_{j,j-1}$ is -1.

3. *For sufficiently large fixed C_γ and c, let*

$$W_j = C_\gamma (1+j)^c \Big\{ \rho_0^2 q_{\mathrm{anc}}^{j-1}/a_0 + \sum_{i=1}^{j-1} q_{\mathrm{anc}}^{j-1-i} \Big[g_i b_i a_i^{2\alpha-2} \sqrt{\log(2 + L/a_i)} + \frac{a_{\mathrm{cap}}^2 b_{i-1}^3 + g_i^2 b_{i-1} + g_i^3 p_i^3}{a_i} \Big] \Big\}.$$

   For each ω separately, $\mathbb{E}_{\nu_K} \mathsf{Y}^{\delta}_{\alpha}(\mathscr{T}^{\omega}_{j,j-1}(\theta_{j-1}, \theta_{j-1})) \leq W_j$, including the coarsest term and all drifts. In particular,

$$\mathbb{E}_{\nu_K} \mathsf{Y}^{\delta}_{\alpha}(\mathcal{Q}_\delta(r_j, r_j)) \leq W_j, \qquad \mathbb{E}_{\nu_K} \mathsf{Y}^{\delta}_{\alpha}(\mathcal{B}_\delta(x_{j-1}, r_j)) \leq 4 W_j.$$

   For every $0 < \eta < \min\{2\alpha - 1, -\log q_{\mathrm{anc}} / \log B\}$ there exists $C_{\gamma,\eta}$ such that $\sum_{j \geq k} W_j \leq C_{\gamma,\eta} a_k^\eta$. By the triangle inequality, the same sum bounds the expected norms of all finite partial sums over $j \geq k$, uniformly in K.

All constants may depend on the fixed coupling, the coarse side, the moment, the exponents, the horizon, and the fixed analytic and column bounds; they do not depend on K, on the number of preceding averaging steps, on i and j, on a/δ, or on the values of the coarser fields. These are estimates on the whole torus.

Proof. Throughout, we use the conditional law and the properties verified in Lemma 27.3; see (27.5), (27.6), and (27.7). The proof has five steps: a pointwise Lipschitz bound, a deterministic net, concentration, the telescope, and the summation.

Step 1: the Lipschitz constant of one evaluation. Let $\Lambda = K_{ji} g_i b_i$. For $t \le H^2$, by the bounds of Theorem 27.5(2) for small times and $\delta \le H$, we have

$$(t+\delta^2)^{\beta} \Lambda \log(1 + t/H^2) + (t+\delta^2)^{\alpha} \Lambda J_H(t) \le C \Lambda H^{2\beta}.$$

For $H^2 \le t \le G^2$, the two terms are at most $C\Lambda t^{\beta} \ell_H(T)$. For $t \ge G^2$, the late bounds, multiplied by their weights, are at most

$$C \Lambda G^{3/2} t^{\alpha - 5/4} \ell_H(T) \le C \Lambda G^{2\alpha - 1} \ell_H(T),$$

since $\alpha < 2/3 < 5/4$ and $t \ge G^2$. These three ranges show that every scalar weighted evaluation, of the value or of a first difference, is Lipschitz in w_i with constant at most $C_J A_{ji}$ on the whole product Ω_i. The sum of the two maxima bounds the norm $\mathsf{Y}_{\alpha}^{\delta}$, at the cost of a factor two. Translations and the finite number of colors and directions cost a fixed factor.

Step 2: a deterministic net. This step uses the bound b_i on the coarser fields rather than a distance between coefficient rows, so its constants depend on the fixed coupling. It suffices to consider $H \le \min(1, \sqrt{T})$; the other levels form a finite set, independent of the number of remaining steps. By (27.23) and heat contraction, the uncentered Duhamel term and its first three differences satisfy

$$\| D_{\delta}^{r} \mathscr{T}(t) \|_{\infty} \le C_{J,r} \mathfrak{A}_{ji}^2 b_i^2 t H^{-1-r}, \qquad 0 \le r \le 3, \tag{27.27}$$

and the corresponding time derivatives for $r = 0, 1$ are bounded by $C_{J,r} \mathfrak{A}_{ji}^2 b_i^2 (H^{-1-r} + tH^{-3-r})$. These bounds are deterministic on the whole product Ω_i. Conditional expectation preserves them, and centering costs a factor two.

For $0 \le t \le H^6$, both weights are bounded by their values at $2H^2$, up to fixed powers of two. The centered weighted term on this interval is at most $C \mathfrak{A}_{ji}^2 b_i^2 H^{6+2\alpha-2}$, and its ratio to A_{ji} is at most

$$C \frac{b_i}{g_i} H^4 (H/G)^{2\alpha - 1} \ell_H(T)^{-1} \le C_{\gamma} (1 + j) H^4, \tag{27.28}$$

by (27.25). The right side tends to zero geometrically in j, uniformly in i and in $j - i$. For all sufficiently fine levels it is less than $1/8$, and enlarging the constant handles the finitely many other levels. This uses the factor t of the Duhamel term, not a bound on a source at time zero.

On $[H^6, T]$ we consider the two scalar processes

$$(t+\delta^2)^{\beta}\big(\mathscr{T} - \mathbb{E}[\mathscr{T} \mid \mathcal{F}_{i-1}]\big)(t,x), \qquad (t+\delta^2)^{\alpha} D_{\delta}\big(\mathscr{T} - \mathbb{E}[\mathscr{T} \mid \mathcal{F}_{i-1}]\big)(t,x).$$

Their Lipschitz constants in physical space follow from one more output difference in (27.27). For their time derivatives we use the bounds following that display and the product rule for the weights. Differentiating a weight costs no power of the mesh: for $\zeta = \beta$ or $\zeta = \alpha$,

$$t(t+\delta^2)^{\zeta-1} \le (t+\delta^2)^{\zeta} \le C_{T,\zeta}.$$

Thus all these Lipschitz constants are bounded by $C_{T,J}\mathfrak{A}_{ji}^2 b_i^2 H^{-4}$. Dividing by A_{ji}, we obtain the bound

$$C_{T,J}\frac{b_i}{g_i} H^{-5} G^{-(2\alpha-1)} \le C_{\gamma}(1+j) H^{-5-(2\alpha-1)} \le C_{\gamma} H^{-7},$$

after enlarging C_{γ}, since $2\alpha - 1 < 1/3$ and $j = O(1 + |\log H|)$ for the fixed sequence of lattices. After another fixed adjustment, these inequalities also hold on the finite set of coarse levels.

We choose a spacing $\varepsilon_H = c_{\gamma} H^{12}$ in physical space and time, with $c_{\gamma} > 0$ small. If $\delta \ge \varepsilon_H$, we take every lattice site; there are at most $C_L \varepsilon_H^{-3}$ of them. If $\delta < \varepsilon_H$, we partition the torus into cubes of side between $\varepsilon_H/2$ and ε_H, and choose one lattice site in each occupied cube. Every lattice site can then be joined to its chosen site by a coordinate lattice path of length at most $C\varepsilon_H$. The bound on physical differences applies along these paths, although the net points need not form a lattice. We add a time net of spacing at most ε_H, including both endpoints. The total number of points is at most

$$C_{\gamma,L,T}(1 + L/\varepsilon_H)^3 (1 + T/\varepsilon_H) \le C_{\gamma,L,T,a_0} H^{-48}. \tag{27.29}$$

After the choice of c_{γ}, the error of interpolation for the centered weighted processes is at most $A_{ji}/8$, and so is the contribution of short times. The finite numbers of components are included in the constant.

Step 3: concentration and conditional moments. Consider an evaluation F at a point of the net. The coarser field is fixed, the domain is the same finite product of balls, and F is a smooth real function that is Lipschitz for the Euclidean distance on a neighborhood of the product. We may apply (27.7) with Lipschitz constant at most $C_J A_{ji}$; Chernoff's inequality with positive and negative z then gives

$$\mathbb{P}\big\{|F - \mathbb{E}[F \mid \mathcal{F}_{i-1}]| > z A_{ji} \;\big|\; \mathcal{F}_{i-1}\big\} \le 2e^{-c_J z^2}.$$

We apply the finite-family clause of Lemma 16.4 with $s = C_J A_{ji}$, $b = 0$, and deterministic error $e \le C A_{ji}$. The logarithm of the number of points is at most $C_{\gamma} \log(2 + L/H)$,

which implies the tail of (1). The moment clause yields all $p \geq 1$, and for $0 < p < 1$ Jensen's inequality gives $\|M\|_p \leq \mathbb{E}M$. The moments in (1) then follow from deterministic comparisons between H, G, and j. By (27.22), $\ell_H(T) \leq C_{T,a_0,B}(1+j)$, and $\log(2+L/H) \leq C(1+j)\log(2+L/G)$. Inserting $K_{ji} = q_{\mathrm{anc}}^{j-1-i}/G$ and absorbing these polynomial factors, we obtain the moment bound of (1) with a fixed finite c independent of K, j, and i. The constant $C_{\gamma,p}$ may absorb $C_{T,a_0,B}$, because L and n are fixed and $a_0 = L/n$.

Step 4: the three orders and the telescope. At $i = j-1$ the product of linearizations is empty, and

$$(\mathsf{U} - \mathsf{V})\theta_{j-1} = H^{-1}P_\cdot^\delta I_H \theta_{j-1} = x_{j-1}, \qquad \mathsf{V}\theta_{j-1} = r_j.$$

For any bilinear map $\mathcal{N}$,

$$\begin{aligned}\mathcal{N}(U-V,V) + \mathcal{N}(V,U-V) &= \mathcal{N}(U,V) + \mathcal{N}(V,U) - 2\mathcal{N}(V,V),\\ \mathcal{N}(U,U) - \mathcal{N}(U-V,U-V) &= \mathcal{N}(U,V) + \mathcal{N}(V,U) - \mathcal{N}(V,V).\end{aligned}$$

Integrating against the same outer heat semigroup gives the identities of (2), including the coefficient -1 for the full difference.

For each order separately, we have the telescoping identity

$$\mathscr{T}^\omega_{j,j-1}(\theta_{j-1},\theta_{j-1}) = \mathscr{T}^\omega_{j,0}(\theta_0,\theta_0) + \sum_{i=1}^{j-1}\big(Z^\omega_{j,i} + e^\omega_{j,i}\big), \tag{27.30}$$

since $Z^\omega_{j,i} + e^\omega_{j,i} = \mathscr{T}^\omega_{j,i}(\theta_i,\theta_i) - \mathscr{T}^\omega_{j,i-1}(\theta_{i-1},\theta_{i-1})$. Each summand uses the conditional expectation $\mathbb{E}_{\nu_K}[\,\cdot \mid \mathcal{F}_{i-1}]$. We take the norm and the expectation, and use the moment bound of (1) with $p = 1$ and the bounds on drifts and on the coarsest term of Theorem 27.5(4). For sufficiently large fixed C_γ and c, we obtain W_j for each order. Here C_γ includes the dependence on a_0 of the weighted bounds on drifts and on the coarsest term. By the identities of (2) and the triangle inequality, we then obtain the bounds W_j and $4W_j$ for $\mathcal{Q}_\delta(r_j,r_j)$ and $\mathcal{B}_\delta(x_{j-1},r_j)$.

Step 5: the tail of the convolution. Let $r_* = 2\alpha - 1 \in (0,1/3)$ and $\lambda_q = -\log q_{\mathrm{anc}}/\log B > 0$. By (27.25), the centered summand of W_j without the factor q_{anc}^m is at most $C_\gamma(1+i)^d a_i^{r_*}$ for a fixed finite d; here $\sqrt{\log(2+L/a_i)} \leq C\sqrt{1+i}$. By (27.26), the summand of the drifts is at most $C_\gamma(1+i)^3 a_i^{1/2}$, and hence also satisfies this weaker bound, after adjusting a constant depending on a_0. The coarsest term is the term $i = 0$, up to a constant depending on a_0. Lemma 27.2(2), with $r = r_*$ and the polynomial factor $(1+j)^{c+d}$, implies that

$$\sum_{j\geq k} W_j \leq C_{\gamma,\eta} a_k^\eta$$

for every $0 < \eta < \min(r_*, \lambda_q)$. For any finite partial sum over $j \geq k$, the triangle inequality bounds its expectation by the corresponding part of this series, uniformly in K. At each

finite K the fields and their differences are continuous in t and have finitely many spatial components, so their suprema are determined by a countable dense set of times and are measurable. This completes the proof, under the conditioned Wilson measure ν_K. □

27.4 The predictable term on the finest lattice

The predictable term of Lemma 26.2 is $u_j = P_\cdot^\delta I_a U_j^0$, with

$$U_j^0 = F_j + H^{-1}\overline{\mathsf{R}}_j(\theta_{j-1}) + m_j^{\mathrm{ph}}, \qquad F_j = H^{-1}\overline{\mathsf{Q}}_j(\theta_{j-1},\theta_{j-1}).$$

In the notation of the introduction, $U_j^{\mathrm{cl}} = F_j + H^{-1}\overline{\mathsf{R}}_j(\theta_{j-1})$ and $U_j^0 = U_j^{\mathrm{cl}} + m_j^{\mathrm{ph}}$. We bound u_j in the norm H_σ^δ of its initial field, which controls both the value and the first difference of the heat evolution. The quadratic part F_j is treated by the same propagation and telescope as in Sections 27.2 and 27.3, now on the lattice of mesh a and without the outer Duhamel integral. The cubic part is bounded deterministically, and the conditional mean correction m_j^{ph} is bounded directly, with an extra factor of the coupling, from the derivative formula for normalized expectations.

Theorem 27.7. *Assume the setting of Section 26.1 and the notation of Theorem 27.5, and let $0 < \sigma < 1 - \alpha$. For $0 \le i \le j-1$ let*

$$\mathsf{Q}_{j,i}(v,z) = H^{-1}\overline{\mathsf{Q}}_j(\mathsf{T}_{ji}v, \mathsf{T}_{ji}z),$$

the quadratic coefficient of F_j propagated from scale i, including the factor $1/H$, on the lattice of mesh $a = a_j$.

1. *The absolute row sum and both volume-normalized column sums with a fixed input of $\mathsf{Q}_{j,i}$ satisfy $(\mathsf{R}_2 + \mathsf{C}_2)(\mathsf{Q}_{j,i}) \le CK_{ji} = Cq_{\mathrm{anc}}^{j-1-i}/a_i$. For $1 \le i \le j-1$ and $G = a_i$, the derivative in w_i after interpolation satisfies*

$$\sup_x \|D_{w_i} P_t^\delta I_a \mathsf{Q}_{j,i}(\theta_i,\theta_i)(x)\|_2 \le C_J K_{ji} g_i b_i \min\{1, G^{3/2}(t+G^2)^{-3/4}\}.$$

   After multiplication by $(t+\delta^2)^{\sigma/2}$ its supremum is at most $C_{T,J}K_{ji}g_i b_i G^\sigma$, for every $0 < \sigma < 3/2$. For every fixed pair of nonnegative integers r, v, the crude bounds

$$\sup_{w_i,t,x} \|D_{w_i}\partial_t^v D_\delta^r P_t^\delta I_a \mathsf{Q}_{j,i}(\theta_i,\theta_i)(x)\|_2 \le C_{J,r,v} K_{ji} g_i b_i a^{-r-2v}$$

   hold. The constant mode of the heat kernel is kept.

2. *For the conditionally centered term $Z_{j,i}^{\mathrm{st}} = \mathsf{Q}_{j,i}(\theta_i,\theta_i) - \mathbb{E}[\mathsf{Q}_{j,i}(\theta_i,\theta_i) \mid \mathcal{F}_{i-1}]$, the conditional logarithmic Sobolev inequality and a net at scale a give, for every $1 \le p < \infty$,*

$$\big\|\mathsf{V}_\sigma^\delta(I_a Z_{j,i}^{\mathrm{st}})\big\|_{L^p(\cdot|\mathcal{F}_{i-1})} \le C_{\gamma,p,J} K_{ji} g_i b_i G^\sigma \big[\sqrt{\log(2 + L/a)} + \sqrt{p}\big].$$

3. *For the conditional drift* $e^{\mathrm{st}}_{j,i} = \mathbb{E}[\mathsf{Q}_{j,i}(\theta_i,\theta_i) \mid \mathcal{F}_{i-1}] - \mathsf{Q}_{j,i-1}(\theta_{i-1},\theta_{i-1})$ *and for the coarsest term,*

$$\mathsf{V}^{\delta}_{\sigma}(I_a e^{\mathrm{st}}_{j,i}) \le C_{T,J}\frac{q_{\mathrm{anc}}^{j-1-i}}{a_i}\big(a_{\mathrm{cap}}^2 b_{i-1}^3 + g_i^2 b_{i-1} + g_i^3 p_i^3\big),$$
$$\mathsf{V}^{\delta}_{\sigma}(I_a \mathsf{Q}_{j,0}(\theta_0,\theta_0)) \le C_{T,J}\rho_0^2 q_{\mathrm{anc}}^{j-1}/a_0.$$

All three contributions to the drift are present. The drift has the same exact splitting into linearization error and fluctuation correction as in Theorem 27.5(4), with the factor $(1+j)K_{ji}$ *there replaced by* $C_{T,J}K_{ji}$ *in the bounds in* $\mathsf{V}^{\delta}_{\sigma}$*. In the bounds on derivatives in* w_i*,* b_i *may be replaced by any bound valid on the whole set* Ω_i *at the fixed coarser field.*

4. *For every array* f *on the lattice of mesh* δ*, including the times* $0 \le t \le \delta^2$*,*

$$\mathsf{H}^{\delta}_{\sigma}(f) \le C_{L,T,\sigma}\mathsf{V}^{\delta}_{\sigma}(f), \qquad \mathsf{X}^{\delta}_{\alpha}(P^{\delta}_{\cdot} f) \le C_{L,T,\alpha,\sigma}\mathsf{H}^{\delta}_{\sigma}(f).$$

5. *The cubic and mean terms of* U_j^0 *satisfy* $\|\overline{\mathsf{R}}_j/H\|_\infty \le C_J b_{j-1}^3/H$ *and* $\|m_j^{\mathrm{ph}}\|_\infty \le C_J g_3^2 b_{j-1}$*. For every* $p \in [1,\infty)$ *and every*

$$0 < \tau < \min\{\sigma, \tfrac{1}{2}, -\log q_{\mathrm{anc}}/\log B\},$$

there exist a finite exponent c *and a constant* $C_{\gamma,p,J,\tau}$ *such that*

$$\sup_{K\ge j}\Big\{\big\|\mathsf{H}^{\delta}_{\sigma}(I_a U_j^0)\big\|_{L^p(\nu_K)} + \big\|\mathsf{X}^{\delta}_{\alpha}(u_j)\big\|_{L^p(\nu_K)}\Big\} \le C_{\gamma,p,J,\tau}(1+j)^c a_{j-1}^{\tau}.$$

In particular,

$$\sup_K \sum_{j=k}^{K} \mathbb{E}_{\nu_K}\mathsf{H}^{\delta}_{\sigma}(I_{a_j}U_j^0) \le C_{\gamma,J,\tau}(1+k)^c a_k^{\tau},$$

and $\mathsf{H}^{\delta}_{\sigma}(I_a U_j^0) \le C_{\gamma,J}(1+j)^c$ *on the small-field event.*

The constants in the bounds on rows and means depend on L*,* T*,* M*,* J*, and the fixed analytic and column bounds; they do not depend on the coupling,* K*,* i*,* j*, the number of preceding averaging steps, or* a/δ*. The constants in the maximal and summed bounds may in addition depend on the fixed* γ*,* n*,* p*,* σ*,* τ*, and the prescription of the cutoff radii. No maximal estimate on regions or uniform in the coupling is asserted.*

Proof. All computations take place on the common lattice of mesh δ, and all uses of conditional concentration are for the kernel of Lemma 27.3. The conditional mean correction is identified below with the nonlinear mean of the reconstruction maps.

Step 1: the propagated quadratic coefficient. The quadratic Taylor coefficient of the zero-fluctuation reconstruction, in the normalization of (26.3), is

$$\overline{\mathsf{Q}}_j(v,z) = \frac{B}{2} D_\theta^2 \mathscr{R}_j(0,0)[v,z],$$

and its coefficient bounds are given by Lemma 17.2. Propagating both arguments through each L_i, we obtain

$$\mathsf{Q}_{j,i}(v,z) = H^{-1}\overline{\mathsf{Q}}_j(\mathsf{T}_{ji}v, \mathsf{T}_{ji}z), \qquad \mathsf{Q}_{j,i-1}(v,z) = \mathsf{Q}_{j,i}(\mathsf{L}_i v, \mathsf{L}_i z).$$

Here $\overline{\mathsf{Q}}_j$ is the symmetric bilinear Taylor coefficient just defined, while the sources of Section 27.2 keep their order. A row acquires the factor a_{cap}^2 at each step. For a column with a fixed input, the argument with the fixed input uses the volume-normalized column of L_i, and the other argument uses its row. The cell volume of the intermediate index then cancels, as in Lemma 27.1(1). Thus

$$(\mathsf{R}_2 + \mathsf{C}_2)(\mathsf{Q}_{j,i}) \le C\frac{a_{\mathrm{cap}}^{2m}}{H} = C\frac{q_{\mathrm{anc}}^{m}}{G} = CK_{ji}. \tag{27.31}$$

The same bound on the propagated coefficient, including its weighted version before heat evolution, is part of Theorem 17.4. Interpolation from the lattice of mesh a by I_a preserves these column bounds, since each column of I_a has physical mass exactly a^3.

Step 2: rows of derivatives and crude bounds. By (27.2), at any point of Ω_i, the derivative in w_i of the two arguments has absolute row and volume-normalized column at most $C_J K_{ji} g_i b_i$. For $t \le G^2$, the absolute row controls the counting ℓ^2 row. For $t \ge G^2$ we split the heat semigroup into two equal halves. For the first half, the Schur bound gives counting operator norm at most $C_J K_{ji} g_i b_i (G/\delta)^{3/2}$, and the second half has counting row norm at most $C\delta^{3/2} t^{-3/4}$. Their product is $C_J K_{ji} g_i b_i G^{3/2} t^{-3/4}$. The bounds for small and for late times give the profile with $t + G^2$ in (1), since this quantity is comparable to G^2 at small times and to t at late times.

For $0 < \sigma < 3/2$, the weighted supremum follows by splitting at G^2. Below that time the weight is at most CG^σ, because $\delta \le G$. Above it the profile gives

$$CG^{3/2} t^{\sigma/2 - 3/4} \le CG^\sigma.$$

For fixed r and v we commute all r differences and the v Laplacians through the heat semigroup and apply them to I_a before smoothing. Using the bound on differences of order $r + 2v$ of the cardinal interpolation and heat contraction, we obtain $C_{J,r,v} K_{ji} g_i b_i a^{-r-2v}$, which proves the crude bounds uniformly on Ω_i.

Step 3: the centered term. We write $Z = Z^{\mathrm{st}}_{j,i}$ and $S_i = K_{ji} g_i b_i G^\sigma$. Since the interpolation is positive and preserves constants, heat contraction gives, for $0 \le t \le a^2$,

$$\sup_{t \le a^2} (t+\delta^2)^{\sigma/2} \| P^\delta_t I_a Z \|_\infty \le C a^\sigma \max_y |Z(y)|, \tag{27.32}$$

where the maximum is over the sites y of the lattice of mesh a. Each scalar output $Z(y)$ is Lipschitz in w_i with constant at most $C_J K_{ji} g_i b_i$. By the conditional logarithmic Sobolev inequality for these finitely many outputs and a union bound over at most $C(L/a)^3$ of them, we control (27.32) at the scale $C_J K_{ji} g_i b_i a^\sigma [\sqrt{\log(2 + L/a)} + \sqrt{u}]$, which is at most the claimed scale since $a \le G$.

On $[a^2, T]$ the uncentered term has deterministic amplitude at most $C K_{ji} b_i^2$, and its interpolation and heat evolution have fixed derivatives in space and time bounded by $C_{J,r,v} K_{ji} b_i^2 a^{-r-2v}$. For $a \le 1$, the weighted process of values has Lipschitz constants in physical space and time at most $C_{T,J} K_{ji} b_i^2 a^{-2}$. For the time derivative of the weight we use $(t+\delta^2)^{\sigma/2-1} \le C_{T,\sigma} a^{-2}$ on this interval. Centering costs a factor two. Dividing these constants by S_i, we find

$$C_{T,J} \frac{b_i}{g_i} a^{-2} G^{-\sigma} \le C_\gamma (1+i) a^{-2-\sigma} \le C_\gamma a^{-4},$$

where we used (27.25), $i \le j$, the fixed sequence of lattices, and $\sigma < 1 - \alpha < 1/2$. A net in space and time of spacing $c_\gamma a^8$ therefore approximates every centered weighted value within $S_i/8$, and it has at most $C_{\gamma,L,T} a^{-32}$ points. To choose lattice sites when this spacing is smaller or larger than δ, we use the two constructions of Step 2 of the proof of Theorem 27.6, with H replaced by a and the exponent 12 by 8. The lengths of coordinate paths and the count follow from the same partition into cubes. If $a^2 > T$, the interval of small times covers all times, and the finitely many levels with $a > 1$ are included in the constant.

By the bounds of Step 2, at each point of the net, the weighted evaluation is Lipschitz in w_i with constant $C_J S_i$. We use the counts of entries on the lattice of mesh a and of the net, and the deterministic errors of interpolation above. The finite-family clause of Lemma 16.4 then implies the tail and the moments of (2). This net uses b_i/g_i, so it holds at fixed coupling. All bounds on rows remain valid with a smaller bound b_i that holds on the whole set Ω_i.

Step 4: the drifts and the coarsest term. The telescoping identity is

$$F_j = \mathrm{Q}_{j,0}(\theta_0, \theta_0) + \sum_{i=1}^{j-1} \big(Z^{\mathrm{st}}_{j,i} + e^{\mathrm{st}}_{j,i} \big). \tag{27.33}$$

Before interpolation, each propagated coefficient belongs to the weighted class of Theorem 17.4. By (27.31), its coefficient norm, including $1/H$, is bounded by $C K_{ji}$; we use

that theorem for its coefficient bound and its telescope. To obtain a constant uniform in the coupling, we instead apply Lemma 27.4 to each scalar output of $\mathsf{Q}_{j,i}$ on the lattice of mesh a, with $k_Q \le CK_{ji}$ and $\phi = \theta_{i-1}$. The propagated coefficients are equivariant under global color rotations, since the zero-fluctuation reconstruction and its linearizations are. The conditional law, the coefficient bounds, and the covariance are those of Lemma 27.3, see (27.5) and (27.10). We obtain

$$\|e^{\mathrm{st}}_{j,i}\|_\infty \le C_J K_{ji}\big(a_{\mathrm{cap}}^2 b_{i-1}^3 + g_i^2 b_{i-1} + g_i^3 p_i^3\big). \tag{27.34}$$

This bounds the whole drift with a constant uniform in the coupling, as in the computation of Theorem 27.5. Applying (27.12) and (27.13) separately gives the splitting into linearization error and fluctuation correction, with all three contributions kept. The output is still on the lattice of mesh a at this step. Using the contraction of the interpolation and of the heat semigroup, together with $\sup_{t\le T}(t+\delta^2)^{\sigma/2} \le C_{L,T,\sigma}$, we obtain the bounds in V^δ_σ of (3). The coarsest term is bounded by substituting $\|\theta_0\|_\infty \le \rho_0$ into (27.31) and applying the same contractions. These bounds do not contain the factor $1+j$ of Theorem 27.5.

Step 5: the first difference, including the smallest times. For every array f on the lattice of mesh δ and $t \ge \delta^2$, we split the heat semigroup at $t/2$ and use Lemma 16.1:

$$\|D_\delta P^\delta_t f\|_\infty \le C(t/2+\delta^2)^{-1/2}\|P^\delta_{t/2} f\|_\infty \le C(t+\delta^2)^{-(\sigma+1)/2}\mathsf{V}^\delta_\sigma(f).$$

For $0 \le t \le \delta^2$, the value term at time zero gives $\|f\|_\infty \le \delta^{-\sigma}\mathsf{V}^\delta_\sigma(f)$, and writing a difference as the difference of two contractions gives

$$\|D_\delta P^\delta_t f\|_\infty \le 2\delta^{-1}\|f\|_\infty \le 2\delta^{-\sigma-1}\mathsf{V}^\delta_\sigma(f).$$

Multiplication by $(t+\delta^2)^{(\sigma+1)/2}$ makes this bound uniform also at $t=0$. Including the value term, we obtain $\mathsf{H}^\delta_\sigma \le C\mathsf{V}^\delta_\sigma$. Since $\alpha > \sigma$, the two components of $\mathsf{X}^\delta_\alpha(P^\delta_\cdot f)$ are those of $\mathsf{H}^\delta_\sigma(f)$ multiplied by $(t+\delta^2)^{(\alpha-\sigma)/2}$, which is at most $[T+(L/4)^2]^{(\alpha-\sigma)/2}$ on the lattices considered. This proves the second comparison of (4), with the stated dependence on L, T, α, and σ. In particular, for a bounded array,

$$\mathsf{H}^\delta_\sigma(f) \le C_{L,T,\sigma}\|f\|_\infty. \tag{27.35}$$

Step 6: the rate of the quadratic part. Applying the conditional and then the unconditional Minkowski inequality to (27.33) for fixed $p \ge 1$, we obtain, with

$$v_i = \frac{a_{\mathrm{cap}}^2 b_{i-1}^3 + g_i^2 b_{i-1} + g_i^3 p_i^3}{a_i},$$

the bound

$$\begin{aligned}\|\mathsf{V}_\sigma^\delta(I_a F_j)\|_{L^p(\nu_K)} \le C_{\gamma,p,J}\Big\{ &\rho_0^2 q_{\mathrm{anc}}^{j-1}/a_0 + \sum_{i=1}^{j-1} q_{\mathrm{anc}}^{j-1-i} v_i \\ &+ \big\{\sqrt{\log(2+L/a)} + \sqrt{p}\big\} \sum_{i=1}^{j-1} q_{\mathrm{anc}}^{j-1-i} g_i b_i a_i^{\sigma-1}\Big\}.\end{aligned} \tag{27.36}$$

The factor in the last sum satisfies

$$g_i b_i a_i^{\sigma-1} \le C_J\big\{g_3\rho_0 a_0^{-\kappa_{\mathrm{term}}} a_i^{\kappa_{\mathrm{term}}+\sigma-1/2} + g_3^2 a_i^\sigma p_i\big\} \le C_\gamma(1+i)a_i^\sigma,$$

since $\kappa_{\mathrm{term}} > 1/2$, and v_i is bounded by (27.26), with rate $a_i^{1/2}$. Also $\log(2+L/a) \le C(1+j)$. For fixed $\tau < \min(\sigma, 1/2, \lambda_q)$ we choose ζ strictly between τ and this minimum, and apply Lemma 27.2(1) with $r = \sigma$ and with $r = 1/2$. The polynomial factors in i are bounded by powers of $1+j$, and the coarsest term is the term $i = 0$. We obtain

$$\sup_{K\ge j} \|\mathsf{H}_\sigma^\delta(I_a F_j)\|_{L^p(\nu_K)} \le C_{\gamma,p,J,\tau}(1+j)^c a_{j-1}^\tau, \tag{27.37}$$

where the comparison of Step 5 has replaced V_σ^δ by H_σ^δ, so the first difference needs no further probability estimate.

Step 7: the cubic term and the conditional mean. The cubic bound follows from the Taylor remainder of the zero-fluctuation reconstruction in Lemma 17.2, normalized as in (26.3):

$$\|\overline{\mathsf{R}}_j/H\|_\infty \le C_J b_{j-1}^3/H \le C_\gamma(1+j)^3 H^{1/2},$$

where the last inequality is (27.25) on the coarser lattice. For the conditional mean correction, we take in Lemma 17.1 the coarse mesh $a_0 = L/n$ and total number K of renormalization group steps. Its numbers of preceding averaging steps are $J(K-j)$, its reconstruction maps are those used here, and its filtration is $\mathcal{F}_j$. Its lattice potentials and zero-fluctuation reconstructions are therefore

$$A_j = a_j^{-1}\theta_j, \qquad C_j = a_j^{-1}\mathscr{R}_j(\theta_{j-1}, 0),$$

and its conditional mean correction $\mathbb{E}[A_j \mid \mathcal{F}_{j-1}] - C_j$ is m_j^{ph} of Lemma 26.2. This identifies the conditional mean correction, including its conditional law.

We prove the uniform bound directly from the derivative formula for normalized expectations, so that no stochastic constant depending on the fixed coarse mesh enters this deterministic bound. Fix $\phi = \theta_{j-1}$, write $r_\phi = \|\phi\|_\infty$, and set

$$\mathscr{G}_\phi(w) = \mathscr{R}_j(\phi, w) - \mathscr{R}_j(\phi, 0).$$

For $0 \le u \le 1$ let $\mathbb{E}_u$, Cov_u denote expectation and covariance under the conditional fluctuation kernel at $u\phi$. The segment of coarser fields and every point of the free coordinates remain in the same domain, as checked in Lemma 27.3, and the product of balls does not change. The bound on the mixed derivative of the potential in Theorem 13.10 and the covariance inequality of Theorem 13.8 apply. The majorant series of the joint Taylor coefficients used in (27.2) gives deterministic envelopes $a_{e,l} \ge 0$ such that, on the whole product and the whole segment, $|\partial_{w_l} \mathscr{G}_{u\phi,e}| \le a_{e,l}$ and $\sum_l a_{e,l} \le C_J t_j$. In particular $\sum_l \|\partial_{w_l} \mathscr{G}_{u\phi,e}\|_{L^2} \le C_J t_j$; this uses the absolute coefficient majorant, rather than an exchange of a supremum with a sum of L^2 norms. The bound on the mixed derivative of the potential is $\sup_l \|\partial_{w_l} \dot{V}_u\|_{L^2} \le C_J t_j r_\phi$, where $\dot{V}_u = \partial_u V_{u\phi}$. The covariance kernel decays exponentially and has a uniformly bounded sum at each index, in the units of the renormalization group step, because the number of fluctuation coordinates in each cell is bounded in terms of J. The covariance inequality then implies that

$$|\mathrm{Cov}_u(\mathscr{G}_{u\phi,e}, \dot{V}_u)| \le C_J t_j^2 r_\phi. \tag{27.38}$$

To see that no volume factor appears, we sum the covariance kernel over its second index first, using the uniform bound on the mixed derivative there, and then sum the absolute row of derivatives at the fixed output e.

The expectation of $\partial_u \mathscr{G}_{u\phi,e}$ has the same bound. Indeed, its series of absolute joint Taylor coefficients has positive degree in the free coordinates, and one insertion of the coarser field costs $C_J r_\phi$. We fix a radius $R_{\mathrm{free}} > 0$ in the free coordinates from the nested domains, with the segment of coarser fields in its inner domain and a fixed positive margin above every cutoff domain. The differentiated coefficient sum at this radius is bounded by $C_J r_\phi$, and $t_j p_j / R_{\mathrm{free}} \le \eta_* < 1$, with a fixed margin. For the term of degree one we use the bound $\|\mathbb{E}_u w\|_\infty \le C_J t_j r_\phi$ of Theorem 13.10; its expectation costs $C_J t_j^2 r_\phi^2$. For degree $k \ge 2$ we put two factors in L^2 and bound the other $k-2$ by the cutoff p_j. The L^2 factors are bounded uniformly: the Poincaré inequality and the bound on the mean give $\mathbb{E}_u |w_l|^2 \le 2 + |\mathbb{E}_u w_l|^2 \le C_J$ for scalar coordinates. After division by the radius of its coefficients, the term of degree k costs at most $C_J t_j^2 R_{\mathrm{free}}^{-2} \eta_*^{k-2}$ times its absolute coefficient mass at R_{free}. Summing this mass, and using the fixed bound on r_ϕ, we obtain

$$|\mathbb{E}_u \partial_u \mathscr{G}_{u\phi,e}| \le C_J t_j^2 r_\phi. \tag{27.39}$$

Repeated coordinates are handled by the same Cauchy–Schwarz inequality for two factors; no independence is used.

The derivative formula for normalized expectations of Theorem 13.10 implies that

$$\frac{d}{du} \mathbb{E}_u \mathscr{G}_{u\phi,e} = \mathbb{E}_u \partial_u \mathscr{G}_{u\phi,e} - \mathrm{Cov}_u(\mathscr{G}_{u\phi,e}, \dot{V}_u).$$

Its hypotheses hold because these maps and their derivatives are continuous on a neighborhood of the fixed compact product, so all difference quotients in finite dimensions

are dominated there. At $u = 0$, the conditional law at the zero coarser field and the reconstruction map are equivariant under global color rotations, so $\mathbb{E}_0 \mathscr{G}_{0,e} = 0$. Integrating (27.38) and (27.39), we obtain the bound on the nonlinear mean of the reconstruction,

$$\|\mathbb{E}_\phi \mathscr{R}_j(\phi, w) - \mathscr{R}_j(\phi, 0)\|_\infty \le C_J t_j^2 \|\phi\|_\infty. \tag{27.40}$$

This is the bound of Theorem 13.10 on the mean of the reconstruction, proved here for the reconstruction maps of this section.

Dividing by the mesh a_j of the reconstructed field keeps the factor of the intermediate scales:

$$\|m_j^{\mathrm{ph}}\|_\infty \le C_J \frac{t_j^2}{a_j} \|\theta_{j-1}\|_\infty = C_J M^{J-1} g_3^2 \|\theta_{j-1}\|_\infty \le C_J g_3^2 b_{j-1}, \tag{27.41}$$

where the last C_J absorbs only the fixed factor M^{J-1}. All constants in this pointwise bound on the mean are uniform in the lattice side, in the number of preceding averaging steps, and in the coupling below g_*. By this bound and (27.25), we have $\|m_j^{\mathrm{ph}}\|_\infty \le C_\gamma (1+j) H^{1/2}$.

Step 8: combination and summation. Contraction of the interpolation and (27.35) bound the contributions of the cubic and mean terms to $\mathsf{H}_\sigma^\delta(I_a U_j^0)$ by $C_\gamma (1+j)^3 H^{1/2}$, pathwise and hence in every L^p. Combining this with (27.37), and using $\tau < 1/2$, we obtain the bound in L^p of $\mathsf{H}_\sigma^\delta(I_a U_j^0)$ in (5). The comparison $\mathsf{X}_\alpha^\delta(P_\cdot^\delta f) \le C \mathsf{H}_\sigma^\delta(f)$ of (4) then implies the bound for u_j under the same law. For the sum we use the bound with $p = 1$ and

$$\sum_{j \ge k} (1+j)^c a_{j-1}^\tau \le B^\tau a_k^\tau (1+k)^c \sum_{l \ge 0} (1+l)^c B^{-\tau l} \le C_{B,\tau,c} (1+k)^c a_k^\tau.$$

The finite sum under ν_K is bounded by this deterministic infinite series, uniformly in K. Finally, by the deterministic bounds on the small-field event, we have

$$\|U_j^0\|_\infty \le C_J \{ b_{j-1}^2 / H + b_{j-1}^3 / H + g_3^2 b_{j-1} \} \le C_\gamma (1+j)^3,$$

and (27.35) gives the pathwise bound of (5). Only the maximal inequalities and the summations use constants depending on the fixed γ and n. □

Remark 27.8. These are the norms needed for the bilinear estimate of Lemma 24.6. If $x = P_\cdot^\delta f$, then x and $u_j = P_\cdot^\delta I_a U_j^0$ are heat evolutions on the same lattice, $\alpha \in (1/2, 2/3)$, and $\sigma \in (0, 1-\alpha)$, so that lemma applies in both orders with the norm H_σ^δ bounded in Theorem 27.7. Its mesh is $\delta = L/(nB^K)$, with integer side $nB^K \ge 4$. If $\delta \le 1$ its clause for the heat semigroup applies, and if $\delta > 1$ its clause for finitely many coarse sides applies, with a constant depending on the fixed L and T.

SECTION 28

Linear and quadratic flow data and convergence of Wilson loops

In this section we prove that the joint law of finitely many flowed Wilson loops under the Wilson measure $\mu_{N_K,\gamma}$ converges along the lattice sides $N_K = n_* B^K$, $B = M^J$, at fixed coupling γ (Theorem 28.2). This is part (1) of Theorem 2.3 along the subsequences of Remark 2.4. The passage to all lattice sides nM^k and the construction of the continuum measure on the trajectory space are carried out in Section 29.

The proof has three steps.

1. *Truncation.* Fix a coarse side n and condition $\mu_{nB^K,\gamma}$ on the small-field event. Under the conditioned Wilson measure the fine field is obtained from the coarse field by a coarse-to-fine reconstruction, one RG step at a time. We compare the linear and quadratic flow data (x, y) of the fine field with those of the finite-scale reconstruction from the first q RG steps, interpolated to the fine lattice. The difference tends to zero in probability as $q \to \infty$, uniformly in K, and the norms of the flow data are tight (Theorem 28.8).
2. *Comparison with smooth flows.* For fixed q the finite-scale reconstruction is a random field on a fixed lattice, with compact support, and its law converges as $K \to \infty$ (Theorem 15.13). Its smooth cardinal interpolant is a smooth initial datum, and the lattice Wilson flow started from it converges to the Yang–Mills heat flow (Lemma 28.4). On bounded sets of flow data, flowed Wilson loops are Lipschitz functions of the flow data, with constants that do not depend on q (Corollary 25.11). We choose first a bound R on the norm of the flow data, then a tolerance η, then q, and finally let $K \to \infty$. This gives convergence of the laws of flowed Wilson loops under the conditioned measure (Theorem 28.1).
3. *Removal of the conditioning.* At a fixed lattice side, conditioning on an event changes the expectation of a bounded function by at most twice the probability of the complement (Lemma 5.5). By Theorem 23.9, the small-field failure probability is bounded uniformly in K by a quantity that tends to zero as the coarse side grows. We let first $K \to \infty$ at a fixed coarse side $n_r = n_* B^r$, and then $r \to \infty$.

The main estimate behind the first step is Lemma 28.5. Each increment d_j of the linear heat evolution is split into four terms (Lemma 26.2): the centered linear fluctuation term s_j, the centered nonlinear heat term z_j, the interpolation defect r_j, and the predictable

term u_j. The increment of the quadratic Picard term consists of a cross term with the previous linear heat evolution and of the sixteen ordered products of these four terms. We bound the expected norm of each ordered product separately, keeping the conditional means of these products, which do not vanish. Since the bilinear Duhamel term is not symmetric, the two orders of each product are treated separately. The stochastic inputs are the estimates of Sections 26 and 27 for the conditional fluctuation kernel. The deterministic inputs are the ordered product inequality Lemma 24.6 and the consistency and stability results of Sections 24 and 25.

The strategy of separating a rough linear evolution from a smoother nonlinear part goes back to Bourgain [32] and to Da Prato and Debussche [63]. Cao and Chatterjee used probabilistic smoothing in this form for the Yang–Mills heat flow with random initial data [42, Section 1.1]. Here the quadratic Picard term is the ordered bilinear Duhamel term of the damped Wilson flow of Section 24, and the stochastic estimates concern the conditioned Wilson measure; no Gaussian hypothesis on the initial data is used. The lattice flow is the Wilson flow of Lüscher [128], in the physical time normalization of Section 2.1.

Section 29 uses Theorems 28.1, 28.2, and 28.8 and the approximation Lemma 28.9 to construct the continuum measure, and Lemma 28.11 to work with the parameters chosen below an arbitrary finite bound on the coupling. Sections 29 and 32 use Lemma 28.4 and the estimates of Lemma 28.10, which are uniform for couplings in a compact subinterval of $(0,\infty)$. Section 34 uses the bounds on the ordered products in Lemma 28.5.

The stochastic truncation estimates are stated at a fixed coarse side and, except in Lemma 28.10, at a fixed coupling. The convergence results for observables concern finitely many Wilson loops. We do not construct a limit of the flow data themselves as random fields, nor a solution map of the flow for rough initial data, and we do not claim a rate of convergence.

Section 28.1 fixes the notation and states the two main theorems. Section 28.2 collects deterministic estimates, including the comparison with smooth flows. Section 28.3 contains the four-term decomposition and the bounds on the ordered products, and Section 28.4 the truncation estimates. The two main theorems are proved in Sections 28.5 and 28.6. Section 28.7 treats compact intervals of couplings and couplings below a finite bound.

28.1 Setting and main results

Standing assumptions. Fix $L > 0$, an odd integer $M \geq 3$, and $0 < \gamma_0 \leq 1$, and let J, $B = M^J$, the tuple Θ of remaining parameters, g_*, and n_0 be as in Theorem 23.2; these are the parameters used in Theorem 23.9. Fix $0 < \gamma \leq \gamma_0$, set $g_3^2 = \gamma / L$, and fix a coarse

side $n \in 4\mathbb{N}$ with $n \geq n_0$. For an integer $K \geq 0$ we set

$$H = L/n, \qquad N = nB^K, \qquad a_j = HB^{-j} \quad (0 \leq j \leq K), \qquad a = a_K, \qquad g_j = g_3\sqrt{a_j}.$$

Thus a_j is the mesh of the lattice of side nB^j, and $g_j^2 = \gamma/(nB^j)$ is its lattice coupling. We work under the conditioned Wilson measure $\nu_{N,n,\gamma} = \mu_{N,\gamma}(\,\cdot \mid S_{N,n,\gamma})$ of Definition 4.4. All fields are defined on the whole torus. Tail indices k, l, m are positive integers, and a sum whose upper limit is smaller than its lower limit is zero.

The coarse-to-fine reconstruction. Let $\widehat{\mathscr{R}}$ be the family of reconstruction maps of Theorem 15.12, and consider its coarse-to-fine disintegration of $\nu_{N,n,\gamma}$ (Lemma 15.10) at the classical depths $J(K-j)$:

$$\widehat{\theta}_j = \widehat{\Phi}_j(\widehat{\theta}_{j-1}, g_{j,\cdot} w_j), \qquad A_j = \widehat{\theta}_j/a_j, \qquad \mathcal{F}_j = \sigma(\widehat{\theta}_0, w_1, \dots, w_j), \qquad 1 \leq j \leq K.$$

Here $\widehat{\theta}_0$ is the link logarithm of the coarse field on Λ_n, in the Borel gauge of Lemma 15.10, so that $\|\widehat{\theta}_0\|_\infty < r$, where r is the radius of the small-link domain B_r. Further, w_j is the vector of normalized fluctuation variables of the jth RG step counted from the coarse side, $g_{j,\cdot}$ are the couplings of the J intermediate scales of this step, $\widehat{\Phi}_j$ is the logarithmic reconstruction map of the family $\widehat{\mathscr{R}}$ for this step, $\widehat{\theta}_j$ is the link logarithm of the reconstructed field on the lattice of side nB^j, and A_j is the corresponding lattice potential on the mesh a_j. In the notation of Section 26.1, $\widehat{\Phi}_j(\theta, g_{j,\cdot} w) = \mathscr{R}_j(\theta, w)$, at the depth $\mathfrak{d}_j = J(K-j)$. Conditionally on $\mathcal{F}_{j-1}$, the law of w_j is the conditional fluctuation kernel (4.8) of the jth RG step at the coarser field $\widehat{\theta}_{j-1}$, including all action, Jacobian, determinant, and effective-interaction factors and the indicator of the fluctuation cutoff domain. This kernel is not Gaussian. All conditional expectations below refer to it, and we write $\bar{w}_j = \mathbb{E}(w_j \mid \mathcal{F}_{j-1})$; this is the conditional mean $m_{\widehat{\theta}_{j-1}}$ of Section 26.1.

Let $t_j = M^{(J-1)/2} g_j$ be the largest coupling of the intermediate scales of the jth RG step, and $p_j = A_{\mathrm{w}} \log(1/t_j) \geq 1$ the corresponding fluctuation cutoff. Let a_{cap} be the contraction factor of the reconstruction amplitude bound of Lemma 15.10, which satisfies $a_{\mathrm{cap}}\sqrt{B} < 1$, and set

$$q_{\mathrm{anc}} = B a_{\mathrm{cap}}^2 < 1, \qquad \lambda_{\mathrm{anc}} = -\log(q_{\mathrm{anc}})/\log B > 0.$$

Interpolation, heat semigroup, and norms. For meshes $a \leq h$ with h/a an integer, $I_{h\to a}$ is the cardinal interpolation from the lattice of mesh h to the lattice of mesh a, recalled in Section 28.2; $I_{a\to a}$ is the identity. The lattice heat semigroup $P_t^a = e^{t\Delta_a}$ acts componentwise and includes the constant mode. For an array f on the lattice of mesh a we write $P_\cdot^a f$ for the heat path $t \mapsto P_t^a f$. Let $\mathcal{N}_a$ be the ordered quadratic coefficient of the damped Wilson flow (Lemma 24.2), and recall the bilinear Duhamel term and its polarization,

$$\mathcal{Q}_a(u,v)(t) = \int_0^t P_{t-s}^a \mathcal{N}_a(u(s), v(s))\, ds, \qquad \mathcal{B}_a(u,v) = \mathcal{Q}_a(u,v) + \mathcal{Q}_a(v,u).$$

The term $\mathcal{Q}_a$ is not symmetric. We fix a horizon $T < \infty$ and exponents

$$1/2 < \alpha = \alpha_{\mathrm{fl}} < 2/3, \quad \beta = \beta_{\mathrm{fl}} = \alpha - 1/2, \quad 0 < \sigma < 1 - \alpha, \quad 0 < \tau < \min\{\sigma, 1/2, \lambda_{\mathrm{anc}}\}.$$

We use the norms of Definition 4.8 on $[0, T]$: with $v_a(t) = t + a^2$,

$$\begin{aligned}
\mathsf{X}^a_\alpha(x) &= \sup_{0\le t\le T} \big\{ v_a(t)^{\alpha/2} \|x(t)\|_\infty + v_a(t)^{(\alpha+1)/2} \|D_a x(t)\|_\infty \big\}, \\
\mathsf{Y}^a_\alpha(y) &= \sup_{0\le t\le T} \big\{ v_a(t)^{\beta} \|y(t)\|_\infty + v_a(t)^{\alpha} \|D_a y(t)\|_\infty \big\}, \\
\mathsf{H}^a_\sigma(f) &= \sup_{0\le t\le T} \big\{ v_a(t)^{\sigma/2} \|P^a_t f\|_\infty + v_a(t)^{(\sigma+1)/2} \|D_a P^a_t f\|_\infty \big\},
\end{aligned}$$

where D_a runs over all physical forward and backward first differences, applied also to the translated components that occur in $\mathcal{N}_a$; $\mathsf{V}^a_\sigma(f)$ is the first term of $\mathsf{H}^a_\sigma(f)$. The linear and quadratic flow data of the reconstructed field at level j, on the fine mesh a, are

$$x_j = P^a_\cdot I_{a_j \to a} A_j, \qquad y_j = \mathcal{Q}_a(x_j, x_j), \qquad \text{and we set} \qquad d_j = x_j - x_{j-1}.$$

Thus x_K is the linear heat evolution of the fine field A_K, and y_K is its quadratic Picard term. For $j < K$, the pair (x_j, y_j) is the flow data of the finite-scale reconstruction A_j, interpolated to the fine mesh. The norm of a pair is $\|(x,y)\|_{\mathrm{fl},a} = \mathsf{X}^a_\alpha(x) + \mathsf{Y}^a_\alpha(y)$, as in Definition 24.3.

By Theorem 15.13, for each fixed q the law of the array A_q under $\nu_{nB^K,n,\gamma}$ converges weakly as $K \to \infty$, and these arrays take values in a fixed compact set. We denote the limit law by π_q.

Dependence of constants. Unless stated otherwise, the constants in the stochastic estimates of this section depend only on L, n, γ, M, J, Θ, T, the exponents, and the moment orders. They do not depend on K, on the level j, on the classical depth $J(K-j)$, or on the ratio a/a_j. The letter $b < \infty$ denotes an exponent with the same dependence, which may increase finitely many times; in a displayed estimate we may replace finitely many such exponents by their maximum. This is the dependence described in item (7) of Definition 4.14. None of the stochastic estimates of this section is claimed to be uniform as $\gamma \to 0$ or as $n \to \infty$.

Wilson loops. Let $\ell_1, \dots, \ell_m$ be piecewise C^1 loops in $\mathbb{T}^3_L$, let $\chi_1, \dots, \chi_m$ be characters of finite-dimensional representations of $\mathrm{SU}(2)$, and let $t_1, \dots, t_m > 0$. For each i let $(\ell_{i,K})_{K\ge 0}$ be an admissible approximation of ℓ_i along the lattices Λ_{nB^K} (Definition 2.1) whose based homotopies to ℓ_i can be chosen with swept area, counted with multiplicity, of order $O(a_K)$. Under $\nu_{nB^K,n,\gamma}$ we consider the vector $W_K = (W_{K,1}, \dots, W_{K,m})$ with

$$W_{K,i} = \chi_i\big(\mathrm{Hol}_{\ell_{i,K}} \Psi^{(N)}_{t_i} U\big), \qquad N = nB^K.$$

Each $W_{K,i}$ takes values in $\{w \in \mathbb{C} : |w| \le \chi_i(I)\}$, where $\chi_i(I)$ is the dimension of the representation.

Main results. The first theorem gives convergence under the conditioned measure at a fixed coarse side; it is proved in Section 28.5.

Theorem 28.1. *Assume the standing assumptions, and let W_K be as above. Then the law of W_K under $\nu_K = \nu_{nB^K,n,\gamma}$ converges weakly as $K \to \infty$. The limit laws are consistent under finite unions of lists of loops and under coordinate projections. For each q and each array ϑ on the lattice of side nB^q, let $G_q(\vartheta) = (\chi_i(\mathrm{Hol}_{\ell_i}\,\Phi_{t_i}[f]))_{i=1}^m$, where f is the smooth cardinal interpolant of ϑ, viewed as a smooth connection, and $\Phi_t[f]$ is the gauge orbit at time t of the Yang–Mills heat flow started from f. Then the limit law of W_K is the weak limit, as $q \to \infty$, of the laws $(G_q)_\# \pi_q$. The moment generating functions $\mathbb{E}_{\nu_K} \exp(\sum_i z_i W_{K,i})$ converge uniformly on every bounded subset of $\mathbb{C}^m$, and their cumulants of every finite order converge, the logarithms being taken on a fixed neighborhood of the origin on which none of these functions vanishes.*

The second theorem removes the conditioning; it is proved in Section 28.6. Here the coarse side varies along the sequence $n_r = n_* B^r$, while the fine lattice Λ_{N_K}, the configuration, and the observable stay the same.

Theorem 28.2. *Assume the standing assumptions, except that the coarse side is not fixed. Fix $n_* \in 4\mathbb{N}$, put $n_r = n_* B^r$, $N_K = n_* B^K$, and $\nu_{K|r} = \nu_{N_K,n_r,\gamma}$ for $K \geq r$, and let W_K be the vector of flowed Wilson loops on Λ_{N_K} defined above, with $D = \max_i \chi_i(I)$. Let C', $\bar{c}$, C_{w}, and a_{w} be the constants of Theorem 23.9, and set*

$$F_\gamma(u) = C' u^3 e^{-\bar{c}u/\gamma} + C_{\mathrm{w}} u^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mu/\gamma}}.$$

Then there exists r_0 such that, for all $r \geq r_0$ and all $K \geq r$,

$$e_{K|r} = \mu_{N_K,\gamma}(S^c_{N_K,n_r,\gamma}) \leq F_\gamma(n_r),$$

and $F_\gamma(n_r) \to 0$ as $r \to \infty$. For $r \geq r_0$ let $Z^{\mathrm{sel}}_r(z)$ be the limit as $K \to \infty$ of $\mathbb{E}_{\nu_{K|r}} \exp(\sum_i z_i W_{K,i})$, which exists by Theorem 28.1. For every $R < \infty$ and all $r, r' \geq r_0$,

$$\sup_{\sum_i |z_i| \leq R} |Z^{\mathrm{sel}}_r(z) - Z^{\mathrm{sel}}_{r'}(z)| \leq 2e^{DR}\big[F_\gamma(n_r) + F_\gamma(n_{r'})\big].$$

There exists a probability measure ρ on $\prod_i \{w \in \mathbb{C} : |w| \leq \chi_i(I)\}$ such that, as $K \to \infty$,

$$\mathrm{Law}_{\mu_{N_K,\gamma}}(W_{K,1}, \dots, W_{K,m}) \Longrightarrow \rho, \qquad \mathbb{E}_{\mu_{N_K,\gamma}} e^{\sum_i z_i W_{K,i}} \longrightarrow \int e^{\sum_i z_i w_i}\, d\rho(w),$$

and the second convergence is uniform on $\{\sum_i |z_i| \leq R\}$ for every $R < \infty$. These limits are consistent under taking subfamilies of the loops. The events $S_{N_K,n_r,\gamma}$ for different r need not be nested.

28.2 Deterministic estimates

This section collects the deterministic facts used below: elementary properties of the cardinal interpolation and of the lattice heat semigroup, a geometric summation, and the comparison of lattice and continuum flows for a fixed family of smooth initial data.

Cardinal interpolation. We recall the cardinal interpolation of Lemma 16.3, explicitly enough to justify the elementary facts needed here. Let b_* be the even nonnegative smooth function of that lemma, denoted b there, which is supported in $[-1,1]$, positive on $(-1,1)$, and flat at ± 1, and set

$$\varphi(u) = \frac{b_*(u)}{\sum_{q\in\mathbb{Z}} b_*(u-q)}, \qquad \varphi_3(u) = \prod_{i=1}^{3} \varphi(u_i).$$

The denominator is positive, smooth, and one-periodic. Hence $\varphi(q) = \mathbf{1}_{q=0}$ for $q \in \mathbb{Z}$ and $\sum_q \varphi(u-q) = 1$. In the notation of that lemma, $\varphi = \zeta$ and $\varphi_3 = \zeta_3$. For an array f on the lattice of mesh h, its periodized smooth interpolant is

$$f_h(x) = \sum_{v\in\Lambda_{L/h}} \varphi_3((x-v)/h) f(v),$$

where the periodic images of v are understood. The formula is applied separately to every directed-link and color component, at the location of that component. For $a \le h$ with h/a an integer, $I_{h\to a} f$ is the restriction of f_h to the lattice of mesh a. For an array f on the lattice of mesh a, we write $J_a f = f_a$ for its interpolant, which is the continuous interpolant $I_a f$ of that lemma. At every point only a bounded number of the translates $\varphi_3((x-v)/h)$ are nonzero.

Lemma 28.3. *Let $a \le h$ be meshes with h/a an integer, let f be an array on the lattice of the indicated mesh, and let F be a smooth periodic field. Take $t \ge 0$ and an integer $q \ge 0$. Let D_a^q be any product of q physical forward or backward differences, possibly applied to translated components. Then*

$$\|J_a f\|_\infty \le \|f\|_\infty, \qquad \|D_a^q I_{h\to a} f\|_\infty \le C_q h^{-q} \|f\|_\infty, \tag{28.1}$$

$$\|J_a(F|_a) - F\|_\infty \le Ca \|\partial F\|_\infty, \tag{28.2}$$

$$\|P_t^a I_{h\to a} f\|_\infty \le \|f\|_\infty, \qquad \|D_a P_t^a I_{h\to a} f\|_\infty \le Ch^{-1} \|f\|_\infty, \tag{28.3}$$

where C_q and C depend only on q and b_*. Further, if $a_j = HB^{-j}$, $\delta > \delta' > 0$, and $c \ge 0$, then for every integer $k \ge 0$,

$$\sum_{j\ge k} (1+j)^c a_j^\delta \le C_{B,c,\delta} (1+k)^c a_k^\delta \le C_{H,B,c,\delta,\delta'} a_k^{\delta'}. \tag{28.4}$$

Proof. The first bound in (28.1) follows from nonnegativity of φ_3 and the partition of unity. For the second, a product of q physical differences of $I_{h\to a}f$ is an average of the corresponding qth derivative of f_h over q segments. Each derivative of order q of $\varphi_3((x-v)/h)$ is bounded by $C_q h^{-q}$, and only a bounded number of terms contribute at each point. This proves the bound, also for backward differences and translated components, with the same constant. For (28.2), every lattice site v that contributes to $J_a(F|_a)(x)$ lies within distance Ca of x. Subtracting $F(x)$ inside the partition sum and integrating the derivative of F along the segment from x to v gives the bound.

For (28.3), we write $\Delta_a = a^{-2}\sum_i (T_i + T_i^{-1} - 2I)$, where T_i is the translation by ae_i. Then $e^{t\Delta_a} = e^{-6t/a^2}\exp(ta^{-2}\sum_i (T_i + T_i^{-1}))$ is a series in translations with nonnegative coefficients of total mass one, so P_t^a is a contraction in the supremum norm. Differences commute with P_t^a. The two bounds then follow from (28.1).

For the first inequality in (28.4), set $j = k + i$ and use $1 + k + i \le (1 + k)(1 + i)$ and $a_{k+i} = a_k B^{-i}$; the remaining series $\sum_{i\ge 0}(1+i)^c B^{-i\delta}$ converges by the ratio test. The second inequality holds because $a_k^\delta = H^{\delta-\delta'}B^{-k(\delta-\delta')}a_k^{\delta'}$ and $\sup_k (1+k)^c B^{-k(\delta-\delta')} < \infty$. □

We use (28.3) only for a fixed finite-scale reconstruction or at times $t < h^2$; it does not transfer between meshes uniformly. Under the standing assumptions, $t_j = t_1 B^{-(j-1)/2}$, so the cutoff $p_j = A_{\mathrm{w}} \log(1/t_j)$ is an affine function of j with slope $A_{\mathrm{w}}(\log B)/2$. In particular

$$p_j \le C_{L,n,\gamma,M,J,A_{\mathrm{w}}}(1 + j). \tag{28.5}$$

Smooth initial data. The next lemma compares the lattice objects with their continuum counterparts for a fixed compact family of smooth initial data. It is used for the finite-scale reconstructions, whose interpolants form such a family. The continuum counterpart of $\mathcal{Q}_a$ is the Duhamel term $\int_0^t P_{t-s}\mathcal{N}(u(s), v(s))\,ds$, where $P_t = e^{t\Delta}$ and $\mathcal{N}$ is obtained from the finite sum of shifted brackets defining $\mathcal{N}_a$ by replacing translations by the identity and physical differences by derivatives.

Lemma 28.4. *Let $h = L/m$ for an integer $m \ge 4$, let $M_h < \infty$ and $0 < T < \infty$, and let $\mathscr{F}$ be the family of cardinal interpolants $f = \vartheta_h$ of arrays ϑ on the lattice of mesh h with $\|\vartheta\|_\infty \le M_h$. For meshes $a \le h$ with h/a an integer, put*

$$x_a = P_\cdot^a(f|_a), \qquad y_a = \mathcal{Q}_a(x_a, x_a), \qquad f \in \mathscr{F},$$

where $f|_a = I_{h\to a}\vartheta$ is the restriction of f to the lattice of mesh a. Then, as $a \to 0$, the four components of (x_a, y_a), embedded as in Definition 24.3, converge uniformly over $\mathscr{F}$ to the continuum heat path $P_\cdot f$, the continuum Duhamel term $\int_0^t P_{t-s}\mathcal{N}(P_s f, P_s f)\,ds$, and their spatial derivatives in the difference components. The norms $\|(x_a, y_a)\|_{\mathrm{fl},a}$ are bounded by a constant depending only on h, M_h, L, T, α, and b_*, and not on a.

Further, let U_a be the configuration on the lattice of mesh a with link variables $\exp(af|_a)$. Fix finitely many characters χ_i of finite-dimensional representations of $\mathrm{SU}(2)$, loops ℓ_i, and closed

lattice paths $\ell_{i,a}$, independent of time, whose physical lengths are bounded uniformly in a and which admit based homotopies to the ℓ_i, including connecting paths between base points, with swept areas counted with multiplicity tending to zero as $a \to 0$. Then for every compact interval $[\tau, T'] \subset (0, \infty)$,

$$\chi_i\big(\mathrm{Hol}_{\ell_{i,a}} \Psi_t^{(L/a)} U_a\big) \longrightarrow \chi_i\big(\mathrm{Hol}_{\ell_i} \Phi_t[f]\big) \qquad (a \to 0),$$

uniformly in $t \in [\tau, T']$ and $f \in \mathscr{F}$, where $\Phi_t[f]$ is the Yang–Mills heat flow started from f. The map from ϑ to the path $t \mapsto \chi_i(\mathrm{Hol}_{\ell_i} \Phi_t[\vartheta_h])$ is continuous. The constants in these convergences may depend on h, M_h, and the smooth bounds on $\mathscr{F}$; no uniformity as $h \to 0$ is asserted.

Proof. Since the cardinal basis is fixed, $\|f\|_{C^k} \le C_{k,h} M_h$ for every k and every $f \in \mathscr{F}$. Let S_a denote sampling on the lattice of mesh a. By Taylor's formula, we have

$$\|\Delta_a S_a P_t f - S_a \Delta P_t f\|_\infty \le C a^2 \|f\|_{C^4}, \qquad \|D_a^k S_a P_t f - S_a \partial^k P_t f\|_\infty \le C_k a \|f\|_{C^{k+1}},$$

where we used that P_t commutes with derivatives and contracts every C^k norm. By variation of constants, we have

$$P_t^a S_a f - S_a P_t f = \int_0^t P_{t-s}^a (\Delta_a S_a - S_a \Delta) P_s f \, ds,$$

so $\|P_t^a S_a f - S_a P_t f\|_\infty \le C t a^2 \|f\|_{C^4}$ by heat contraction. Commuting finitely many differences with P_t^a and using the second Taylor estimate, we obtain the same convergence, with error $O_{h,M_h}(a)$, for every fixed number of differences, uniformly over $\mathscr{F}$ and $t \in [0, T]$.

The ordered coefficient $\mathcal{N}_a$ of Lemma 24.2 is a fixed finite sum of shifted brackets with one physical difference. Its first difference is a sum of terms with $(1,1)$ or $(0,2)$ differences on the two factors. By the heat convergence just proved, the value and the first difference of $\mathcal{N}_a(x_a, x_a)$ agree with those of the continuum source $S_a \mathcal{N}(P_\cdot f, P_\cdot f)$ up to an error $O_{h,M_h}(a)$, uniformly. The same holds in each order of the two arguments. The error $y_a - S_a y$, where y is the continuum Duhamel term, solves the lattice heat equation with zero initial value and with source equal to this source error plus the heat residual $(\Delta_a S_a - S_a \Delta) y$ of the smooth continuum output. By heat contraction, also for the equation after commuting one difference, the value and the first differences of y_a converge, uniformly down to time zero. The bounds (28.1) and (28.2) then imply the convergence of the four embedded components. The same bounds on sources and derivatives, multiplied by the weights in the norms, bound $\|(x_a, y_a)\|_{\mathrm{fl},a}$ uniformly in a.

For the Wilson flow we use the consistency of the flow, with all its nonlinear terms, for smooth initial data, namely Lemma 25.2 and Theorem 25.4; no quadratic truncation of the equation is used. The family $\mathscr{F}$ is compact in every fixed smooth norm. Theorem 24.10 gives a finite reference family of local smooth continuum solutions that covers the flows started from $\mathscr{F}$ on a fixed time horizon. On each of these solutions, Lemma 25.5 compares

the lattice flow and the sampled smooth flow in values and first physical differences, in the same gauge frame. The consistency of smooth samples gives a residual of order a for the potential, or a^2 for the link variables, including each of the finitely many sampled gauge transformations between the local solutions. We choose this finite family and the corresponding thresholds at the fixed h, before letting $a \to 0$. Thus the lattice flow is uniformly close, on all local solutions, to the sampled smooth flow. Since transports are unitary, the error of the transport along a closed lattice path telescopes into a sum of edge errors; a path of physical length at most ℓ has at most ℓ/a edges, so the error in its character is $O(\ell a)$.

It remains to compare the lattice paths with the continuum loops for the smooth continuum flow; for this only bounds on the smooth curvature are needed. Differentiating parallel transport along a smooth piece of a based homotopy $H(u, v)$ gives an integral of $F_A(H)(\partial_u H, \partial_v H)$, conjugated by unitary transports. Its norm is at most $C\|F_A\|_\infty$ times the swept area of that piece, counted with multiplicity. Subdivision and smooth approximation in C^1 give the same bound for piecewise C^1 homotopies. The terms coming from moving base points are removed by the transport along the connecting paths. The transport along each edge of a lattice path, with the frozen sampled link variable, differs from the continuum parallel transport along that edge by $O(a^2)$, by the transport equation and a C^1 bound. Writing A_a for the swept area of the homotopy at mesh a, counted with multiplicity, the total error in each character is therefore at most $C_{h,M_h}(a + A_a)$, uniformly in $t \in [\tau, T']$ and in $f \in \mathscr{F}$. Only characters are used, so conjugations at the base point cancel. Continuity with respect to ϑ follows, on the same finite family of local solutions, from the smooth dependence of the flow in Theorem 24.10 and the continuous dependence of the transport equation on the connection. □

28.3 The four-term decomposition and the ordered bilinear terms

Since $\mathcal{Q}_a$ is bilinear and $y_j = \mathcal{Q}_a(x_{j-1} + d_j, x_{j-1} + d_j)$, we have

$$y_j - y_{j-1} = \mathcal{B}_a(x_{j-1}, d_j) + \mathcal{Q}_a(d_j, d_j), \qquad 1 \le j \le K. \tag{28.6}$$

Summing over j expresses the truncation error of the quadratic Picard term through the cross terms $\mathcal{B}_a(x_{j-1}, d_j)$ and the quadratic increments $\mathcal{Q}_a(d_j, d_j)$; both sums are taken on the same fine mesh and with the same ordered operator $\mathcal{Q}_a$. The next lemma splits d_j into four terms and bounds the expected norm of each of the sixteen ordered products $\mathcal{Q}_a(v_j, w_j)$. The centered linear fluctuation term s_j is linear in the centered new fluctuations $w_j - \bar{w}_j$. The centered nonlinear heat term z_j is the heat evolution of the rest of the conditionally centered part of A_j, which is nonlinear in w_j. The interpolation defect r_j is the difference between the linearized reconstruction of the coarser field and the cardinal interpolation of that field; it is a deterministic function of $\widehat{\theta}_{j-1}$. The predictable term u_j

is the nonlinear part of the zero-fluctuation reconstruction plus the conditional mean correction. The cross terms are treated in Section 28.4.

Lemma 28.5. *Assume the standing assumptions of Section 28.1. For $1 \le j \le K$ define*

$$\widehat{P}_j(v) = \widehat{\Phi}_j(v,0), \qquad \widehat{L}_j = D\widehat{P}_j(0), \qquad \mathsf{E}_{j,v} = g_j^{-1} D_w \widehat{\Phi}_j(v, g_{j,\cdot} w)|_{w=0},$$

and the following four heat paths on the mesh a:

$$\begin{aligned}
s_j &= \frac{g_j}{a_j} P_\cdot^a I_{a_j \to a} \mathsf{E}_{j,\widehat{\theta}_{j-1}}(w_j - \bar{w}_j),\\
z_j &= P_\cdot^a I_{a_j \to a}\big(A_j - \mathbb{E}[A_j \mid \mathcal{F}_{j-1}]\big) - s_j,\\
r_j &= P_\cdot^a \Big(I_{a_j \to a} \frac{\widehat{L}_j \widehat{\theta}_{j-1}}{a_j} - I_{a_{j-1} \to a} \frac{\widehat{\theta}_{j-1}}{a_{j-1}} \Big),\\
u_j &= P_\cdot^a I_{a_j \to a} U_j^0, \qquad U_j^0 = \mathbb{E}[A_j \mid \mathcal{F}_{j-1}] - \widehat{L}_j \widehat{\theta}_{j-1}/a_j.
\end{aligned}$$

Then the following statements hold.

1. *We have $d_j = s_j + z_j + r_j + u_j$. The paths s_j and z_j have zero conditional mean given $\mathcal{F}_{j-1}$, and r_j and u_j are $\mathcal{F}_{j-1}$-measurable. The difference defining r_j involves the two input meshes a_j and a_{j-1}.*
2. *For any two heat paths $v = P_\cdot^a v_0$ and $w = P_\cdot^a w_0$ on the mesh a, the two orders satisfy separately, without cancellation,*

$$\mathsf{Y}_\alpha^a(\mathcal{Q}_a(v,w)) + \mathsf{Y}_\alpha^a(\mathcal{Q}_a(w,v)) \le C_{L,T,\alpha,\sigma,J,\Theta}\, \mathsf{X}_\alpha^a(v) \mathsf{H}_\sigma^a(w_0).$$

   The constant does not depend on γ, n, or K.
3. *The reconstructed fields satisfy deterministic bounds $\|\widehat{\theta}_j\|_\infty \le \bar{b}_j$, where $\bar{b}_0 = r$ and*

$$\bar{b}_j \le C\big[r a_{\mathrm{cap}}^j + g_3 \sqrt{a_j}(p_j + 1)\big], \qquad a_{\mathrm{cap}}\sqrt{B} < 1 \qquad (j \ge 1).$$

   For every fixed $p \ge 1$ define

$$\begin{aligned}
S_{p,j} &= C_p g_3 a_j^\beta \big[\sqrt{\log(2 + L/a_j)} + \sqrt{p}\big],\\
Z_{p,j}^- &= C_p\big[g_3^2 a_j^\sigma (1+j) + g_3^3 a_j^{1/2} p_j^3\big],\\
Z_{p,j}^+ &= C_p\big[g_3^2 a_j^\alpha (1+j) + g_3^3 a_j^{1/2} p_j^3\big],\\
R_j &= C\bar{b}_{j-1} a_{j-1}^{\alpha-1}, \qquad U_{p,j} = C_{p,\tau}(1+j)^b a_j^\tau.
\end{aligned}$$

   Then $\|\mathsf{X}_\alpha^a(s_j)\|_p \le S_{p,j}$, $\|\mathsf{H}_\sigma^a(z_j(0))\|_p \le Z_{p,j}^-$, $\|\mathsf{X}_\alpha^a(z_j)\|_p \le Z_{p,j}^+$, $\mathsf{X}_\alpha^a(r_j) \le R_j$ pathwise, and $\|\mathsf{H}_\sigma^a(I_{a_j \to a} U_j^0)\|_p \le U_{p,j}$ and $\|\mathsf{X}_\alpha^a(u_j)\|_p \le U_{p,j}$. The first three bounds also hold conditionally on $\mathcal{F}_{j-1}$, for every value of the coarser field. Further, $\mathcal{U}_j = \mathsf{H}_\sigma^a(I_{a_j \to a} U_j^0)$ satisfies $\mathcal{U}_j \le C(1+j)^b$ pathwise.

4. *There is a nonnegative deterministic sequence* (W_j) *with* $\mathbb{E}\mathrm{Y}^a_\alpha(\mathcal{Q}_a(r_j,r_j)) \le W_j$ *and such that* $W_j \le C_\zeta(1+j)^b a_j^\zeta$ *for every* $0<\zeta<\min\{2\alpha-1,\lambda_{\mathrm{anc}}\}$.
5. *Put* $F_j = g_3^2[a_j^{2\alpha-1}(1+j)+\bar b_{j-1}]$. *For* $v,w\in\{s,z,r,u\}$, *the expectation* $\mathbb{E}\mathrm{Y}^a_\alpha(\mathcal{Q}_a(v_j,w_j))$ *is bounded by a constant times the entry in row* v *and column* w *of the following table:*

	s	z	r	u
s	F_j	$S_{2,j}Z^-_{2,j}$	$S_{1,j}R_j$	$S_{1,j}U_{1,j}$
z	$S_{2,j}Z^-_{2,j}$	$Z^+_{2,j}Z^-_{2,j}$	$R_jZ^-_{1,j}$	$U_{1,j}Z^-_{1,j}$
r	$R_jS_{1,j}$	$R_jZ^-_{1,j}$	W_j	$R_jU_{1,j}$
u	$U_{1,j}S_{1,j}$	$U_{1,j}Z^-_{1,j}$	$R_jU_{1,j}$	$(1+j)^bU_{1,j}$

6. *For every* $0<\zeta_2<\min\{2\alpha-1,\tau\}$,

$$\sup_{K\ge j}\sum_{v,w\in\{s,z,r,u\}}\mathbb{E}_{\nu_{N,n,\gamma}}\mathrm{Y}^a_\alpha(\mathcal{Q}_a(v_j,w_j)) \le C_{\zeta_2}(1+j)^b a_j^{\zeta_2}.$$

The constants in (3)–(6) have the dependence stated in Section 28.1; the same holds in the remaining results of this section.

The lemma uses the expansion at $w=0$. By Remark 26.3, s_j and $z_j = P^a_\cdot I_{a_j\to a}Z^{(0)}_j$ are the terms $s^{(0)}_j$ and $z^{(0)}_j$ of Lemma 26.2, while s_j+z_j, r_j, and u_j are the same as in the expansion at the conditional mean. In the notation of that lemma, $\widehat P_j(\theta)/a_j = C_j(\theta)$ is the zero-fluctuation reconstruction in physical units; the linearization $\widehat L_j$ of $\widehat P_j$ acts on link logarithms, and $\mathsf{P}_j = B\widehat L_j$ acts on lattice potentials, so that the linear part of C_j is $a_j^{-1}\widehat L_j\theta = a_{j-1}^{-1}\mathsf{P}_j\theta$.

Three groups of entries in the table require different inputs. The entry F_j for $\mathcal{Q}_a(s_j,s_j)$, which includes the conditional mean of this product at a nonzero coarser field, and the two entries $S_{1,j}R_j$ for $\mathcal{Q}_a(s_j,r_j)$ and $\mathcal{Q}_a(r_j,s_j)$ rely on the conditional concentration estimates of Section 26. The entry W_j for $\mathcal{Q}_a(r_j,r_j)$ is a separate estimate from Theorem 27.6. The remaining twelve entries follow from the product inequality (2) and the bounds in (3), combined either with the Cauchy–Schwarz inequality or with conditioning on $\mathcal{F}_{j-1}$. All entries decay like positive powers of a_j; by (28.12) below, $\bar b_{j-1}\le C(1+j)^b a_j^{1/2}$, R_j and $S_{p,j}$ are $O((1+j)^b a_j^\beta)$, and $2\beta = 2\alpha-1>0$.

Proof of Lemma 28.5. We first prove the decomposition and the bounds on the four factors, then the product inequality, then the table, and finally the summed bound (6).

Step 1: the decomposition. The arrays A_j are bounded at every finite K by the amplitude bounds in (3), so conditional expectation commutes with the fixed linear heat and cardinal maps. By the definition of z_j, we have

$$s_j+z_j = P^a_\cdot I_{a_j\to a}\big(A_j-\mathbb{E}[A_j\mid\mathcal{F}_{j-1}]\big).$$

Adding u_j replaces the conditional expectation by $\widehat{L}_j\widehat{\theta}_{j-1}/a_j$, and adding r_j cancels this linearized reconstruction and subtracts $P_{\cdot}^{a} I_{a_{j-1}\to a} A_{j-1} = x_{j-1}$. This proves $d_j = s_j + z_j + r_j + u_j$. The vector $w_j - \bar{w}_j$ has conditional mean zero under the conditional fluctuation kernel, and the derivative $\mathsf{E}_{j,\widehat{\theta}_{j-1}}$ and the conditional mean of A_j are $\mathcal{F}_{j-1}$-measurable. This gives the four assertions on conditional means and measurability.

Step 2: the linear fluctuation term and the centered nonlinear term. We use the convention of Theorems 26.10 to 26.12 in which the reconstruction is Taylor expanded at $w = 0$. The input mesh, coarser mesh, and common fine mesh of those theorems are a_j, $a_{j-1} = Ba_j$, and a_K, and the refinement ratios are the integers B and B^{K-j}. The classical depth is $J(K-j)$, and the coarser dimensionless field is $\widehat{\theta}_{j-1}$. The parameter choice of Theorem 23.2 gives $t_1 \le g_*$, where g_* is the bound on the coupling under which the conditional fluctuation kernel is controlled (Theorem 13.8). Hence $t_j = t_1 B^{-(j-1)/2} \le g_*$ for every $j \ge 1$. The coarser fields that occur lie in the inner domain of the small-field event, and their reconstructions are evaluated on the fixed larger analytic domain. All conditional estimates below use the conditional fluctuation kernel on its fluctuation cutoff domain and its mean $\bar{w}_j$. The larger domain supplies bounds on coefficients only; no conditional law on a larger domain of coarser fields is used. Thus the terms of those theorems in the convention at $w = 0$ are precisely s_j and z_j. By the conditional estimates of the first two theorems, we obtain $S_{p,j}$, $Z^{-}_{p,j}$, and $Z^{+}_{p,j}$, and taking expectations of their conditional pth moments gives the same unconditional bounds. The amplitude bounds in Theorem 26.12 give the displayed $\bar{b}_j$, where r is the radius of B_r.

Step 3: the interpolation defect. Let $H_j = a_{j-1}$ and $d_{H_j}(t) = H_j(t + H_j^2)^{-1/2}$. In the notation of Lemma 27.1, the linearized reconstruction in physical units is $B\widehat{L}_j$, since

$$\widehat{L}_j\widehat{\theta}_{j-1}/a_j = (B\widehat{L}_j)\widehat{\theta}_{j-1}/H_j.$$

The difference of the two interpolations in that lemma is therefore the one in r_j. The bounds of that lemma on the rows of the heat-evolved difference and of its first differences imply

$$\|r_j(t)\|_\infty \le C\bar{b}_{j-1}H_j^{-1}d_{H_j}(t), \qquad \|D_a r_j(t)\|_\infty \le C\bar{b}_{j-1}H_j^{-1}(t+H_j^2)^{-1/2}d_{H_j}(t).$$

Since $a \le H_j$ and $\alpha < 1$, each of the two weighted terms in $\mathsf{X}^{a}_{\alpha}(r_j)$ is at most $C\bar{b}_{j-1}H_j^{\alpha-1}$: we replace $t + a^2$ by $t + H_j^2$ in the weights, and the remaining power $(t+H_j^2)^{(\alpha-1)/2}$ is largest at $t = 0$. This proves the pathwise bound R_j.

Step 4: the predictable term. The field U_j^0 is the nonlinear part of the zero-fluctuation reconstruction, in physical units, plus the conditional mean correction under the conditional fluctuation kernel. It is the field of Theorem 27.7. That theorem bounds the

moments of $\mathsf{H}^a_\sigma(I_{a_j\to a}U^0_j)$, including the first differences at times $t \le a^2$, and of $\mathsf{X}^a_\alpha(u_j)$, and it gives the pathwise polynomial bound. Its moment bound has $H^\tau_j = a^\tau_{j-1}$ in place of a^τ_j; the fixed factor B^τ is absorbed into $C_{p,\tau}$. This gives $U_{p,j}$ and the pathwise bound on $\mathcal{U}_j$.

Step 5: the product inequality. Statement (2) is Lemma 24.6, with the two orders kept separately. Its hypotheses hold, since the side $N = nB^K \ge 4$ is an integer, $a = L/N$, $1/2 < \alpha < 2/3$, and $0 < \sigma < 1 - \alpha$. For $a \le 1$ its heat-kernel proof applies. For $1 < a \le L/4$ we use its clause for coarse meshes, which we check directly. Lemma 24.2 gives the finite stencil of shifted brackets on every periodic lattice of side $N \ge 4$. Its bilinear polynomial defines $\mathcal{N}_a$ on arbitrary arrays; this does not require the smallness of link logarithms needed for the nonlinear equation. A physical first difference has supremum operator norm at most $2/a$, translations are isometries, and $\mathcal{N}_a$ is a fixed finite sum of brackets with one difference. Together with heat contraction, these facts imply that

$$\|\mathcal{Q}_a(v,w)(t)\|_\infty \le Cta^{-1}\|v_0\|_\infty\|w_0\|_\infty, \qquad \|D_a\mathcal{Q}_a(v,w)(t)\|_\infty \le Cta^{-2}\|v_0\|_\infty\|w_0\|_\infty;$$

for the second bound we commute the output difference with the outer heat semigroup and use the bound $2/a$ on the source. The reversed order has the same bound. Evaluating the input norms at $t = 0$, we find $\|v_0\|_\infty \le a^{-\alpha}\mathsf{X}^a_\alpha(v)$ and $\|w_0\|_\infty \le a^{-\sigma}\mathsf{H}^a_\sigma(w_0)$. Since $a > 1$, the sum of the two output norms is at most

$$CT\big[(T + (L/4)^2)^\beta + (T + (L/4)^2)^\alpha\big]\mathsf{X}^a_\alpha(v)\mathsf{H}^a_\sigma(w_0). \tag{28.7}$$

If $L \le 4$ this case does not occur. For $a \le 1$ the factor $(T + a^2)^{(\alpha-\sigma)/2}$ in Lemma 24.6 is bounded by a constant depending only on L, T, α, and σ, since $\alpha > \sigma$ and $a \le L/4$. Taking the larger of the two constants proves (2) for every mesh that occurs, independently of the coupling, the coarse side, and K. In particular, if $x = P^a_\cdot f$ for an array f on the mesh a, then x and u_j are heat paths on the same mesh, and (2) applies to $\mathcal{Q}_a(x, u_j)$ and $\mathcal{Q}_a(u_j, x)$ with the norm $\mathsf{H}^a_\sigma(I_{a_j\to a}U^0_j)$ bounded in Theorem 27.7.

Step 6: the sequence W_j. Let W_j be the nonnegative deterministic bound of Theorem 27.6, with $\rho_0 = r$ and with the amplitude bounds of that theorem replaced by $\bar{b}_i$. After enlarging its constant to account for this choice, both conclusions of that theorem remain valid:

$$\mathbb{E}\mathsf{Y}^a_\alpha(\mathcal{Q}_a(r_j, r_j)) \le W_j, \qquad \mathbb{E}\mathsf{Y}^a_\alpha(\mathcal{B}_a(x_{j-1}, r_j)) \le 4W_j. \tag{28.8}$$

The tail estimate of that theorem, for any $\zeta < \min(2\alpha - 1, \lambda_{\mathrm{anc}})$, implies that $W_j \le \sum_{i\ge j} W_i \le C_\zeta a_j^\zeta$, which is stronger than (4). Both quantities in (28.8) include all contributions of the coarse field and all propagated conditional means.

Step 7: all products except those of s_j and r_j. The bound on $\mathcal{Q}_a(s_j, s_j)$, including its conditional mean at a nonzero coarser field, is Theorem 26.12; the expectation it gives is at most CF_j.

For $\mathcal{Q}_a(s_j, z_j)$ and $\mathcal{Q}_a(z_j, s_j)$ we put s_j in the argument measured by X^a_α and $z_j(0)$ in the argument measured by H^a_σ, in (2). By the Cauchy–Schwarz inequality under the same measure, we have

$$\mathbb{E}\big[\mathsf{X}^a_\alpha(s_j)\mathsf{H}^a_\sigma(z_j(0))\big] \le S_{2,j}Z^-_{2,j}.$$

For $\mathcal{Q}_a(z_j, z_j)$ the same argument with z_j in the X^a_α argument gives $Z^+_{2,j}Z^-_{2,j}$.

For $\mathcal{Q}_a(z_j, r_j)$ and $\mathcal{Q}_a(r_j, z_j)$ we use the pathwise bound R_j on $\mathsf{X}^a_\alpha(r_j)$ and the bound on $\mathsf{H}^a_\sigma(z_j(0))$; each expectation is at most $CR_jZ^-_{1,j}$, in either order, without any symmetry of $\mathcal{Q}_a$.

For $\mathcal{Q}_a(s_j, u_j)$ and $\mathcal{Q}_a(u_j, s_j)$, statement (2) gives the bound $C\mathsf{X}^a_\alpha(s_j)\mathcal{U}_j$. Here $\mathcal{U}_j$ is $\mathcal{F}_{j-1}$-measurable, and the conditional first moment of $\mathsf{X}^a_\alpha(s_j)$ is at most $S_{1,j}$ for every value of the coarser field. Taking first the conditional expectation and then the expectation, we obtain $CS_{1,j}U_{1,j}$. For $\mathcal{Q}_a(z_j, u_j)$ and $\mathcal{Q}_a(u_j, z_j)$ we put u_j in the X^a_α argument and $z_j(0)$ in the H^a_σ argument; conditioning on $\mathcal{F}_{j-1}$ and using the conditional bound $Z^-_{1,j}$ gives $CU_{1,j}Z^-_{1,j}$. In these four products one factor is $\mathcal{F}_{j-1}$-measurable and the other has a conditional moment bound that is uniform in the coarser field; this is why their bounds are products of first moments.

For $\mathcal{Q}_a(r_j, u_j)$ and $\mathcal{Q}_a(u_j, r_j)$, statement (2) gives $CR_j\mathcal{U}_j$, hence $CR_jU_{1,j}$ after taking expectations. For $\mathcal{Q}_a(u_j, u_j)$, the splitting of the heat semigroup in Theorem 27.7 gives $\mathsf{X}^a_\alpha(u_j) \le C\mathcal{U}_j$, so the product is at most $C\mathcal{U}_j^2$. By the pathwise bound on $\mathcal{U}_j$, we have

$$\mathbb{E}\,\mathcal{U}_j^2 \le C(1+j)^b\,\mathbb{E}\,\mathcal{U}_j \le C(1+j)^bU_{1,j}.$$

Finally, $\mathcal{Q}_a(r_j, r_j)$ is bounded by the first estimate in (28.8).

Step 8: the products of s_j and r_j. For $\mathcal{Q}_a(s_j, r_j)$ and $\mathcal{Q}_a(r_j, s_j)$ we use the clause of Theorem 26.10 on predictable heat backgrounds on the common fine mesh. To check its hypotheses, let $h = a_j$, $H_j = a_{j-1} = Bh$, $\delta = a_K$, $\theta = \widehat{\theta}_{j-1}$, and $\mathsf{P}_j = B\widehat{L}_j$, and let E_{H_j} be the identity map of arrays on the lattice of mesh H_j. Then the background in that clause is exactly

$$r_j(t) = H_j^{-1}P^\delta_t\big(I_{h\to\delta}\mathsf{P}_j - I_{H_j\to\delta}\mathsf{E}_{H_j}\big)\theta, \qquad R^\sharp_j = C_J\|\theta\|_\infty H_j^{\alpha-1}. \tag{28.9}$$

It is a predictable heat path on the whole torus, and both input meshes are kept. That clause gives, for each integer $0 \le q \le 4$ and every choice of differences and shifts,

$$\|D^q_\delta r_j(t)\|_\infty \le C_qR^\sharp_j(t+h^2)^{-(\alpha+q)/2}, \tag{28.10}$$

which are the hypotheses on higher differences in its class of backgrounds, including times $t < h^2$. The finitely many constants C_q depend on the ratio B, the cardinal basis,

the stencil, L, T, and the exponents, but not on the coarser field or on δ/h. Since r_j is a heat path, $\partial_t D_\delta^q r_j = \Delta_\delta D_\delta^q r_j$; the time increments of its values and of its first and second differences involve differences of order at most four, which are controlled by (28.10). The same clause gives a bounded diameter for the normalized coefficient metric and the covering bound $N(v) \le C(1+L/h)^P v^{-Q}$, $0 < v \le 1$, independently of $\delta/h = B^{-(K-j)}$. Thus the conditional maximum is taken over a cover at the input mesh h.

In the expansion at $w = 0$ used in that theorem, the linear coefficient is $\mathsf{E}_{j,\theta}$ and the centered vector is $w_j - \bar{w}_j$, so the theorem concerns the same s_j and the same conditional fluctuation kernel as here. For each order separately let V_j be the norm Y_α^δ of the product. For each value of the coarser field, the theorem implies that

$$\mathbb{P}\Big\{ V_j > C g_3 h^\beta R_j^\sharp \sqrt{\log(2+L/h) + u} \;\Big|\; \mathcal{F}_{j-1} \Big\} \le C e^{-u}, \qquad u \ge 0.$$

If $R_j^\sharp = 0$, then $r_j = 0$ and the product vanishes. Otherwise we integrate this tail. With $\Lambda_h = \log(2 + L/h)$ and $A_j^\sharp = C g_3 h^\beta R_j^\sharp$, the layer-cake formula and the substitution $v = A_j^\sharp \sqrt{\Lambda_h + u}$ give

$$\mathbb{E}[V_j \mid \mathcal{F}_{j-1}] \le A_j^\sharp \sqrt{\Lambda_h} + \frac{C A_j^\sharp}{2} \int_0^\infty \frac{e^{-u}}{\sqrt{\Lambda_h + u}}\, du \le C g_3 h^\beta \big(\sqrt{\Lambda_h} + 1\big) R_j^\sharp,$$

where we used $\Lambda_h \ge \log 2$. The amplitude bound gives $R_j^\sharp \le C_J \bar{b}_{j-1} H_j^{\alpha-1} \le C R_j$. By the tower property we obtain, separately for the two orders,

$$\mathbb{E}\mathsf{Y}_\alpha^a(\mathcal{Q}_a(s_j, r_j)) \le C S_{1,j} R_j, \qquad \mathbb{E}\mathsf{Y}_\alpha^a(\mathcal{Q}_a(r_j, s_j)) \le C S_{1,j} R_j. \tag{28.11}$$

No cancellation between the two orders is used. This completes the proof of (5).

Step 9: summation. Let $\kappa_{\mathrm{cap}} = -\log a_{\mathrm{cap}} / \log B$, so that $\kappa_{\mathrm{cap}} > 1/2$. For $j \ge 2$, by the amplitude bounds, (28.5), and (28.4), we have

$$\begin{gathered} \bar{b}_{j-1} \le C(1+j)^b a_j^{1/2}, \\ R_j \le C(1+j)^b a_j^\beta, \qquad S_{p,j} \le C_p (1+j)^b a_j^\beta, \\ Z_{p,j}^- \le C_p (1+j)^b a_j^\sigma, \qquad Z_{p,j}^+ \le C_p (1+j)^b a_j^{1/2}, \qquad U_{p,j} \le C_{p,\tau} (1+j)^b a_j^\tau. \end{gathered} \tag{28.12}$$

In the first line, the contribution of the coarse field is $r a_{\mathrm{cap}}^{j-1} = r(a_{j-1}/H)^{\kappa_{\mathrm{cap}}}$, whose exponent is strictly larger than $1/2$. The first level $j = 1$ is absorbed into a constant. In

the bounds on $Z^{\pm}_{p,j}$ we used $\sigma < 1-\alpha < 1/2$ and $\alpha > 1/2$. By (28.12), the slowest powers of a_j in the sixteen entries of the table are

	s	z	r	u
s	2β	$\beta+\sigma$	2β	$\beta+\tau$
z	$\beta+\sigma$	$1/2+\sigma$	$\beta+\sigma$	$\tau+\sigma$
r	2β	$\beta+\sigma$	ζ	$\beta+\tau$
u	$\beta+\tau$	$\tau+\sigma$	$\beta+\tau$	τ

where we choose ζ strictly between ζ_2 and $\min(2\beta, \lambda_{\mathrm{anc}})$; such a choice exists since $\zeta_2 < 2\beta$ and $\zeta_2 < \tau < \lambda_{\mathrm{anc}}$. The term of F_j that contains the conditional mean has power $1/2 > 2\beta$. Every displayed power exceeds ζ_2. Absorbing the fixed powers of H into the constant, we obtain (6). □

28.4 Truncation estimates

We now bound the truncation error $(x_K - x_{k-1}, y_K - y_{k-1})$. Its first component is the sum of the increments d_j, $k \le j \le K$, which we control by the factor bounds of Lemma 28.5. By (28.6), its second component is the sum of the cross terms $\mathcal{M}_j = \mathcal{B}_a(x_{j-1}, d_j)$ and of the quadratic increments $\mathcal{Q}_a(d_j, d_j)$. The quadratic increments are controlled by Lemma 28.5(6). For the cross terms we use the splitting $\mathcal{M}_j = \mathcal{M}^s_j + \mathcal{M}^z_j + \mathcal{M}^r_j + \mathcal{M}^u_j$ with $\mathcal{M}^v_j = \mathcal{B}_a(x_{j-1}, v_j)$. The terms $\mathcal{M}^s_j$ and $\mathcal{M}^z_j$ are conditionally centered fields with the predictable background x_{j-1}; we bound them by the conditional estimates of Section 26, in terms of a radius of the background at the input scale a_j. The bound on $\mathcal{M}^r_j$ is part of (28.8), and $\mathcal{M}^u_j$ is bounded by the product inequality and the Cauchy–Schwarz inequality. In every case we bound the first moments of the norms and sum them over j; the norms themselves are not centered.

Theorem 28.6. *Assume the standing assumptions, and use the notation of Lemma 28.5. For every fixed $p \ge 1$ and every $0 < \zeta_1 < \min\{\beta, \tau\}$,*

$$\sup_{K \ge m \ge l \ge k} \Big\| \mathsf{X}^{a_K}_{\alpha}\Big(\sum_{j=l}^{m} d_j\Big)\Big\|_p \le C_{p,\zeta_1} a_k^{\zeta_1}, \qquad \sup_{K \ge 0} \sup_{0 \le j \le K} \|\mathsf{X}^{a_K}_{\alpha}(x_j)\|_p \le C_p.$$

For $1 \le j \le K$ the radius of the background x_{j-1} at the input scale,

$$\mathcal{R}_{j-1} = \sup_{0 \le t \le T} \big\{ (t + a_j^2)^{\alpha/2} \|x_{j-1}(t)\|_\infty + (t + a_j^2)^{(\alpha+1)/2} \|D_{a_K} x_{j-1}(t)\|_\infty \big\},$$

satisfies $\sup_{K,j}\|\mathcal{R}_{j-1}\|_p \le C_p$. *With* $\mathcal{M}_j^v = \mathcal{B}_{a_K}(x_{j-1}, v_j)$ *we have*

$$\sup_{K\ge m\ge l\ge k} \mathbb{E}\,\mathsf{Y}_\alpha^{a_K}\Big(\sum_{j=l}^{m}\mathcal{M}_j^s\Big) \le C g_3 \sum_{j\ge k} a_j^\beta \sqrt{1+j},$$

$$\sup_{K\ge m\ge l\ge k} \mathbb{E}\,\mathsf{Y}_\alpha^{a_K}\Big(\sum_{j=l}^{m}\mathcal{M}_j^z\Big) \le C \sum_{j\ge k}\big[g_3^2 a_j^\alpha (1+j) + g_3^3 a_j^{1/2} p_j^3\big],$$

$$\sup_{K\ge m\ge l\ge k} \mathbb{E}\,\mathsf{Y}_\alpha^{a_K}\Big(\sum_{j=l}^{m}\mathcal{M}_j^r\Big) \le 4 \sum_{j\ge k} W_j.$$

All three right sides tend to zero as $k\to\infty$. *The fields* $\mathcal{M}_j^s$ *and* $\mathcal{M}_j^z$ *have zero conditional mean given* $\mathcal{F}_{j-1}$, *while* $\mathcal{M}_j^r$ *includes all propagated conditional means. These statements include the level* $j = K$, *for which* $I_{a_K\to a_K}$ *is the identity.*

Proof. Let $a = a_K$. By the triangle inequality for the path norm and Minkowski's inequality,

$$\|\mathsf{X}_\alpha^a(d_j)\|_p \le S_{p,j} + Z_{p,j}^+ + R_j + U_{p,j}.$$

By (28.12) and (28.4), the sum of the right side over $j \ge k$ is at most $C_{p,\zeta_1} a_k^{\zeta_1}$ for every $\zeta_1 < \min(\beta, \tau)$. This proves the first bound, uniformly over all partial sums and all K.

On the coarse lattice, of mesh $H = L/n$, we have $\|A_0\|_\infty \le r/H$. By (28.3) and the bounded horizon,

$$\mathsf{X}_\alpha^a(x_0) \le (T+H^2)^{\alpha/2} r/H + C(T+H^2)^{(\alpha+1)/2} r/H^2.$$

This bound is deterministic and independent of K. Adding the sum of the increments from level 1 to level j proves the uniform moment bound on x_j, including the case $K = j = 0$.

For the radius $\mathcal{R}_{j-1}$, let $h = a_j$ and $H_j = Bh$. For $t \ge h^2$ we have $t + h^2 \le 2(t + a^2)$, so the two weighted terms in $\mathcal{R}_{j-1}$ are bounded by a fixed multiple of $\mathsf{X}_\alpha^a(x_{j-1})$. For $t < h^2$, (28.3) applied to A_{j-1}, an array on the mesh H_j with $\|A_{j-1}\|_\infty \le \bar b_{j-1}/H_j$, bounds the sum of the two terms by

$$C\big(h^\alpha + h^{\alpha+1}/H_j\big)\bar b_{j-1}/H_j \le C_B \bar b_{j-1} H_j^{\alpha-1}.$$

This bound is deterministic, bounded uniformly in j, and decays at fine levels by (28.12); at the first level it uses only $\bar b_0 = r$ and the fixed mesh H. Taking pth moments proves the bound on $\mathcal{R}_{j-1}$. At short times the weight is the one at the input scale a_j, not the one at the output mesh a.

For $\mathcal{M}_j^s$ note that the background x_{j-1} is the heat path of a cardinal interpolation from the coarser mesh, so it satisfies the hypothesis on backgrounds of Theorem 26.10. The coarser mesh is $a_{j-1} = Ba_j$, the common fine mesh is a_K, an integer refinement of both

input meshes, the input is A_{j-1}, the radius of the background is $\mathcal{R}_{j-1}$, and the horizon is T. The clause of that theorem on cardinal backgrounds from the coarser mesh gives the bounds on their higher differences with fixed geometric constants; the larger class of backgrounds is needed only for (28.9). The conditional kernel and the convention of Taylor expansion at $w = 0$ are those matched in Step 2 of the proof of Lemma 28.5. For each value of the coarser field we use $\mathcal{R}_{j-1}$ as the number R in the conditional tail bound of that theorem. Integrating the tail in u, which is justified since $\int_0^\infty e^{-u}(1+\sqrt{u})\,du < \infty$, we obtain

$$\mathbb{E}\big[\mathsf{Y}_\alpha^a(\mathcal{M}_j^s) \mid \mathcal{F}_{j-1}\big] \le C g_3 \mathcal{R}_{j-1} a_j^\beta \big[\sqrt{\log(2 + L/a_j)} + 1\big].$$

Using the bound on the first moment of $\mathcal{R}_{j-1}$ and $\log(2 + L/a_j) \le C(1+j)$, we obtain the bound on each summand. The triangle inequality and expectation then sum it over $l \le j \le m$, and the sum is at most the sum over $j \ge k$.

The same background satisfies the hypotheses of Theorem 26.11. Integrating its conditional tail, which has a quadratic part and a remainder, we obtain

$$\mathbb{E}\big[\mathsf{Y}_\alpha^a(\mathcal{M}_j^z) \mid \mathcal{F}_{j-1}\big] \le C\mathcal{R}_{j-1}\big[g_3^2 a_j^\alpha (1+j) + g_3^3 a_j^{1/2} p_j^3\big].$$

Taking expectations and using the moment bound on $\mathcal{R}_{j-1}$, we obtain the second bound. The fields $\mathcal{M}_j^s$ and $\mathcal{M}_j^z$ have zero conditional mean, since their backgrounds are predictable and $s_j(0)$ and $z_j(0)$ have zero conditional mean.

For $\mathcal{M}_j^r$ we use the second estimate in (28.8), which is a conclusion of Theorem 27.6; the triangle inequality gives $4\sum_{j\ge k} W_j$. All three right sides tend to zero as $k \to \infty$, by (28.4), (28.5), and the summability of W_j in Theorem 27.6. At the last level $I_{a_K \to a_K}$ is the identity, and none of these estimates omits that level. □

Theorem 28.7. *Assume the standing assumptions, use the notation of Lemma 28.5, and write $\mathcal{M}_j = \mathcal{B}_{a_K}(x_{j-1}, d_j)$ and $\mathcal{M}_j^v = \mathcal{B}_{a_K}(x_{j-1}, v_j)$ for $v \in \{s, z, r, u\}$. There exist $b \ge 0$ and $C < \infty$ such that, for every $k \ge 1$,*

$$\sup_{K \ge m \ge l \ge k} \mathbb{E}_{\nu_{nBK,n,\gamma}} \mathsf{Y}_\alpha^{a_K}\Big(\sum_{j=l}^m \mathcal{M}_j^u\Big) \le C(1+k)^b a_k^\tau.$$

Further, both

$$\sup_{K \ge m \ge l \ge k} \mathbb{E}\,\mathsf{Y}_\alpha^{a_K}\Big(\sum_{j=l}^m \mathcal{M}_j\Big) \qquad \text{and} \qquad \sup_{K \ge m \ge l \ge k} \mathbb{E}\,\mathsf{Y}_\alpha^{a_K}\Big(\sum_{j=l}^m \mathcal{Q}_{a_K}(d_j, d_j)\Big)$$

tend to zero as $k \to \infty$. In particular, the sums $\sum_{j=l}^m \mathcal{M}_j$ and $\sum_{j=l}^m \mathcal{Q}_{a_K}(d_j, d_j)$ tend to zero in probability in the norm $\mathsf{Y}_\alpha^{a_K}$, at every fixed threshold, uniformly over $K \ge m \ge l \ge k$. The constants have the dependence stated in Section 28.1, with the exponents added.

Proof. Let $a = a_K$, $X_j = \mathsf{X}^a_\alpha(x_{j-1})$, and $\mathcal{U}_j = \mathsf{H}^a_\sigma(I_{a_j \to a} U^0_j)$. The case $p = 2$ of Theorem 28.6 gives $\|X_j\|_2 \le C_2$, uniformly in K and j. The case $p = 2$ of Theorem 27.7, applied under the same conditioned measure to the predictable term, which includes the contributions of the coarse field, the cubic part of the zero-fluctuation reconstruction, and the conditional mean correction, gives

$$\|\mathcal{U}_j\|_2 \le C(1+j)^b a_{j-1}^\tau \le C'(1+j)^b a_j^\tau,$$

since $a_{j-1} = B a_j$ with B fixed. Neither input uses an estimate of Section 34.

We apply Lemma 24.6 separately to $\mathcal{Q}_a(x_{j-1}, u_j)$ and $\mathcal{Q}_a(u_j, x_{j-1})$; both arguments are heat paths on the mesh a, and the argument measured by H^a_σ has initial datum $I_{a_j \to a} U^0_j$. The factor $(T + a^2)^{(\alpha-\sigma)/2}$ in that lemma is bounded uniformly, since $a \le L/n$. By this inequality and the Cauchy–Schwarz inequality under the same measure, we have

$$\mathbb{E}\, \mathsf{Y}^a_\alpha(\mathcal{M}^u_j) \le C\, \mathbb{E}(X_j \mathcal{U}_j) \le C \|X_j\|_2 \|\mathcal{U}_j\|_2 \le C(1+j)^b a_j^\tau.$$

By the triangle inequality for the path norm and (28.4), for every $K \ge m \ge l \ge k$,

$$\mathbb{E}\, \mathsf{Y}^a_\alpha\Big(\sum_{j=l}^{m} \mathcal{M}^u_j\Big) \le C \sum_{j \ge k} (1+j)^b a_j^\tau \le C'(1+k)^b a_k^\tau.$$

This proves the first assertion.

By Lemma 28.5(1), $\mathcal{M}_j = \mathcal{M}^s_j + \mathcal{M}^z_j + \mathcal{M}^r_j + \mathcal{M}^u_j$. Combining the three bounds on first moments in Theorem 28.6 with the bound just proved, we obtain a bound on the first moment of the sum of the $\mathcal{M}_j$ that tends to zero as $k \to \infty$. The means of $\mathcal{M}^r_j$ are included in W_j by Theorem 27.6. At fixed coupling $p_j \le C(1+j)$ by (28.5), so all the sums of powers converge and their tails tend to zero, and the same holds for $\sum_j W_j$ by Theorem 27.6.

For the quadratic increments, let $0 < \zeta_2 < \min(2\alpha - 1, \tau)$. By Lemma 28.5(6), at every level the sum of the expected norms of the sixteen ordered products is at most $C_{\zeta_2}(1+j)^b a_j^{\zeta_2}$. We expand $\mathcal{Q}_a(d_j, d_j)$ by bilinearity, using $d_j = s_j + z_j + r_j + u_j$, apply the triangle inequality, and sum the geometric series (28.4). This proves the last limit, with the bound $C_{\zeta_2}(1+k)^b a_k^{\zeta_2}$. Markov's inequality at a fixed positive threshold implies the two statements in probability. All these operations take place under the same conditioned measure and on the same fine mesh, including the level $j = K$. □

The next theorem combines the two previous results. Here the finite-scale reconstruction A_j is extended to the fine mesh by cardinal interpolation, not by further reconstruction with zero fluctuations, and the quadratic operator is the same ordered $\mathcal{Q}_{a_K}$ for every j.

Theorem 28.8. *Assume the standing assumptions, with the norms taken on a fixed horizon* $[0, T_0]$, $0 < T_0 < \infty$, *and let* $\nu_K = \nu_{nB^K,n,\gamma}$. *Let the arrays* A_j, $0 \le j \le K$, *be those of the coarse-to-fine reconstruction of the fine configuration, at the classical depths* $J(K-j)$, *and put*

$$\mathcal{E}_{K,j} = (x_j, y_j), \qquad x_j = P^{a_K}_{\cdot} I_{a_j \to a_K} A_j, \qquad y_j = \mathcal{Q}_{a_K}(x_j, x_j),$$

$d_j = x_j - x_{j-1}$ *for* $1 \le j \le K$, *and* $\mathsf{R}_K = \|\mathcal{E}_{K,K}\|_{\mathrm{fl},a_K} = \mathsf{X}^{a_K}_\alpha(x_K) + \mathsf{Y}^{a_K}_\alpha(y_K)$, *as in Definition 24.3. Then, for* $1 \le k \le K$,

$$\mathcal{E}_{K,K} - \mathcal{E}_{K,k-1} = \Big(\sum_{j=k}^{K} d_j,\ \sum_{j=k}^{K} \big\{ \mathcal{B}_{a_K}(x_{j-1}, d_j) + \mathcal{Q}_{a_K}(d_j, d_j) \big\} \Big). \tag{28.13}$$

For every $\eta > 0$,

$$\lim_{k \to \infty} \sup_{K \ge k} \nu_K \big\{ \mathsf{X}^{a_K}_\alpha(x_K - x_{k-1}) + \mathsf{Y}^{a_K}_\alpha(y_K - y_{k-1}) > \eta \big\} = 0, \tag{28.14}$$

and $\rho(R) = \sup_{K \ge 0} \nu_K\{\mathsf{R}_K > R\}$ *tends to zero as* $R \to \infty$. *All norms include the physical first differences and shifts. For each fixed* q, *the laws of the arrays* A_q *converge, on a fixed compact set, to the law* π_q *(Theorem 15.13), and their smooth cardinal interpolants satisfy the uniform consistency and the deterministic norm bound of Lemma 28.4. For every sample, the configuration* $e^{a_K A_K}$ *on* Λ_{nB^K} *is gauge equivalent to the sampled configuration* U. *The constants and the rates of convergence in these statements are taken at fixed coarse side and fixed coupling, uniformly in* K.

Proof. Summing (28.6) over $k \le j \le K$ gives (28.13). We apply Theorems 28.6 and 28.7 with $T = T_0$. The first component in (28.14) tends to zero by Markov's inequality and Theorem 28.6. For the second component we apply Theorem 28.7 separately to the two sums in (28.13), with threshold $\eta/3$ for each of the three contributions, and use a union bound. This proves (28.14).

For the tightness, let $\varepsilon > 0$ and choose k such that the probability in (28.14) with $\eta = 1$ is less than ε for all $K \ge k$. The array A_{k-1} lies in a fixed compact set, and $x_{k-1} = P^{a_K}_{\cdot}(f|_{a_K})$, where f is its cardinal interpolant. By Lemma 28.4, $\|\mathcal{E}_{K,k-1}\|_{\mathrm{fl},a_K} \le C_k$ for a deterministic C_k that does not depend on K. By the triangle inequality, $\mathsf{R}_K \le C_k + 1$ outside the exceptional event. The finitely many $K < k$ have bounded arrays, so their linear heat evolutions and quadratic Picard terms have a common finite bound. This proves that $\rho(R) \to 0$. The remaining assertions, including the gauge equivalence of $e^{a_K A_K}$ and U, are Theorem 15.13 applied to the family $\widehat{\mathscr{R}}$ at the classical depths $J(K-j)$. □

28.5 Convergence under the conditioned measure

We first state an approximation lemma for laws, a version of the standard approximation theorem for weak convergence (compare [28, Theorem 3.2]). In that theorem the limit of

the approximating laws is assumed to exist; here its existence is part of the conclusion, so we include the proof. For a metric space E let $\mathscr{L}$ be the set of functions $f : E \to \mathbb{R}$ with $\|f\|_\infty \le 1$ and Lipschitz constant at most one, and let $d_{\mathrm{BL}}(\mu,\nu) = \sup_{f\in\mathscr{L}} \left|\int f\,d\mu - \int f\,d\nu\right|$ be the bounded-Lipschitz distance between probability measures on E.

Lemma 28.9. *Let (E,d) be a complete separable metric space. For each $K \ge 0$ let Z_K be an E-valued random variable with law μ_K, and for $0 \le k \le K$ let $Z_{K,k}$ be E-valued random variables defined on the same probability space as Z_K. Suppose that for each fixed k the laws of $Z_{K,k}$ converge weakly as $K \to \infty$, that the union over $K \ge k$ of the supports of these laws has compact closure, that each μ_K has compact support, and that for every $\eta > 0$*

$$\lim_{k\to\infty} \sup_{K\ge k} \mathbb{P}\{d(Z_K, Z_{K,k}) > \eta\} = 0.$$

Then μ_K converges weakly to a probability measure on E.

Proof. We show that (μ_K) is a Cauchy sequence for d_{BL} and is tight, and then identify the limit.

Step 1: the Cauchy property. For $f \in \mathscr{L}$ and $\eta > 0$ we have

$$|\mathbb{E} f(Z_K) - \mathbb{E} f(Z_{K,k})| \le \eta + 2\mathbb{P}\{d(Z_K, Z_{K,k}) > \eta\}.$$

Fix k, and let C_k be the compact closure of the union of the supports of the laws of $Z_{K,k}$, $K \ge k$. Given $\varepsilon > 0$, let $x_1, \dots, x_N$ be a finite ε-net of C_k. We group the functions $f \in \mathscr{L}$ according to the values $f(x_1), \dots, f(x_N)$ rounded to multiples of ε. There are finitely many groups, and two functions in the same group differ by at most 3ε on C_k. Choosing one representative in each group and applying weak convergence to the finitely many representatives, we find that $\sup_{f\in\mathscr{L}} |\mathbb{E} f(Z_{K,k}) - \mathbb{E} f(Z_{K',k})| \le 6\varepsilon + o(1)$ as $K, K' \to \infty$. Combining the two bounds and letting first $K, K' \to \infty$ with k fixed, then $k \to \infty$, and then $\eta, \varepsilon \to 0$, we obtain that (μ_K) is a Cauchy sequence for d_{BL}.

Step 2: tightness. Fix $\varepsilon > 0$, and choose increasing k_h such that $\mathbb{P}\{d(Z_K, Z_{K,k_h}) > 2^{-h}\} \le \varepsilon 2^{-h}$ for all $K \ge k_h$. Let C_h be the compact closure of the union of the supports of the laws of Z_{K,k_h}, $K \ge k_h$, together with the supports of the finitely many μ_K with $K < k_h$. For $K \ge k_h$ we have $d(Z_K, C_h) \le 2^{-h}$ unless $d(Z_K, Z_{K,k_h}) > 2^{-h}$, and for $K < k_h$ we have $Z_K \in C_h$ almost surely. By the union bound, the closed set

$$C_\varepsilon = \bigcap_{h\ge 1} \{z : d(z, C_h) \le 2^{-h}\}$$

has μ_K-mass at least $1 - \varepsilon$ for every K. It is totally bounded: for a given tolerance, choose h large and a finite net of the compact set C_h. Since C_ε is closed in a complete space, it is compact. Hence (μ_K) is tight.

Step 3: the limit. By Prokhorov's theorem [138], in the direction that holds on every metric space [28, Theorem 5.1], every subsequence of (μ_K) has a further subsequence that converges weakly to a probability measure. By Step 1, $\int f\,d\mu_K$ converges for every $f \in \mathscr{L}$, so any two subsequential limits μ and μ' satisfy $\int f\,d\mu = \int f\,d\mu'$ for all bounded Lipschitz f. For a closed set F, the functions $\max(0, 1 - m\,d(\cdot, F))$ decrease to $\mathbf{1}_F$ as $m \to \infty$, so $\mu(F) = \mu'(F)$. Closed sets form a π-system generating the Borel σ-algebra, so $\mu = \mu'$. Since every subsequence has a further subsequence converging weakly to the same limit, the whole sequence converges weakly to it. □

Proof of Theorem 28.1. We compare W_K with the Wilson loops of the flow started from the finite-scale reconstruction from the first q RG steps. By Theorem 28.8 and the stability of flowed Wilson loops, this approximation is uniform in K. We then identify the limit law of the approximation at fixed q and apply Lemma 28.9. We fix a horizon $T_0 > 0$ and use Theorem 28.8 with it.

Step 1: comparison with finite-scale reconstructions. On the same probability space, let $W_K^{[q]}$ be the vector of the same characters of holonomies for the Wilson flow on Λ_{nB^K} started from

$$U_K^{[q]} = \exp\bigl(a_K I_{a_q \to a_K} A_q\bigr),$$

and let $D_{K,q} = \|\mathcal{E}_{K,K} - \mathcal{E}_{K,q}\|_{\mathrm{fl},a_K}$. The Wilson flow commutes with lattice gauge transformations and characters of holonomies are gauge invariant. Since $e^{a_K A_K}$ is gauge equivalent to U (Theorem 28.8), W_K is also the vector of Wilson loops of the flow started from $e^{a_K A_K} = e^{a_K x_K(0)}$, while $U_K^{[q]} = e^{a_K x_q(0)}$. On the event $\{\mathrm{R}_K \le R,\ D_{K,q} \le \eta \le 1\}$ both flow data $\mathcal{E}_{K,K}$ and $\mathcal{E}_{K,q}$ have norm at most $R + 1$. By Corollary 25.11 there exist $a_* > 0$ and C_R such that $|W_K - W_K^{[q]}| \le C_R \eta$ on this event whenever $a_K \le a_*$. These constants depend on R, the loops, the characters, the times, and the deterministic data of the flow, but not on q, on the higher derivatives of the finite-scale reconstruction, or on the coupling. Thus for $f \in \mathscr{L}$ the replacement error is at most

$$C_R \eta + 2\rho(R) + 2\nu_K\{D_{K,q} > \eta\}. \tag{28.15}$$

We choose R first, then η, and then q, increasing q until $a_q \le a_*$; then $a_K \le a_*$ for all $K \ge q$. By Theorem 28.8, the last term in (28.15) tends to zero as $q \to \infty$, uniformly in $K \ge q$. In particular, for every $\eta' > 0$, $\lim_{q\to\infty} \sup_{K \ge q} \nu_K\{|W_K - W_K^{[q]}| > \eta'\} = 0$.

Step 2: the limit at fixed q. Fix q. The vector $W_K^{[q]}$ is a function of the array A_q, which lies in a fixed compact set. By Lemma 28.4, applied with $h = a_q$, these functions converge as $K \to \infty$, uniformly on that compact set, to the continuous map G_q of the statement. By Theorem 15.13 the law of A_q converges weakly to π_q. Together, these two facts imply that $\mathrm{Law}(W_K^{[q]}) \Rightarrow (G_q)_\# \pi_q$. All the vectors W_K and $W_K^{[q]}$ take values in the compact

box $\prod_i \{w \in \mathbb{C} : |w| \le \chi_i(I)\}$. We apply Lemma 28.9 in this box, with $Z_K = W_K$ and $Z_{K,q} = W_K^{[q]}$; its hypotheses were verified in Step 1 and above. Hence the law of W_K converges weakly. Applying the same argument to the union of two lists of loops proves the consistency under finite unions and projections. Taking $K \to \infty$ at fixed q in the bound (28.15), we find that the d_{BL}-distance between the limit law of W_K and $(G_q)_\# \pi_q$ is at most $C_R \eta + 2\rho(R) + 2 \sup_{K \ge q} \nu_K\{D_{K,q} > \eta\}$. This tends to zero in the order R, η, q chosen above, which identifies the limit law of W_K as the limit of $(G_q)_\# \pi_q$.

Step 3: moment generating functions. Let $D \ge \max_i \chi_i(I)$. On the box, $|\exp(z \cdot w)| \le e^{D\|z\|_1}$, and on $\{\|z\|_1 \le Z\}$ the function $z \mapsto \exp(z \cdot w)$ is Lipschitz with constant at most De^{DZ}, uniformly in w. Weak convergence of the laws of W_K implies convergence of the moment generating functions at each z. With the common Lipschitz constant and a finite net of z, we obtain uniform convergence on $\{\|z\|_1 \le Z\}$. On the ball where $e^{D\|z\|_1} - 1 < 1/2$, we have $|\mathbb{E} \exp(z \cdot W_K) - 1| \le e^{D\|z\|_1} - 1 < 1/2$, so the logarithm with value zero at the origin is defined and holomorphic. Cauchy's formula on a smaller ball gives the convergence of every finite logarithmic derivative, that is, of the cumulants. □

28.6 Removal of the small-field conditioning

Proof of Theorem 28.2. We first bound the small-field failure probability, then compare conditioned and unconditioned expectations at the same fine lattice, and finally pass to the limit, first in K and then in r.

Step 1: the failure probability. Theorem 23.9 implies that, for every $u \in 4\mathbb{N}$ with $u \ge n_0$ and every $K' \ge 0$, we have $\mu_{uB^{K'},\gamma}(S^c_{uB^{K'},u,\gamma}) \le F_\gamma(u)$, uniformly in K'. For fixed $\gamma > 0$ both terms of $F_\gamma(u)$ tend to zero as $u \to \infty$. For the second term, with $v = \log u$, the exponent is $3v - (a_{\mathrm{w}}/4)(v + \log(M/\gamma))^2$, which tends to $-\infty$. Let r_0 be such that $n_r \ge n_0$ and $F_\gamma(n_r) < 1$ for $r \ge r_0$. For $r \ge r_0$ and $K \ge r$ the conditioned hierarchy with coarse side n_r has $K - r$ RG steps and fine side $n_r B^{K-r} = n_* B^K = N_K$. Applying the bound with $u = n_r$ and $K' = K - r$, we obtain $e_{K|r} \le F_\gamma(n_r)$. This bounds the probability of the complement of the event that defines $\nu_{K|r}$, including its initial test and the tests at the end of each RG step.

Step 2: conditioning at a fixed fine lattice. For $K \ge r$, the observable $W_K = (W_{K,1}, \dots, W_{K,m})$ under $\nu_{K|r}$ is the same measurable function of the configuration on Λ_{N_K} as under $\mu_{N_K,\gamma}$. Lemma 5.5, applied to the measure $\mu_{N_K,\gamma}$, the event $S_{N_K,n_r,\gamma}$, and this map, gives, for every bounded complex measurable f on the range of W_K,

$$\left|\mathbb{E}_{\mu_{N_K,\gamma}} f(W_K) - \mathbb{E}_{\nu_{K|r}} f(W_K)\right| \le 2\|f\|_\infty e_{K|r}. \tag{28.16}$$

The events for different r need not be nested.

Step 3: the Cauchy property of the limits. We take $f(w) = \exp(\sum_i z_i w_i)$, so that $\|f\|_\infty \le e^{DR}$ on $\{\sum_i |z_i| \le R\}$. For $K \ge \max(r, r')$, we compare both conditioned expectations with the same unconditioned expectation in (28.16) and obtain

$$\sup_{\sum_i |z_i| \le R} \left| \mathbb{E}_{\nu_{K|r}} e^{\sum_i z_i W_{K,i}} - \mathbb{E}_{\nu_{K|r'}} e^{\sum_i z_i W_{K,i}} \right| \le 2e^{DR} \left(e_{K|r} + e_{K|r'} \right).$$

At fixed r and r' the conditioned moment generating functions converge uniformly by Theorem 28.1, applied with coarse side n_r, respectively $n_{r'}$. Letting $K \to \infty$ and using Step 1, we obtain the estimate of the theorem for Z_r^{sel} and $Z_{r'}^{\mathrm{sel}}$. In particular these functions form a uniform Cauchy family on every ball as $r, r' \to \infty$.

Step 4: the limit law. We show that the laws of W_K under $\mu_{N_K,\gamma}$ converge. For $r \ge r_0$ let ρ_r be the weak limit of the laws of W_K under $\nu_{K|r}$, which exists by Theorem 28.1. For $f \in \mathscr{L}$, by (28.16) and Step 1, we have $|\mathbb{E}_{\mu_{N_K,\gamma}} f(W_K) - \mathbb{E}_{\nu_{K|r}} f(W_K)| \le 2F_\gamma(n_r)$ for all $K \ge r$. Letting $K \to \infty$, we obtain

$$\limsup_{K,K' \to \infty} \left| \mathbb{E}_{\mu_{N_K,\gamma}} f(W_K) - \mathbb{E}_{\mu_{N_{K'},\gamma}} f(W_{K'}) \right| \le 4F_\gamma(n_r),$$

and the right side tends to zero as $r \to \infty$. Hence $\mathbb{E}_{\mu_{N_K,\gamma}} f(W_K)$ converges for every bounded Lipschitz f. The vectors W_K take values in the compact box $\prod_i \{w \in \mathbb{C} : |w| \le \chi_i(I)\}$, so every subsequence of their laws has a weakly convergent further subsequence. All these subsequential limits agree on bounded Lipschitz functions, and therefore coincide, as in Step 3 of the proof of Lemma 28.9. Hence the laws of W_K under $\mu_{N_K,\gamma}$ converge weakly to a unique probability measure ρ on the box. Passing to the limit $K \to \infty$ in the bound above also gives $d_{\mathrm{BL}}(\rho, \rho_r) \le 2F_\gamma(n_r)$.

Step 5: moment generating functions and consistency. Weak convergence to ρ implies pointwise convergence of the unconditioned moment generating functions. Their common Lipschitz constant on $\{\sum_i |z_i| \le R\}$ is at most De^{DR}, so the finite-net argument of the proof of Theorem 28.1 gives uniform convergence on this set. Further, letting $K \to \infty$ in (28.16) at fixed r, we find

$$\sup_{\sum_i |z_i| \le R} \left| \int e^{\sum_i z_i w_i} \, d\rho(w) - Z_r^{\mathrm{sel}}(z) \right| \le 2e^{DR} F_\gamma(n_r),$$

which shows how the error at a fixed coarse side disappears as $r \to \infty$. For a subfamily of the loops, the laws at each fixed K are coordinate projections of the laws of the larger family. Coordinate projection is continuous on the compact box, so the weak limits have the same relation. This proves the consistency under taking subfamilies. Along the limit only the coarse side n_r changes, within the single sequence $n_* B^r$. □

28.7 Compact intervals of couplings and couplings below a finite bound

The results above use the parameters of Theorem 23.2, chosen for couplings $0 < \gamma \le \gamma_0 \le 1$, and their constants depend on the fixed coupling. This section gives two extensions. The first concerns the parameters of Theorem 23.5, chosen for couplings up to an arbitrary finite bound Γ, and shows that the truncation and tightness estimates hold uniformly for γ in a compact interval $[\gamma_-, \gamma_+] \subset (0, \Gamma]$. This uniformity requires checking how each constant depends on the coupling; taking the supremum of constants obtained at fixed coupling would not suffice. The second extension states that all fixed-coupling results of this section hold for these parameters at every fixed $\gamma \le \Gamma$.

Lemma 28.10. *Fix $L > 0$, an odd integer $M \ge 3$, and $0 < \Gamma < \infty$, and let J, $B = M^J$, Θ, g_*, and n_Γ be as in Theorem 23.5. Fix a horizon $T_0 > 0$ and an interval $I = [\gamma_-, \gamma_+] \subset (0, \Gamma]$ with $\gamma_- > 0$, and fix exponents $1/2 < \alpha < 2/3$, $\beta = \alpha - 1/2$, $0 < \sigma < 1 - \alpha$, and $0 < \tau < \min\{\sigma, 1/2, \lambda_{\mathrm{anc}}\}$. There is a threshold $n_I \ge n_\Gamma$, which does not depend on $\gamma \in I$, such that the following holds for every coarse side $n \in 4\mathbb{N}$ with $n \ge n_I$. Put $H = L/n$ and $a_j = HB^{-j}$. Under $\nu_{nB^k,n,\gamma}$ use the arrays $A_j = \widehat{\theta}_j / a_j$ of the coarse-to-fine reconstruction, and on the fine mesh $a = a_k$ set*

$$x_j = P^a_\cdot I_{a_j \to a} A_j, \qquad y_j = \mathcal{Q}_a(x_j, x_j), \qquad d_{k,q} = \mathsf{X}^a_\alpha(x_k - x_q) + \mathsf{Y}^a_\alpha(y_k - y_q), \quad 0 \le q \le k,$$

with norms on $[0, T_0]$ that include all first differences and shifts. Then every estimate of Lemma 28.5 and Theorems 28.6 and 28.7 holds with constants that are uniform for $\gamma \in I$, and with the coupling factors displayed there. In particular, for each $\eta > 0$ there exist $b < \infty$, $C_{I,\eta} < \infty$, $0 < \xi < \tau$, and $\delta > 0$ such that

$$\sup_{\gamma \in I} \sup_{k \ge q} \nu_{nB^k,n,\gamma}\{d_{k,q} > \eta\} \le C_{I,\eta}\big[(1+q)^b (a_q^\delta + a_q^{\tau-\xi}) + a_q^\xi\big], \tag{28.17}$$

and the right side tends to zero as $q \to \infty$. Further, the norms of the flow data are tight uniformly in $\gamma \in I$:

$$\lim_{R \to \infty} \sup_{\gamma \in I,\, k \ge 0} \nu_{nB^k,n,\gamma}\big\{\mathsf{X}^{a_k}_\alpha(x_k) + \mathsf{Y}^{a_k}_\alpha(y_k) > R\big\} = 0. \tag{28.18}$$

All constants may depend on I, L, n, M, J, Θ, T_0, the exponents, and the moment orders. They do not depend on $\gamma \in I$, k, the classical depth, or the ratio of the fine mesh to a_j. For a one-point interval $I = \{\gamma\}$ this gives the assertions at every fixed $\gamma \in (0, \Gamma]$.

Proof. We go through the inputs of Lemma 28.5 and Theorems 28.6 and 28.7 and check that their constants, including the constants in the conditional maximal estimates, are uniform on I. Let $g_\pm = \sqrt{\gamma_\pm / L}$ and $\kappa = a_{\mathrm{cap}}\sqrt{B} < 1$.

Step 1: cutoffs and amplitude bounds. The cutoffs in the definition of the small-field event differ from $p(t_j) = A_{\mathrm{w}} \log(1/t_j)$ by at most a fixed c_J. Let $p_{\max,j}$ be the largest of them in the jth RG step. We have

$$t_j^2 = \frac{\gamma}{MnB^{j-1}}, \qquad p(t_j) = \frac{A_{\mathrm{w}}}{2}\big[\log(Mn/\gamma) + (j-1)\log B\big], \qquad p_{\max,j} \le P_I(1+j),$$
$$\frac{\bar b_j}{\sqrt{a_j}} \le C\big[rH^{-1/2}\kappa^j + g_+ P_I(1+j)\big], \qquad \frac{\bar b_j}{g_j} \le C\big[r(g_-\sqrt{H})^{-1}\kappa^j + P_I(1+j)\big]. \tag{28.19}$$

Here the amplitude bounds are those of Lemmas 17.1 and 15.10; we used $ra_{\mathrm{cap}}^j/\sqrt{a_j} = rH^{-1/2}\kappa^j$, and the first level is included by enlarging C. For every fixed integer v we have $p_{\max,j}^v \le C_{I,v} a_j^{-1}$, since $\sup_j HB^{-j}(1+j)^v < \infty$. None of these bounds requires $\gamma_+ \le 1$.

Step 2: hypotheses of the conditional estimates. The conditional fluctuation potential, the lower bound $I/2$ on its Hessian in w, the conditional means, the local bounds on derivatives of the conditional log-density, and the volume-normalized column sums are given by Theorems 13.8, 13.10, and 15.12 and Lemma 26.1. Their hypotheses are the fixed domains and finitely many smallness conditions on $t[p(t) + c_J]^v$, including (26.1). We choose a small $t_* > 0$ such that these conditions hold for $0 < t \le t_*$. We require $n \ge \gamma_+/(Mt_*^2)$, so that $t_1^2 = \gamma/(Mn) \le t_*^2$ for all $\gamma \in I$, together with the thresholds on the coarse side and on the levels in Theorem 23.5; this defines n_I. Then every conditional fluctuation kernel at a finer level satisfies these hypotheses, for every value of the coarser field. Factors that depend only on coarser fields cancel in a normalized conditional kernel; no factor that depends on w is dropped.

Step 3: uniform maximal constants. In Lemma 26.9 the deterministic moduli contain only the fixed coefficients, powers of g_3, and powers of $p_{\max,j}$. By Step 1 they give the same normalized modulus $C_I a_j^{-30}$ in space and time as in the proof of that lemma. A physical net of spacing $c_I a_j^{30}$ has at most $C_I(1 + La_j^{-30})^3(1 + T_0 a_j^{-30})$ points, and the logarithm of this number is at most $C_I \log(2 + L/a_j)$. The part with short times is estimated at the outputs on the mesh a_j before this net is used. The conditional linear and quadratic concentration of Theorem 5.4, with the Hessian lower bound $1/2$, followed by a union bound and the deterministic modulus, gives maximal constants that are uniform on I. Alternatively, Lemmas 26.7 and 26.8 already give entropy bounds for the coefficients that do not depend on the coupling.

Let $\widetilde{x}_j = x_{j-1} + r_j$. The three ordered terms $\mathcal{Q}_a(\widetilde{x}_j, r_j)$, $\mathcal{Q}_a(r_j, \widetilde{x}_j)$, and $\mathcal{Q}_a(r_j, r_j)$ of Theorem 27.6, with their propagation through the coarser levels as in that theorem, are estimated separately there. The cross term satisfies $\mathcal{B}_a(x_{j-1}, r_j) = \mathcal{Q}_a(\widetilde{x}_j, r_j) + \mathcal{Q}_a(r_j, \widetilde{x}_j) - 2\mathcal{Q}_a(r_j, r_j)$, which explains the factor 4 in (28.8). For each of these three terms the ratio of the contribution of short times to the scale of the estimate is at most $C_I(1+j)a_{j-1}^4$ (see (27.28)). A single threshold on the level makes it small, and the finitely many coarser

levels are handled by increasing C_I. The normalized modulus is $C_I a_{j-1}^{-7}$, and a net of spacing $c_I a_{j-1}^{12}$ has at most $C_I a_{j-1}^{-48}$ points (see (27.29)). Conditional concentration, the union bound, and the modulus give the same conditional moments as in that theorem, now uniformly on I. In Theorem 27.7 the normalized modulus is $C_I a_j^{-4}$, and a net of spacing $c_I a_j^8$ has at most $C_I a_j^{-32}$ points (see the estimates following (27.32)); this covers its centered terms. The estimates of Lemma 27.1 and the coefficient estimates of Theorem 27.5 are deterministic under the same amplitude bounds. Their conditional drifts keep the explicit terms

$$a_{\mathrm{cap}}^2 \bar{b}_{i-1}^3 + g_i^2 \bar{b}_{i-1} + g_i^3 p_{\max,i}^3.$$

These arguments use $g_- > 0$ only to bound the inverse coupling in $\bar{b}_j / g_j$, and $g_+ < \infty$ only in upper bounds.

Step 4: the factor bounds. By Steps 1–3, the four-term decomposition of Lemma 26.2 and Theorems 26.10 to 26.12 give, in the notation of Lemma 28.5,

$$\begin{aligned}
S_{p,j} &\le C_{I,p}(1+j)^{1/2} a_j^{\beta}, \\
Z_{p,j}^{+} &\le C_{I,p}(1+j)^{3}(a_j^{\alpha} + a_j^{1/2}), \\
Z_{p,j}^{-} &\le C_{I,p}(1+j)^{3}(a_j^{\sigma} + a_j^{1/2}), \\
R_j &\le C_I(1+j) a_j^{\beta}, \\
U_{p,j} &\le C_{I,p}(1+j)^{b} a_j^{\tau}, \\
\sum_{j \ge q} W_j &\le C_{I,\zeta}(1+q)^{b} a_q^{\zeta} \qquad (0 < \zeta < \min(2\beta, \lambda_{\mathrm{anc}})).
\end{aligned}$$

For the last line we insert (28.19) into the sum over earlier levels in Theorem 27.6, with factor q_{anc}^{j-1-i}, keeping the term from the coarse field. A convolution of two geometric sequences multiplied by polynomials decays with every exponent strictly below the smaller of the two exponents. Explicitly, if $\lambda = -\log q_{\mathrm{anc}} / \log B$, $\varrho > \zeta$, and $\lambda > \zeta$, then

$$\frac{q_{\mathrm{anc}}^{j-1-i} a_i^{\varrho}}{a_j^{\zeta}} = H^{\varrho-\zeta} B^{\zeta} B^{-(\lambda-\zeta)(j-1-i)} B^{-(\varrho-\zeta)i}.$$

We bound the sum over i by dropping the first geometric factor, which is at most one, and summing the second. The polynomial factors contribute at most $(1+j)^b$. The term from the coarse field is geometric by itself.

Step 5: the ordered products. With these factors, each of the sixteen ordered products is bounded by a constant, uniform on I, times the entry of the table in Lemma 28.5(5). Indeed, the proof of that table uses only the product inequality, whose constant does not depend on the coupling, and the following inputs. For (s, s) it uses Theorem 26.12,

including the conditional mean; for (s,r) and (r,s), the two ordered estimates with a predictable background from Theorem 26.10; for (r,r), the separate estimate for $\mathcal{Q}_a(r_j,r_j)$ in Theorem 27.6; for (u,u), the pathwise bound on $\mathcal{U}_j$ and one moment; and for the remaining products, conditional estimates, the deterministic bound on r_j, or the Cauchy–Schwarz inequality under the same measure. No product of first moments of unrelated quantities occurs. The hypotheses of all these inputs were verified above, without an upper bound $\gamma \le 1$. Every entry is summable with a positive power of a_j, after an arbitrarily small loss in the exponent.

Step 6: the truncation error. By Minkowski's inequality applied to $d_j = s_j + z_j + r_j + u_j$, we obtain the bounds on partial sums of the increments of the linear heat evolution, and all fixed moments of $\mathsf{X}^q_\alpha(x_j)$, uniformly on I. The term of the coarse field is bounded deterministically by $C_{H,T_0,\alpha} r/H$. At the fixed order $p = 2$ the factor bounds have constants uniform on I, and the constant of the product inequality does not depend on the coupling. Hence the proof of Theorem 28.7 gives its bounds on first moments uniformly on I: the cross terms with s_j and z_j are bounded by their conditional estimates times the moments of the background radius, the cross term with r_j is bounded by $4W_j$, and the cross term with u_j is bounded, by the Cauchy–Schwarz inequality, by $C_I(1+j)^b a_j^\tau$. By (28.4), for every $v > 0$,

$$\sum_{j\ge q} (1+j)^b a_j^v \le (1+q)^b a_q^v \sum_{h\ge 0} (1+h)^b B^{-hv} < \infty.$$

We apply this to every cross term and every ordered product, with $\delta > 0$ smaller than all the positive exponents that occur, and with $\delta \le \tau$.

The identity

$$y_k - y_q = \sum_{j=q+1}^{k} \{\mathcal{B}_a(x_{j-1},d_j) + \mathcal{Q}_a(d_j,d_j)\}$$

follows from (28.6). Together with $x_k - x_q = \sum_{j=q+1}^k d_j$ and Markov's inequality, it implies that $\sup_{\gamma\in I} \sup_{k\ge q} \nu_{nB^k,n,\gamma}\{d_{k,q} > \eta\} \le C_{I,\eta}(1+q)^b a_q^\delta$. Since $a_q \le H$, the right side of (28.17) is at least a constant multiple of $(1+q)^b a_q^\delta$, for every choice of $0 < \xi < \tau$. This proves (28.17).

Step 7: tightness. For fixed q the array A_q lies in a deterministic compact ball of a finite-dimensional space, uniformly for $\gamma \in I$, by (28.19). By Lemma 28.4, its flow data on every finer lattice have a deterministic norm bound C_q. We choose q so that the probability in (28.17) with $\eta = 1$ is as small as desired, uniformly for $\gamma \in I$ and $k \ge q$. Outside this event the norm $\mathsf{X}^{a_k}_\alpha(x_k) + \mathsf{Y}^{a_k}_\alpha(y_k)$ is at most $C_q + 1$. The finitely many $k < q$ have bounded arrays and bounded norms, uniformly on I. This proves (28.18). □

Lemma 28.11. *Fix $L > 0$, an odd integer $M \ge 3$, and $0 < \Gamma < \infty$, let J, $B = M^J$, Θ, g_*, and n_Γ be as in Theorem 23.5, and fix $0 < \gamma \le \Gamma$. Then Lemmas 28.4 and 28.5 and Theorems 28.1,*

28.2, and 28.6 to 28.8 hold with these parameters in place of those of Theorem 23.2, for coarse sides $n \in 4\mathbb{N}$ with $n \geq n_\Gamma$ above finitely many further thresholds, which may depend on γ. They hold for the same conditional fluctuation kernels, conditional means, laws of finite-scale reconstructions, reconstruction maps, and configurations of the Wilson measure, and their constants have the dependence on the fixed coupling stated in Section 28.1. In Theorem 28.2 the constants of F_γ are those of Theorem 23.10. No bound on the norms of the flow data, and no rate of convergence, that is uniform over $\gamma \in (0, \Gamma]$ is asserted.

Proof. From Theorems 23.5 and 23.10 we use only the common smallness conditions and the bound on the small-field failure probability. The convergence of the laws of finite-scale reconstructions is Theorem 15.13. The smallness condition at the first RG step is $t_1^2 = \gamma/(Mn) \leq g_*^2$, and $t_j = t_1 B^{-(j-1)/2}$ for $j \geq 1$. The local estimates on coefficients and means in Lemmas 27.1 and 26.2 and Theorems 26.10 to 26.12, 27.6, and 27.7 use these conditions and the same product domains. Their summations over levels use only $p_j \leq C_{\gamma,n,J}(1+j)$, which holds at fixed positive coupling. Thus the factor bounds of Lemma 28.5 and Theorems 28.6 and 28.7 keep their proofs and constants. Lemma 28.4 is deterministic and does not involve the coupling. The proofs of Theorems 28.1 and 28.8 use only these results, the convergence of the laws of finite-scale reconstructions, and deterministic flow estimates, which do not require a bound on the coupling. The proof of Theorem 28.2 uses Theorem 23.10 in place of Theorem 23.9, at coarse sides n_r tending to infinity; the bound (23.13) has the same form as the bound used there. □

PART IX

The continuum measure

SECTION 29

The continuum measure on gauge orbits

In this section we construct the continuum measure $\lambda_{L,\gamma,[n]_M}$ on the trajectory space $\mathcal{X}_L$ of Definition 2.2 and prove Theorem 2.3. The main result is Theorem 29.28. Fix $L > 0$, $\gamma > 0$, an odd integer $M \geq 3$, and $n \in 4\mathbb{N}$. Along the full sequence of lattice sides $N_k = nM^k$, every finite vector of flowed Wilson loops, evaluated on admissible approximations of loops in the sense of Definition 2.1, converges in law under the Wilson measure $\mu_{N_k,\gamma}$, jointly with the lattice energies at positive times. The limits are the joint laws of the corresponding continuum observables under one Borel probability measure on $\mathcal{X}_L$. This measure is the limit of the images of $\mu_{N_k,\gamma}$ under Borel maps π_k that are invariant under all lattice gauge transformations. The energies of the trajectories $\pi_k(U)$ are tight at every positive time, and the measure depends only on L, γ, and the class $[n]_M$ of n under the relation $nM^a = n'M^b$.

There are three inputs. The first is the convergence of the joint laws of flowed Wilson loops under the conditioned Wilson measures at a fixed coarse side, proved in Section 28, together with the description of these limits through continuum flows started from finite-scale reconstructions (Theorems 28.1 and 28.8). Combined with the bounds of Section 23 on the small-field failure probability, these results give convergence of finite families of flowed loops under the Wilson measures (Theorem 28.2). The second is the deterministic theory of the Wilson flow and its comparison with the Yang–Mills heat flow, from Sections 24 and 25. The third is the trajectory-space framework of Cao and Chatterjee [43]: compactness modulo gauge, smoothing by the heat flow at positive times, and the Borel structure of the space of trajectories.

Convergence of finite families of flowed loops does not by itself produce a measure on $\mathcal{X}_L$. The determining coordinates w_j of Theorem 29.3 define a metric d_c that determines Borel probability measures on $\mathcal{X}_L$, but the energy $X \mapsto E_L(X(t))$ is not known to be continuous for d_c or for the Wilson topology. We therefore also use the topology of Cao and Chatterjee on trajectories of Sobolev connections modulo gauge. Compactness of trajectories comes from simultaneous bounds on their energies at the times $s_j = L^2 2^{-j}$. Energy at each positive time is continuous in the Sobolev trajectory topology because the heat flow regularizes weakly convergent data (Lemma 29.7), and this identifies the limits of the lattice energies. To realize the limit as a limit of the lattice measures themselves, we construct the maps π_k explicitly, by a search over a countable family of smooth trajectories subject to one-sided energy bounds (Theorem 29.19).

Section 29.1 collects the properties of $\mathcal{X}_L$ that we use, and Section 29.2 the deterministic lattice estimates. Sections 29.3 to 29.5 prove joint convergence of energies and loops under the conditioned Wilson measures, construct the maps π_K, and remove the conditioning, for the parameters of Theorem 23.2; Section 29.6 extends this to couplings below an arbitrary fixed bound and treats general admissible approximations. Section 29.7 states the resulting limit theorems along the sequences $N_K = n_* M^{JK}$, and Section 29.8 passes to the full sequence nM^k and completes the proof of Theorem 2.3. The remaining parts of Theorem 2.5 are proved in Section 30. The results of this section are used in Section 32 and in the weak-coupling analysis of Sections 34 to 36, mainly through Theorems 29.23 to 29.25 and Corollary 29.26.

Conventions. Constants in deterministic flow estimates depend only on the data listed in each statement, with the dependence described in item (7) of Definition 4.14. Stochastic convergence moduli and the number of constraints $m(K)$ used to define π_K may in addition depend on the fixed coupling, on the parameters of the renormalization group hierarchy, on the base side, and on the observables. We claim no rate of convergence, no convergence of moments of the energy, and no uniformity as $\gamma \to 0$. We use the Lie-algebra norm $|\cdot|$ of Section 4 on connections, and for a lattice potential A at mesh a we write

$$\|A\|_{C^1_a} = \|A\|_\infty + \max_{j\in\{1,2,3\},\ \epsilon\in\{+,-\}} \|D^\epsilon_{a,j} A\|_\infty,$$

where $D^\pm_{a,j}$ are the forward and backward physical differences. The finite-difference norms of Definition 4.8 likewise include both directions and all translates.

29.1 The trajectory space and its Borel structure

Recall from Definition 2.2 the space $\mathcal{A}_L = C^\infty(\mathbb{T}^3_L; \mathfrak{su}(2)^3)$ of smooth connections, the group $\mathcal{G}_L = C^\infty(\mathbb{T}^3_L; \mathrm{SU}(2))$ of smooth periodic gauge transformations (including all its connected components), acting by $A^k = kAk^{-1} - (dk)k^{-1}$, and the Yang–Mills heat semigroup $(\Phi_t)_{t\ge 0}$ on $\mathcal{A}_L/\mathcal{G}_L$. Global existence of smooth solutions for smooth initial data is due to Råde [139]; we use it in the form of [43, Theorem 3.14, p. 25], which also relies on Charalambous and Gross [47]. The trajectory space is

$$\mathcal{X}_L = \big\{ X : (0,\infty) \to \mathcal{A}_L/\mathcal{G}_L :\ X(t) = \Phi_{t-s} X(s) \text{ for all } 0 < s < t \big\},$$

the Wilson topology $\mathcal{T}_W$ is the weakest topology for which all the functions $W_{\ell,\chi,t}(X) = \chi(\mathrm{Hol}_\ell\, X(t))$ are continuous, where ℓ ranges over piecewise C^1 loops, χ over characters of finite-dimensional representations of $\mathrm{SU}(2)$, and t over $(0,\infty)$. The energy E_L is defined in (2.3). Our parallel transport solves $H'(s) = H(s)A(\ell(s))\dot\ell(s)$ with $H(0) = I$, as in Definition 4.10, and our gauge variable is the inverse of the one in [43, (1.1), p. 2].

In [43], Cao and Chatterjee introduced trajectories of the heat flow at positive times as a state space for three-dimensional Yang–Mills theory, following the proposal of Charalambous and Gross [47] to regularize Wilson loops by the heat flow. We work in their framework. The separation of smooth gauge orbits by holonomies is due to Sengupta [144]; we use it in the formulation of [43, Lemma 1.2, p. 4]. The compactness of energy sublevel sets modulo gauge is the form of gauge compactness proved in [43, Theorem 3.8 and Theorem 3.51], which rests on Uhlenbeck's theorem [151]. We add a countable determining metric, a comparison of its Borel structure with that of the Wilson topology, and the continuity of the energy after a positive time in the form needed below.

Sobolev connections modulo gauge

Definition 29.1. Let $\mathcal{G}_L^{2,2}$ be the group of all periodic maps $\mathbb{T}_L^3 \to \mathrm{SU}(2)$ of class $W^{2,2}$, including all connected components, and set

$$\mathcal{H}_L = H^1(\mathbb{T}_L^3; \mathfrak{su}(2)^3)/\mathcal{G}_L^{2,2}.$$

For $[A_n], [A] \in \mathcal{H}_L$ we write $[A_n] \rightharpoonup_q [A]$ if there exist representatives B_n of $[A_n]$ and B of $[A]$ such that $B_n \rightharpoonup B$ weakly in H^1. The *sequential weak quotient topology* $\mathcal{T}_q$ on $\mathcal{H}_L$ is defined by declaring a set $\mathcal{U}$ open if every sequence $[A_n] \rightharpoonup_q [A]$ with $[A] \in \mathcal{U}$ eventually lies in $\mathcal{U}$. We write $\Phi_t^{1,2}$, $t \geq 0$, for the Yang–Mills heat semigroup on $\mathcal{H}_L$ of Cao and Chatterjee [43]; the properties of it that we use are recalled, with locators, in Lemma 29.2. Let $\mathcal{X}_L^{1,2}$ be the set of trajectories $Z : (0, \infty) \to \mathcal{H}_L$ with $Z(t) = \Phi_{t-s}^{1,2} Z(s)$ for all $0 < s < t$, with the weakest topology $\mathcal{T}_{1,2}$ for which every evaluation $Z \mapsto Z(t)$, $t > 0$, is continuous into $(\mathcal{H}_L, \mathcal{T}_q)$. This is the point-evaluation topology of [43, Definition 3.70, p. 41]; it is not a topology of uniform weak H^1 convergence on time intervals. Finally, let $i^{1,2} : \mathcal{X}_L \to \mathcal{X}_L^{1,2}$ send a trajectory of smooth orbits to the trajectory of the Sobolev orbits containing them.

For a finite energy bound R, we write $\Omega_R = \{[A] \in \mathcal{H}_L : E_L(A) \leq R\}$. We also need a countable family of regularized Wilson loop functions on $\mathcal{H}_L$: let $\Psi_0 : \mathcal{H}_L \to \mathbb{C}^{\mathbb{N}}$ be the map whose components are the functions $[A] \mapsto \chi(\mathrm{Hol}_\ell \Phi_v^{1,2}[A])$, where ℓ ranges over the countable family of loops of Theorem 29.3 below, v over $L^2\mathbb{Q}_{>0}$, and χ over the characters of the irreducible representations of $\mathrm{SU}(2)$. The following facts are taken from [43].

Lemma 29.2. *Let $L > 0$. Then the following statements hold.*

1. *The group $\mathcal{G}_L^{2,2}$ coincides with the set of continuous maps $k : \mathbb{T}_L^3 \to \mathrm{SU}(2)$ with a weak derivative such that $k^{-1}dk \in H^1$, and with the set of maps $s \exp \xi$, where $s : \mathbb{T}_L^3 \to \mathrm{SU}(2)$ is smooth and $\xi \in H^2(\mathbb{T}_L^3; \mathfrak{su}(2))$.*
2. *Every $A \in H^1(\mathbb{T}_L^3; \mathfrak{su}(2)^3)$ has finite energy, and $\|F_A\|_2 \leq C_L(\|A\|_{H^1} + \|A\|_{H^1}^2)$ with C_L depending only on L.*

3. *The space $(\mathcal{H}_L, \mathcal{T}_q)$ is Hausdorff, each Ω_R is closed and compact metrizable, and the map Ψ_0 is continuous and injective, with $\Psi_0(F \cap \Omega_R)$ compact for every closed set $F \subset \mathcal{H}_L$ and every R.*
4. *For every $v \geq 0$ the map $\Phi_v^{1,2}$ is continuous on $(\mathcal{H}_L, \mathcal{T}_q)$.*
5. *Restriction to times in $L^2\mathbb{Q}_{>0}$ is a homeomorphism of $\mathcal{X}_L^{1,2}$ onto the corresponding space of compatible trajectories at these times, and the Borel σ-algebra of $(\mathcal{X}_L^{1,2}, \mathcal{T}_{1,2})$ is generated by the evaluations at these times.*
6. *For every $t > 0$, every orbit $Z(t)$ of a trajectory $Z \in \mathcal{X}_L^{1,2}$ has a smooth representative, and a $W^{2,2}$ gauge transformation relating two smooth connections is smooth, so that the map $j^{1,2} : \mathcal{X}_L^{1,2} \to \mathcal{X}_L$ that replaces each orbit by its smooth representatives is well defined. This map satisfies $j^{1,2} i^{1,2} = \mathrm{Id}$ and $i^{1,2} j^{1,2} = \mathrm{Id}$, it is continuous from $\mathcal{T}_{1,2}$ to $\mathcal{T}_W$, and it preserves every function $W_{\ell,\chi,t}$.*
7. *Every function $W_{\ell,\chi,t} \circ j^{1,2}$ is continuous on $(\mathcal{X}_L^{1,2}, \mathcal{T}_{1,2})$.*

Proof. On the unit torus, (1) is [43, Definition 3.5 and (3.2), p. 22] (we verify the identification below), (2) is [43, Lemma 3.7, p. 23], (3) is [43, Lemma 3.49, p. 35; Definition 3.50 and Theorem 3.51, pp. 35–36], (4) is [43, Lemma 3.68, p. 40], (5) is [43, Definitions 3.70 and 3.74, pp. 41–42; Lemmas 3.75 and 3.78, pp. 42–44], (6) is [43, Lemma 3.10, p. 24; Lemmas 3.84–3.85, pp. 47–48; Definition 3.86 and Lemmas 3.87–3.89, pp. 48–49], and (7) is [43, Definition 3.82, p. 47]. In (3) the countable family of regularized Wilson loop functions may be chosen as above, from our dense loop family, rational positive delays, and all characters. The identity $i^{1,2} j^{1,2} = \mathrm{Id}$ in (6) holds because at each time the smooth representative lies in the given Sobolev orbit. It remains to check the hypotheses of these results and to transfer them to side L.

The bundle is trivial, the base is the periodic three-torus, and the group $\mathrm{SU}(2)$ belongs to the class allowed in [43, Section 1.1, p. 2]. All connected components of the gauge group are included. For $y = x/L$ let $\widetilde{A}(y) = LA(Ly)$. Differentiating, we find

$$F_{ij}(\widetilde{A})(y) = L^2 F_{ij}(A)(Ly), \qquad E_1(\widetilde{A}) = L E_L(A), \qquad \widetilde{t} = t/L^2,$$

where $\widetilde{t}$ is the time of the rescaled flow. Gauge transformations transform by composition with $y \mapsto Ly$, and inversion converts the gauge convention of [43] into ours. All results on the unit torus therefore apply at every fixed L to the spaces defined here. For $f_L(y) = f(Ly)$ we have

$$\|f_L\|_{L^p(\mathbb{T}_1^3)} = L^{-3/p} \|f\|_{L^p(\mathbb{T}_L^3)}, \qquad \|f_L\|_{H^1(\mathbb{T}_1^3)}^2 = L^{-3} \|f\|_{L^2(\mathbb{T}_L^3)}^2 + L^{-1} \|\nabla f\|_{L^2(\mathbb{T}_L^3)}^2.$$

Applying the Sobolev inequality $\|f\|_p \leq C_p \|f\|_{H^1}$ on the unit torus for $1 \leq p \leq 6$, with compact embedding for $p < 6$ [43, Theorem 3.3, p. 21], componentwise to Lie-algebra and matrix coefficients, we obtain at each fixed $L > 0$

$$\|f\|_{L^p(\mathbb{T}_L^3)} \leq C_p \big(L^{3/p - 3/2} \|f\|_{L^2(\mathbb{T}_L^3)} + L^{3/p - 1/2} \|\nabla f\|_{L^2(\mathbb{T}_L^3)} \big), \qquad 1 \leq p \leq 6, \tag{29.1}$$

and the compactness for $p < 6$ transfers under the same linear rescaling. Below we use $p = 6$ for the gauge group and $p = 4$ for the curvature. The constants depend only on L, p, and the fixed coefficient norms.

We now verify (1), that is, that $\mathcal{G}_L^{2,2}$ is the full group used in [43]. The description there, as the set of maps $s \exp \xi$ with s smooth (ranging over all components) and $\xi \in H^2$, and as the set of continuous maps with $k^{-1}dk \in H^1$, transfers to side L by composition with $y \mapsto Ly$. A periodic H^2 matrix function is continuous, since its Fourier series converges absolutely and uniformly by the Cauchy–Schwarz inequality and $\sum_{p \in \mathbb{Z}^3} (1 + |p|^2)^{-2} < \infty$. For a $W^{2,2}$ group-valued map k we have $dk \in H^1 \subset L^6$ by (29.1). The derivative of $k^{-1}dk$ consists of a bounded matrix times $d^2k \in L^2$ and products of two factors dk, which lie in $L^3 \subset L^2$. This shows that $k^{-1}dk \in H^1$. Conversely, let k be continuous with values in the compact group, with $\alpha = k^{-1}dk \in H^1$. Then $dk = k\alpha \in L^6$, the derivative of this identity consists of $dk\,\alpha \in L^3$ and $k\,d\alpha \in L^2$, and we conclude that $k \in W^{2,2}$. These product identities hold weakly, by smooth convolution and convergence in the displayed Lebesgue norms. This identifies the two groups, including all periodic components. Finally, for (2) we apply [43, Lemma 3.7] to $\widetilde{A}$; its only hypothesis is $A \in H^1$ on the unit torus. We then use the scaling of curvature and energy displayed above. The constant C_L depends only on L and the fixed coefficient norms. □

The determining metric

The trajectory space carries the Wilson topology, which is defined by uncountably many functions. The following theorem replaces it, for measure-theoretic purposes, by a countable family.

Theorem 29.3. *Let $L > 0$. On piecewise C^1 loops $\ell, \ell' : [0,1] \to \mathbb{T}_L^3$ consider the metric*

$$d_{\mathcal{L}}(\ell, \ell') = \sup_{u \in [0,1]} d_{\mathbb{T}_L^3}(\ell(u), \ell'(u)) + \int_0^1 |\dot{\ell}(u) - \dot{\ell}'(u)|\, du.$$

Fix a countable family of piecewise C^1 loops that is dense for $d_{\mathcal{L}}$ and contains loops of every winding class (such families exist; see the proof), and enumerate its product with $L^2\mathbb{Q}_{>0}$ as $(\ell_j, t_j)_{j \geq 1}$. Set

$$w_j(X) = \tfrac{1}{2} \operatorname{tr} \operatorname{Hol}_{\ell_j} X(t_j), \qquad d_c(X, Y) = \sum_{j \geq 1} 2^{-j} |w_j(X) - w_j(Y)|, \qquad X, Y \in \mathcal{X}_L.$$

Then the following statements hold.

1. *d_c is a metric on $\mathcal{X}_L$, and $(\mathcal{X}_L, d_c)$ is separable.*
2. *$(\mathcal{X}_L, \mathcal{T}_W)$ is separable, and the identity map from $(\mathcal{X}_L, \mathcal{T}_W)$ to $(\mathcal{X}_L, d_c)$ is continuous.*
3. *The Borel σ-algebras satisfy*

$$\mathcal{B}(d_c) = \sigma(w_j : j \geq 1) = \mathcal{B}(\mathcal{T}_W).$$

4. *Two Borel probability measures on $\mathcal{X}_L$ under which all finite vectors $(w_1, \dots, w_b)$ have the same laws are equal. In particular, a Borel probability measure on $\mathcal{X}_L$ is determined by the joint laws of all finite families of the functions $W_{\ell,\chi,t}$.*

Remark 29.4. We do not claim that the two topologies coincide, that d_c is complete, or that $\mathcal{X}_L$ or $\mathcal{H}_L$ is a Polish space. Weak convergence on $\mathcal{X}_L$ is always stated in two forms: against bounded $\mathcal{T}_W$-continuous functions, and weakly with respect to d_c.

We call the functions w_j the determining coordinates. Each is one half of a regularized Wilson loop for the fundamental character. The proof of Theorem 29.3 uses the reduction of all characters of $\mathrm{SU}(2)$ to the fundamental trace. Let P_p be the polynomials defined by

$$P_0(u) = 1, \qquad P_1(u) = u, \qquad P_{p+1}(u) = uP_p(u) - P_{p-1}(u).$$

Lemma 29.5. *The character of every finite-dimensional representation of* $\mathrm{SU}(2)$ *is a finite sum of the functions $H \mapsto P_p(\operatorname{tr} H)$, $p \geq 0$.*

Proof. This is the classical highest-weight classification; we include the short argument. If H has eigenvalues z, z^{-1}, the recursion shows that $P_p(z + z^{-1}) = z^p + z^{p-2} + \cdots + z^{-p}$ for $z \neq \pm 1$, and by continuity the identity also holds for $z = \pm 1$. Averaging a Hermitian inner product over the Haar probability measure makes a finite-dimensional representation ρ unitary. An invariant subspace then has an invariant orthogonal complement, and by induction on the dimension ρ is a direct sum of irreducible representations. If ρ is only continuous, convolving its matrix coefficients with a smooth bump supported near the identity gives a matrix arbitrarily close to I, and in particular an invertible one. Translating the bump on the left shows that ρ multiplied by this matrix is smooth, which implies that ρ is smooth. In the complexified differential of an irreducible ρ we set $H = d\rho(h)$, $E = d\rho(e)$, $F = d\rho(f)$ for

$$h = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \qquad e = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad f = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}.$$

Then $[H, E] = 2E$, $[H, F] = -2F$, $[E, F] = H$, $H^* = H$, and $E^* = F$, the last two because ih, $e - f$, and $i(e + f)$ are anti-Hermitian. Since $\exp(2\pi i h) = I$, the eigenvalues of H are integers. Let n be the largest one and $Hv = nv$ with $v \neq 0$; then $Ev = 0$, and by induction, using the commutation relations, we obtain

$$EF^q v = q(n - q + 1)F^{q-1}v, \qquad \|F^{q+1}v\|^2 = (q + 1)(n - q)\|F^q v\|^2.$$

The case $q = 0$ shows that $n \geq 0$. The vectors $v, Fv, \dots, F^n v$ are nonzero with distinct weights $n, n - 2, \dots, -n$, and $F^{n+1}v = 0$. Their span is invariant under H, E, F. It is also invariant under the group, since every element of $\mathrm{SU}(2)$ is an exponential after unitary diagonalization. By irreducibility the span is the whole space, and the character on $\operatorname{diag}(z, z^{-1})$ is $P_n(z + z^{-1})$. Unitary diagonalization covers every group element. □

Proof of Theorem 29.3. The proof has six steps.

Step 1: a dense family. The continuity and separability results [43, Lemmas 3.24–3.25 and 3.28, p. 28] apply to every fixed smooth connection and character here. A dense countable family of loops can be chosen among polygonal loops whose lifts have vertices in $L\mathbb{Q}^3$ and rational subdivision parameters, with final vertex equal to the initial vertex plus Lz, for every $z \in \mathbb{Z}^3$. To see that this family is dense for $d_{\mathcal{L}}$, we approximate each C^1 piece of a loop by its polygonal interpolant and then perturb the finitely many vertices and subdivision parameters within these dense sets. The first approximation converges uniformly, with derivatives in L^1, by uniform continuity of the derivative on each piece; for a fixed interpolant the second does so because the velocities are constant on finitely many intervals. The final vertex is imposed using the same Lz. This family contains every winding class and the constant loops at rational points.

Step 2: separation. Suppose that $w_j(X) = w_j(Y)$ for all j. Fix $t \in L^2\mathbb{Q}_{>0}$. Then $\operatorname{tr}\operatorname{Hol}_\ell X(t) = \operatorname{tr}\operatorname{Hol}_\ell Y(t)$ for every loop ℓ of the dense family, and by the continuity of holonomies in $d_{\mathcal{L}}$ [43, Lemmas 3.24–3.25] for every piecewise C^1 loop. By Lemma 29.5, all characters of $\operatorname{Hol}_\ell X(t)$ and $\operatorname{Hol}_\ell Y(t)$ agree on every piecewise C^1 loop. The holonomy separation theorem [43, Lemma 1.2, p. 4], whose hypotheses are exactly these, implies that $X(t) = Y(t)$. For an arbitrary $t > 0$, let $s \in L^2\mathbb{Q}_{>0}$ with $s < t$; by compatibility we have $X(t) = \Phi_{t-s}X(s) = \Phi_{t-s}Y(s) = Y(t)$. No backward uniqueness is used. Thus d_c separates points.

Step 3: metric properties. Symmetry and the triangle inequality hold termwise. Since $|w_j| \le 1$, the tail $\sum_{j>b} 2^{-j}|w_j(X) - w_j(Y)|$ is at most 2^{1-b}. This implies that convergence in d_c is equivalent to convergence of every coordinate, and the coordinate map $X \mapsto (w_j(X))_{j\ge1}$ is a homeomorphism of $(\mathcal{X}_L, d_c)$ onto a subspace of $[-1,1]^{\mathbb{N}}$. The countable base of cylinder sets of the product restricts to a countable base, and choosing a point in each nonempty member, we obtain a countable dense set. The same observation shows that $\mathcal{B}(d_c) = \sigma(w_j : j \ge 1)$. The partial sums defining d_c are $\mathcal{T}_W$-continuous and the tails are uniformly small. Then the coordinate map is continuous from $\mathcal{T}_W$ into the product, and the identity from $(\mathcal{X}_L, \mathcal{T}_W)$ to $(\mathcal{X}_L, d_c)$ is continuous.

Step 4: the reverse Borel inclusion. Since every w_j is $\mathcal{T}_W$-continuous, it remains to show that $\mathcal{B}(\mathcal{T}_W) \subset \sigma(w_j : j \ge 1)$. We first show that the coordinates of Ψ_0 generate the Borel σ-algebra of $(\mathcal{H}_L, \mathcal{T}_q)$. By Lemma 29.2(2), every element of $\mathcal{H}_L$ has finite energy, and the sets Ω_b, $b \in \mathbb{N}$, exhaust $\mathcal{H}_L$. For a closed set $F \subset \mathcal{H}_L$ we therefore have

$$\Psi_0(F) = \bigcup_{b\ge1} \Psi_0(F \cap \Omega_b). \tag{29.2}$$

By Lemma 29.2(3), the right side is a countable union of compact, hence closed, subsets of the Hausdorff space $\mathbb{C}^{\mathbb{N}}$, and in particular it is Borel. Since Ψ_0 is injective,

$F = \Psi_0^{-1}(\Psi_0(F))$ lies in the σ-algebra generated by the coordinates of Ψ_0; the converse inclusion holds because Ψ_0 is continuous. This argument uses the compactness of the images $\Psi_0(F \cap \Omega_b)$; injectivity and measurability of Ψ_0 alone would not give measurability of its inverse.

Now let $u \in L^2\mathbb{Q}_{>0}$ and $X \in \mathcal{X}_L$. Each component of $\Psi_0(i^{1,2}X(u))$ is of the form $\chi(\mathrm{Hol}_\ell X(u+v))$ with ℓ in the dense family and $v \in L^2\mathbb{Q}_{>0}$. By Lemma 29.5 it is a polynomial in $(\operatorname{tr}\mathrm{Hol}_\ell X(u+v))/2$, which is one of the functions w_j, since $u+v \in L^2\mathbb{Q}_{>0}$. Since the coordinates of Ψ_0 generate the Borel σ-algebra of $\mathcal{H}_L$, the map $X \mapsto i^{1,2}X(u)$ is measurable from $\sigma(w_j : j \geq 1)$ into the Borel σ-algebra of $\mathcal{H}_L$. By Lemma 29.2(5), the map $i^{1,2}$ is measurable from $\sigma(w_j : j \geq 1)$ into the Borel σ-algebra of $\mathcal{X}_L^{1,2}$. Let $\mathcal{B} \in \mathcal{B}(\mathcal{T}_W)$. Since $j^{1,2}$ is continuous (Lemma 29.2(6)), the set $(j^{1,2})^{-1}(\mathcal{B})$ is Borel in $\mathcal{X}_L^{1,2}$, and since $j^{1,2}i^{1,2} = \mathrm{Id}$,

$$\mathcal{B} = (i^{1,2})^{-1}\big((j^{1,2})^{-1}(\mathcal{B})\big) \in \sigma(w_j : j \geq 1).$$

This proves the Borel identity in (3).

Step 5: separability of the Wilson topology. We consider the countable set of trajectories $t \mapsto \Phi_t[b]$, where b ranges over the trigonometric polynomial one-forms with rational coefficients. Let $X \in \mathcal{X}_L$, and fix a basic Wilson neighborhood of X determined by finitely many functions $W_{\ell,\chi,t}$. The shifted trajectories $X_\epsilon(t) = X(t+\epsilon)$ approach X in every finite list of these functions as $\epsilon \downarrow 0$, since X is the smooth solution started at any earlier positive time. Each X_ϵ is the trajectory started from a smooth representative of $X(\epsilon)$. Approximating this representative in C^3 by a rational trigonometric polynomial and using Theorem 24.10 on a finite horizon containing the listed times, we find a trajectory of the countable set in the given neighborhood.

Step 6: determination of probability measures. If two measures have the same finite joint laws of the w_j, then their image measures on $[-1,1]^{\mathbb{N}}$ agree on the cylinder sets. The class of sets on which the two image measures agree is a Dynkin class containing the class of cylinder sets, which is closed under intersections. By Dynkin's π–λ theorem, it contains the σ-algebra generated by the cylinders. Pulling back and using (3), we find that the two measures agree on $\mathcal{B}(\mathcal{T}_W)$. The joint laws of finite families of the functions $W_{\ell,\chi,t}$ include those of the w_j, which proves the last assertion. This also verifies the hypotheses of the uniqueness statement [43, Lemma 1.4, p. 7]. □

Compactness of energy sublevel sets

Theorem 29.6. *Let $L > 0$. On the Borel space of Theorem 29.3, the function $X \mapsto E_L(X(t))$ is measurable for every $t > 0$, and $t \mapsto E_L(X(t))$ is nonincreasing for every $X \in \mathcal{X}_L$. Let $s_j = L^2 2^{-j}$ for $j \geq 1$. For every sequence $R = (R_j)_{j\geq 1}$ of finite numbers $R_j \geq 0$, the set*

$$\mathcal{K}(R) = \big\{X \in \mathcal{X}_L : E_L(X(s_j)) \leq R_j \text{ for all } j \geq 1\big\}$$

is compact for $\mathcal{T}_W$ and for d_c. Let $\{\lambda_\iota\}$ be a family of Borel probability measures on $\mathcal{X}_L$ such that

$$\lim_{R\to\infty} \sup_{\iota} \lambda_\iota\{E_L(X(s_j)) > R\} = 0 \qquad \text{for every } j \geq 1.$$

Then for every $\eta > 0$ there exists R with $\lambda_\iota(\mathcal{K}(R)) \geq 1-\eta$ for all ι, and every sequence in the family has a subsequence that converges, against every bounded $\mathcal{T}_W$-continuous function and weakly with respect to d_c, to a Borel probability measure on $\mathcal{X}_L$. Finally, if A is a smooth connection with $\|A\|_{C^1} \leq R$, then

$$E_L(\Phi_t[A]) \leq E_L(A) \leq CL^3(R+R^2)^2 \qquad (t \geq 0),$$

where C depends only on the normalization of the Lie-algebra norm.

No moment condition on the measures λ_ι is needed. Subsequential compactness from energy tightness is due to Cao and Chatterjee [43, Theorem 1.6, p. 7]. The theorem adds the explicit compact sets $\mathcal{K}(R)$, which are used in Section 29.4. We say that a family of Borel probability measures on $\mathcal{X}_L$ has *compact containment* if for every $\eta > 0$ some set $\mathcal{K}(R)$ has mass at least $1-\eta$ under every member of the family. Since the sets $\mathcal{K}(R)$ are compact for both $\mathcal{T}_W$ and d_c, this is compact containment in both topologies.

Proof. For probability measures on the trajectory space with its Wilson Borel σ-algebra, the energy at each positive time is measurable and nonincreasing in time [43, Lemma 1.5, p. 7; Lemma 4.1, p. 50]. The hypotheses on the group, the bundle, the scaling, and the gauge group were checked in Lemma 29.2, and the energy in the statement has exactly this normalization.

We consider the product $\prod_{j\geq 1} \Omega_{R_j}$ of subsets of $\mathcal{H}_L$. It is compact and metrizable, by Lemma 29.2(3) and a diagonal extraction of subsequences in the factors, using a summable bounded product metric. We impose the compatibility conditions

$$x_i = \Phi^{1,2}_{s_i - s_j} x_j \qquad (j > i). \tag{29.3}$$

Each of these equations defines a closed set, since $\mathcal{H}_L$ is Hausdorff and $\Phi^{1,2}_v$ is continuous for $\mathcal{T}_q$ (Lemma 29.2(3),(4)). The compatible subset is therefore compact. Given a compatible sequence (x_j), we define $Z(t) = \Phi^{1,2}_{t-s_j} x_j$ for any j with $s_j < t$. By (29.3) and the semigroup property, $Z(t)$ does not depend on j, and Z is compatible at all times. Fixing one j with $s_j < t$ for each t, we see that $Z(t)$ is a continuous function of x_j, and therefore the map $(x_j) \mapsto Z$ is continuous into $(\mathcal{X}_L^{1,2}, \mathcal{T}_{1,2})$. By Lemma 29.2(6), composing with $j^{1,2}$, we obtain a continuous map into $(\mathcal{X}_L, \mathcal{T}_W)$.

The image of this map is exactly $\mathcal{K}(R)$. To see this, let $k > j$; then $Z(s_j) = \Phi^{1,2}_{s_j - s_k} x_k = x_j$ by (29.3). Every x_j is therefore the orbit at time s_j of the trajectory, it has a smooth representative, and its energy is at most R_j. Conversely, the values $i^{1,2}X(s_j)$ of any

$X \in \mathcal{K}(R)$ form such a compatible sequence. As a continuous image of a compact set, $\mathcal{K}(R)$ is $\mathcal{T}_W$-compact, and by Theorem 29.3(2) it is also d_c-compact. It is Borel because the energies are measurable. The argument also covers an empty compatible set and thresholds equal to zero.

Let $\eta > 0$, and for each j fix R_j such that $\sup_\iota \lambda_\iota\{E_L(X(s_j)) > R_j\} \le \eta 2^{-j}$. By the union bound, we have $\lambda_\iota(\mathcal{K}(R)) \ge 1 - \eta$ for every ι. For any $t > 0$, choosing $s_j < t$ and using monotonicity, we see that the energy laws at time t are also tight. The subsequence theorem [43, Theorem 1.6, p. 7] applies to probability measures on this Borel space with tight energy laws at each positive time, and it yields a subsequence converging against every bounded $\mathcal{T}_W$-continuous function. Every bounded d_c-continuous function is $\mathcal{T}_W$-continuous by Theorem 29.3(2), and the same subsequence converges weakly for d_c.

Finally, $|[X, Y]| \le |X||Y|$ in our normalization, which implies that $|F_{ij}(A)| \le C(R + R^2)$ if $\|A\|_{C^1} \le R$. There are three pairs $i < j$ and the volume is L^3, which gives the bound on $E_L(A)$; the bound along the flow follows from monotonicity. □

Continuity of energy after a positive time

The determining coordinates w_j do not control the energy, and we do not know whether $X \mapsto E_L(X(t))$ is continuous for d_c or for $\mathcal{T}_W$. The heat flow provides a substitute: on the Sobolev quotient, the energy after any positive time is a continuous function of the initial orbit. This property lets us identify limits of lattice energies with energies of the limiting trajectories in Theorem 29.18.

Lemma 29.7. *Let $L > 0$ and $u > 0$. The function $[A] \mapsto E_L(\Phi_u^{1,2}[A])$ is continuous on $(\mathcal{H}_L, \mathcal{T}_q)$. Moreover, for every $t > 0$ the function $Z \mapsto E_L(Z(t))$ is continuous on $(\mathcal{X}_L^{1,2}, \mathcal{T}_{1,2})$. Here the energy of an orbit at a positive time is the energy of its smooth representatives, which does not depend on the representative.*

The lemma does not assert that $[A] \mapsto E_L(A)$ itself is continuous on $(\mathcal{H}_L, \mathcal{T}_q)$.

Proof. We work on the unit torus first. Let $A_n \rightharpoonup A$ weakly in H^1, and set $R_0 = \sup_n \|A_n\|_{H^1} + \|A\|_{H^1}$, which is finite. Fix $0 < v < \min(u, \tau_0(R_0))$, where $\tau_0(R_0)$ is the existence time of [43, Lemma 3.23, pp. 27–28]. By that lemma, the local solutions B_n, B of the gauge-fixed heat equation (in the DeTurck gauge) started at A_n, A satisfy $B_n(v) \to B(v)$ strongly in H^1. These endpoints are smooth, by [43, Proposition 3.19, pp. 26–27], and they represent the orbits $\Phi_v[A_n]$ and $\Phi_v[A]$, by [43, Lemma 3.21, p. 27]. Applying [43, Lemma 3.15, p. 25] to the smooth, strongly convergent initial data $B_n(v) \to B(v)$, we obtain strong H^1 convergence of representatives of the solutions of the covariant flow at time $u - v$, that is, of representatives of $\Phi_u[A_n]$ and $\Phi_u[A]$. The smooth-data lemma is applied only after the smoothing step, and never to the weakly convergent data A_n.

Strong H^1 convergence implies convergence of the energy, by the embedding $H^1 \subset L^4$:

$$\|F(C) - F(D)\|_2 \le C\big(1 + \|C\|_{H^1} + \|D\|_{H^1}\big)\|C - D\|_{H^1}.$$

Indeed, the derivative part of F is linear, and $[C_i, C_j] - [D_i, D_j] = [C_i - D_i, C_j] + [D_i, C_j - D_j]$ is bounded in L^2 by Hölder's inequality and the embedding. Multiplying by $\|F(C)\|_2 + \|F(D)\|_2$, we obtain convergence of the squared norms. By gauge invariance, $E_1(\Phi_u[A_n]) \to E_1(\Phi_u[A])$.

If $[A_n] \rightharpoonup_q [A]$, we apply this argument to weakly convergent representatives. Since $\mathcal{T}_q$ is generated by exactly this sequential convergence, [43, Lemma 3.38 and Corollary 3.39, p. 32; Lemma 3.41, p. 33] give continuity into $\mathbb{R}$; we do not replace weakly convergent nets by bounded sequences. For trajectories, we fix $s \in (0, t)$ and factor the energy as $Z \mapsto Z(s) \mapsto E_1(\Phi^{1,2}_{t-s} Z(s))$. Finally, the rescaling $\widetilde{A}(y) = LA(Ly)$, $\widetilde{t} = t/L^2$, $E_1(\widetilde{A}) = LE_L(A)$ of Lemma 29.2 transfers every assertion to side L. □

A countable dense family of trajectories and finite-dimensional approximation

Fix an enumeration $(b_q)_{q \ge 1}$ of the real $\mathfrak{su}(2)$-valued trigonometric polynomial one-forms on $\mathbb{T}^3_L$ with rational coefficients in a fixed basis, with $b_1 = 0$, and set

$$X_q(t) = \Phi_t[b_q], \qquad t > 0.$$

In particular, X_1 is the zero trajectory, $X_1(t) = [0]$ for all t. The trajectories X_q are the candidates among which the maps π_K of Section 29.4 choose.

Lemma 29.8. *Let $X \in \mathcal{X}_L$, let $W_{\ell_1,\chi_1,t_1}, \dots, W_{\ell_b,\chi_b,t_b}$ be finitely many Wilson loop functions, let $v_1, \dots, v_p > 0$, and let $\delta > 0$. Then there exists q such that*

$$|W_{\ell_h,\chi_h,t_h}(X_q) - W_{\ell_h,\chi_h,t_h}(X)| < \delta \quad (h \le b), \qquad |E_L(X_q(v_i)) - E_L(X(v_i))| < \delta \quad (i \le p).$$

Proof. Rational trigonometric polynomials are dense in C^3 in the space of smooth real one-forms. Indeed, integration by parts bounds the Fourier coefficients of a smooth form by $C_p(1 + |k|)^{-p}$, so for $p > 6$ the Fourier truncations converge in C^3, and the finitely many real sine and cosine coefficients of a truncation can be approximated by rational numbers. Since the frequencies are $2\pi k/L$, no rationality condition on L is needed.

For $\eta > 0$, let c_η be a smooth representative of $X(\eta)$. By compatibility, $\Phi_t[c_\eta] = X(t + \eta)$ for $t > 0$. Smooth forward evolution from an earlier positive time shows that the energy and the holonomies are continuous in time at each of the finitely many listed times. Then the listed values on $X(\cdot + \eta)$ converge to those on X as $\eta \downarrow 0$. Fix η such that all these errors are less than $\delta/2$. By Theorem 24.10, the listed energies and loops of the flow are continuous functions of the initial datum in C^3 on the finite horizon. Approximating c_η in C^3 by some b_q, we make the remaining errors less than $\delta/2$. The representative c_η is used only to prove the existence of q. □

Lemma 29.9. *Let $\mathcal{C} \subset \mathcal{X}_L$ be $\mathcal{T}_W$-compact, and let $h : \mathcal{X}_L \to \mathbb{R}$ be $\mathcal{T}_W$-continuous with $|h| \le D$. For every $\delta > 0$ there exist $b < \infty$ and a continuous function $G : [-1,1]^b \to [-D, D]$ such that*

$$\sup_{X \in \mathcal{C}} |h(X) - G(w_1(X), \dots, w_b(X))| < \delta.$$

This applies in particular to the compact sets $\mathcal{K}(R)$ of Theorem 29.6 and to $h = f(W_{\ell_1,\chi_1,t_1}, \dots, W_{\ell_m,\chi_m,t_m})$ with f bounded and continuous.

Proof. If $\mathcal{C}$ is empty, we take $G = 0$. Otherwise, by Theorem 29.3(2) the identity from $(\mathcal{C}, \mathcal{T}_W)$ to $(\mathcal{C}, d_c)$ is a continuous bijection from a compact space to a Hausdorff space, and it is a homeomorphism: closed subsets of the compact domain have compact, hence closed, images. Thus h is uniformly continuous on $(\mathcal{C}, d_c)$. Let $\rho > 0$ be such that $d_c(X, Y) < \rho$ with $X, Y \in \mathcal{C}$ implies $|h(X) - h(Y)| < \delta$. Fix b with $2^{1-b} < \rho/4$ and a finite $\rho/8$-net $X^1, \dots, X^l$ of $(\mathcal{C}, d_c)$. For $u, v \in [-1,1]^b$ and $X \in \mathcal{X}_L$ write

$$d_b(u,v) = \sum_{j \le b} 2^{-j} |u_j - v_j|, \qquad p_b X = (w_j(X))_{j \le b}, \qquad h_\alpha(u) = \big(\rho/2 - d_b(u, p_b X^\alpha)\big)_+,$$

and let $h_0(u)$ be the d_b-distance from u to the compact set $p_b\mathcal{C}$. The function $h_0 + \sum_\alpha h_\alpha$ is positive on the cube: off $p_b\mathcal{C}$ we have $h_0 > 0$, and on $p_b\mathcal{C}$ the net property gives some $h_\alpha > 0$. We define

$$G(u) = \frac{\sum_\alpha h_\alpha(u) h(X^\alpha)}{h_0(u) + \sum_\alpha h_\alpha(u)}.$$

Then G is continuous and $|G| \le D$. For $X \in \mathcal{C}$ we have $h_0(p_b X) = 0$, and $h_\alpha(p_b X) > 0$ implies $d_c(X, X^\alpha) < \rho/2 + 2^{1-b} < \rho$. Thus $G(p_b X)$ is a convex combination of values $h(X^\alpha)$ within δ of $h(X)$. □

29.2 Lattice observables and deterministic estimates

Lattice approximations of loops

Let $\ell, \ell' : [0,1] \to \mathbb{T}_L^3$ be piecewise C^1 loops with base points $x = \ell(0)$ and $x' = \ell'(0)$, and let c be a piecewise C^1 path from x to x' (the constant path if $x = x'$). A *comparison homotopy* between ℓ and ℓ' with connector c is a piecewise C^1 map $H : [0,1]^2 \to \mathbb{T}_L^3$ such that $H(\cdot, 0) = \ell$, $H(\cdot, 1)$ is a parametrization of the concatenation $c * \ell' * c^{-1}$, and $H(0, v) = H(1, v) = x$ for all $v \in [0,1]$. Its swept area is

$$\mathrm{Area}(H) = \int_0^1 \int_0^1 |\partial_u H \wedge \partial_v H| \, du \, dv,$$

where for $v, w \in \mathbb{R}^3$ we write $|v \wedge w|$ for the area of the parallelogram spanned by v and w. The swept area is counted with multiplicity: parts of the homotopy with opposite

orientations do not cancel. Since transport along a concatenation is the product of the transports, $\mathrm{Hol}_{c*\ell'*c^{-1}} A = (\mathrm{Hol}_c A)(\mathrm{Hol}_{\ell'} A)(\mathrm{Hol}_c A)^{-1}$, and the characters of $\mathrm{Hol}_{\ell'} A$ and $\mathrm{Hol}_{c*\ell'*c^{-1}} A$ coincide. In this language, a sequence of closed lattice paths (ℓ_k), with ℓ_k in Λ_{N_k} and $N_k \to \infty$, is an admissible approximation of ℓ in the sense of Definition 2.1 if the physical lengths of the ℓ_k are bounded and, for all sufficiently large k, there exists a comparison homotopy H_k between ℓ and ℓ_k (with some connector) such that $\mathrm{Area}(H_k) \to 0$.

Lemma 29.10. *Let $L > 0$, let ℓ be a piecewise C^1 loop in $\mathbb{T}^3_L$, and let $a = L/N$ with an integer $N \geq 4$. There exist a closed lattice path ℓ_a in Λ_N and a comparison homotopy H_a between ℓ and ℓ_a, whose connector is a straight segment of length at most $\sqrt{3}a/2$, such that*

$$\mathrm{length}(\ell_a) \leq C\big(\mathrm{length}(\ell) + L\big), \qquad \mathrm{Area}(H_a) \leq Ca\big(\mathrm{length}(\ell) + L\big), \tag{29.4}$$

where C is an absolute constant. The path ℓ_a has the same winding class as ℓ. The homotopy H_a is piecewise C^1, and piecewise smooth if ℓ is polygonal. If ℓ is constant, then ℓ_a is constant and $\mathrm{Area}(H_a) = 0$. The path ℓ_a and the homotopy H_a depend only on the parametrized loop ℓ and on a.

In particular, for every sequence of sides $N_k \to \infty$ the paths $\ell_{a_{N_k}}$ form an admissible approximation of ℓ, with swept areas $O(a_{N_k})$.

Proof. Let $x : [0,1] \to \mathbb{R}^3$ be the lift of ℓ with $x(0) \in [0,L)^3$; then $x(1) = x(0) + Lz$ for a unique $z \in \mathbb{Z}^3$. Set $\mathfrak{l} = \mathrm{length}(\ell)$. Suppose first that $\mathfrak{l} > 0$, and set $p = \lceil \mathfrak{l}/a \rceil$, so that $p \leq 1 + \mathfrak{l}/a$. We subdivide ℓ by arclength into p pieces of length $\mathfrak{l}/p \leq a$. At an interior subdivision value we take the earliest parameter with that accumulated length, and we keep the two endpoint parameters; this fixes the choice also when x is stationary on some subintervals. We write x_j, $0 \leq j \leq p$, for the subdivision points.

We round each coordinate by the rule

$$q_j^i = a\lfloor x_j^i/a + \tfrac{1}{2} \rfloor, \qquad \text{so that} \qquad |q_j - x_j| \leq \tfrac{\sqrt{3}}{2} a.$$

Since $L/a = N \in \mathbb{N}$, this rule commutes with translations by $L\mathbb{Z}^3$, and therefore $q_p = q_0 + Lz$. Let σ_j be the lattice path from q_j to q_{j+1} that changes first the first coordinate, then the second, and then the third, each monotonically, and let ℓ_a be the projection of the concatenation of the σ_j to the torus. It is closed and has the same winding class as ℓ. Its length satisfies

$$\sum_{j=0}^{p-1} |q_{j+1} - q_j|_1 \leq \sqrt{3} \sum_{j=0}^{p-1} |x_{j+1} - x_j| + 3pa \leq (\sqrt{3} + 3)\mathfrak{l} + 3a,$$

where we used $|q_{j+1} - q_j|_1 \leq \sqrt{3}|q_{j+1} - q_j| \leq \sqrt{3}|x_{j+1} - x_j| + 3a$ and $pa \leq \mathfrak{l} + a$. Since $a \leq L/4$, this proves the first bound in (29.4), including coarse meshes.

Let η_j be the jth subarc of the lift, from x_j to x_{j+1}, let $c_j = [x_j, q_j]$ be the straight segments, and let $\delta_j = c_j * \sigma_j * c_{j+1}^{-1}$, which also runs from x_j to x_{j+1}. The curves η_j, σ_j, c_j, and c_{j+1} lie in a ball of radius Ca about x_j. We parametrize η_j and δ_j on $[0,1]$, piecewise C^1, and consider the strip $H_j(u,v) = (1-v)\eta_j(u) + v\delta_j(u)$, whose endpoints are fixed. Since $|\partial_v H_j| = |\delta_j(u) - \eta_j(u)| \le Ca$, its swept area satisfies

$$\begin{aligned}\int_0^1\int_0^1 |\partial_u H_j \wedge \partial_v H_j|\,du\,dv &\le Ca\int_0^1\int_0^1 \big((1-v)|\eta_j'(u)| + v|\delta_j'(u)|\big)\,du\,dv\\ &\le Ca\big(\operatorname{length}(\eta_j) + \operatorname{length}(\delta_j)\big) \le Ca^2.\end{aligned}$$

For polygonal loops we may instead triangulate these strips by coning their polygonal boundaries to x_j; each triangle has area at most Ca times the length of its boundary edge, which gives the same bound and piecewise smooth strips. We concatenate the strips. The interior pairs $c_j^{-1} * c_j$ are removed by retracing homotopies, whose differentials have rank at most one and which therefore have zero swept area. The final connector is the initial one translated by Lz. After projection to the torus we obtain a comparison homotopy H_a between ℓ and ℓ_a with connector c_0, and since swept areas add,

$$\operatorname{Area}(H_a) \le Cpa^2 \le Ca(\mathfrak{l} + a) \le Ca(\mathfrak{l} + L).$$

All constructions take place in the lift before projection, and they are valid across the periodic identifications and at self-intersections. For piecewise C^1 loops the strips are piecewise C^1, which suffices for the holonomy variation formula of Lemma 29.11. If $\mathfrak{l} = 0$, we round $x(0)$ by the same rule and take the constant lattice loop at the rounded point; the connector followed by its inverse and the constant loop are related by a retracing homotopy of zero area. These rules involve only ℓ and a. □

Lemma 29.11. *Let $L > 0$ and let A be a smooth connection on $\mathbb{T}^3_L$.*

1. *Let $H : [0,1]^2 \to \mathbb{T}^3_L$ be piecewise C^1, with $H(0,v)$ and $H(1,v)$ independent of v. Then*

$$\big\|\operatorname{Hol}_{H(\cdot,1)} A - \operatorname{Hol}_{H(\cdot,0)} A\big\|_{\mathrm{op}} \le C\|F_A\|_\infty \operatorname{Area}(H),$$

   where C is an absolute constant. In particular, if H is a comparison homotopy between loops ℓ and ℓ' with connector c, then $\operatorname{Hol}_\ell A$ and $(\operatorname{Hol}_c A)(\operatorname{Hol}_{\ell'} A)(\operatorname{Hol}_c A)^{-1}$ differ by at most $C\|F_A\|_\infty \operatorname{Area}(H)$ in operator norm, and for every character χ and every A with $\|A\|_{C^1} \le R$,

$$|\chi(\operatorname{Hol}_\ell A) - \chi(\operatorname{Hol}_{\ell'} A)| \le C_\chi(R + R^2)\operatorname{Area}(H).$$

2. *Let $a = L/N$, and let U^A be the lattice configuration $U^A_{(x,x+ae_i)} = \exp(aA_i(x))$. If $\|A\|_{C^1} \le R$ and ℓ_a is a closed lattice path of physical length at most $\mathfrak{l}$, then $\|\operatorname{Hol}_{\ell_a} A - \operatorname{Hol}_{\ell_a} U^A\|_{\mathrm{op}} \le C_R \mathfrak{l} a$, and $|\chi(\operatorname{Hol}_{\ell_a} A) - \chi(\operatorname{Hol}_{\ell_a} U^A)| \le C_{\chi,R}\mathfrak{l} a$.*

3. *Let $\ell, \ell_K : [0,1] \to \mathbb{T}^3_L$ be piecewise C^1 loops with $\sup_K \operatorname{length}(\ell_K) < \infty$ and $\delta_K = \sup_u d_{\mathbb{T}^3_L}(\ell(u), \ell_K(u)) \to 0$. If $\delta_K < L/2$, then ℓ_K has the same winding class as ℓ, and there exists a comparison homotopy H_K between ℓ and ℓ_K, whose connector is the shortest segment from $\ell(0)$ to $\ell_K(0)$, such that*

$$\operatorname{Area}(H_K) \le \frac{\delta_K}{2}\big(\operatorname{length}(\ell) + \operatorname{length}(\ell_K)\big). \tag{29.5}$$

In particular, a sequence of closed lattice paths of bounded physical length that converges uniformly to ℓ, as parametrized loops, is an admissible approximation of ℓ.

The constants C_χ, C_R, and $C_{\chi,R}$ depend only on the indicated quantities.

Proof. (1) We first consider a piece of H on which H is C^2, and write $B = A(H)\partial_u H$ and $\widetilde{C} = A(H)\partial_v H$ for the pulled-back components of the connection. Let P solve $\partial_u P = PB$ with $P(0,v) = I$, so that $P(1,v) = \operatorname{Hol}_{H(\cdot,v)} A$, and set $Q = \partial_v P - P\widetilde{C} + \widetilde{C}(0,v)P$. Differentiating, we find

$$\partial_u Q = QB - P\big(\partial_u \widetilde{C} - \partial_v B + [B, \widetilde{C}]\big), \qquad Q(0,v) = 0.$$

The expression in parentheses is the curvature $F_A(H)(\partial_u H, \partial_v H)$. Since $\partial_u(QP^{-1}) = -PF_A(H)(\partial_u H, \partial_v H)P^{-1}$ and all transports are unitary, we obtain

$$\|Q(1,v)\|_{\mathrm{op}} \le C\|F_A\|_\infty \int_0^1 |\partial_u H \wedge \partial_v H|\, du. \tag{29.6}$$

If $H(0,v)$ and $H(1,v)$ do not depend on v, then $\widetilde{C}(0,v) = \widetilde{C}(1,v) = 0$, so $Q(1,v) = \partial_v P(1,v)$. Integrating (29.6) over $v \in [0,1]$, we obtain the first assertion. For a piece that is only C^1, we extend a C^1 lift slightly beyond its parameter rectangle by reflection, $f(-u,v) = 2f(0,v) - f(u,v)$ at the boundary $u = 0$ and analogously at the other sides, and mollify. The mollified maps and their first derivatives converge uniformly. By their integral form, the solutions of the transport equations then converge uniformly, and the integrands in (29.6) converge in L^1. The integrated identity and the inequality therefore pass to the C^1 piece. For a piecewise C^1 map we apply this on a finite subdivision of the parameter square into rectangles and cancel the internal transport terms, which refer to the same boundary curves. This holds irrespective of crossings and orientations. For a comparison homotopy, $H(0,v) = H(1,v)$ is the base point of ℓ, and $H(\cdot,1)$ is the concatenation $c * \ell' * c^{-1}$. A fixed character is Lipschitz on the compact group, and $\|F_A\|_\infty \le C(R + R^2)$ if $\|A\|_{C^1} \le R$.

(2) Let P be the exact transport along the edge from x to $x + ae_i$, that is, $P'(v) = P(v)A_i(x + ve_i)$, $P(0) = I$. By Duhamel's formula and unitarity,

$$\|P(a) - e^{aA_i(x)}\|_{\mathrm{op}} \le C \int_0^a |A_i(x + ve_i) - A_i(x)|\, dv \le C_R a^2.$$

Reversed edges satisfy the same bound. A closed lattice path of physical length at most ℓ has at most ℓ/a edges, and by telescoping the product of unitary matrices we obtain the bound $C_R \ell a$. The character bound follows since χ is Lipschitz on $\mathrm{SU}(2)$.

(3) Since $\delta_K < L/2$, the shortest displacement from $\ell(u)$ to $\ell_K(u)$ is unique and has a unique continuous lift $d_K(u) \in \mathbb{R}^3$ with $|d_K(u)| \le \delta_K$. Let q be a lift of ℓ, and set $q_K = q + d_K$, a lift of ℓ_K. Since $\ell(1) = \ell(0)$ and $\ell_K(1) = \ell_K(0)$, we have $d_K(1) = d_K(0)$. The two lifts therefore have the same displacement $q(1) - q(0)$ and the loops have the same winding class. The ruled homotopy $G_K(u, v) = q(u) + v d_K(u)$ descends to the torus. Differentiating piecewise, we find

$$|\partial_v G_K| \le \delta_K, \qquad \partial_u G_K = (1 - v) q'(u) + v q_K'(u),$$

so $\mathrm{Area}(G_K) \le \delta_K \int_0^1 \int_0^1 ((1 - v)|q'| + v|q_K'|)\, du\, dv$, which is the right side of (29.5). The endpoints $G_K(0, v) = G_K(1, v)$ move along the segment $c_K(v) = q(0) + v d_K(0)$ from $\ell(0)$ to $\ell_K(0)$. The homotopy $v \mapsto c_K|_{[0,v]} * G_K(\cdot, v) * (c_K|_{[0,v]})^{-1}$, suitably parametrized, is a comparison homotopy between ℓ and ℓ_K with connector c_K; the added retracing parts have differentials of rank at most one and contribute no swept area. This proves (29.5). The finitely many paths with $\delta_K \ge L/2$ may have another winding class; this does not affect convergence statements. □

Remark 29.12. Uniform convergence of the paths alone does not suffice for convergence of holonomies; the bound on the lengths in Definition 2.1 is needed. Consider a smooth periodic connection that agrees in a coordinate ball with $A = b x_1 \tau_3\, dx_2$, where $b \notin 4\pi\mathbb{Z}$, and the loops that traverse a square of side δ based at the origin $m_\delta = \lfloor \delta^{-2} \rfloor$ times. These loops converge uniformly to the constant loop, but their lengths $4 m_\delta \delta$ tend to infinity, and their holonomies $\exp(b m_\delta \delta^2 \tau_3)$ converge to $\exp(b\tau_3) \ne I$. Taking the sides of the squares to be integer multiples of the mesh gives the same example with lattice loops. The length and area conditions of Definition 2.1 exclude it.

Lattice loop observables

Definition 29.13. Let $N \ge 4$, let ℓ be a piecewise C^1 loop, let χ be a character of a finite-dimensional representation of $\mathrm{SU}(2)$, let $t > 0$, and let ℓ_N be a closed lattice path in Λ_N. Set

$$W^{\mathrm{lat}}_{N,\ell,\chi,t}(U) = \chi\big(\mathrm{Hol}_{\ell_N}(\Psi^{(N)}_t U)\big), \qquad U \in \mathcal{U}_N, \tag{29.7}$$

where the dependence on ℓ_N is suppressed. For the loops and times (ℓ_j, t_j) of Theorem 29.3, let ℓ_{j,a_N} be the lattice paths of Lemma 29.10, fixed once and for all j and N, and set

$$W^{\mathrm{lat}}_{N,j}(U) = \tfrac{1}{2} \operatorname{tr} \mathrm{Hol}_{\ell_{j,a_N}}\big(\Psi^{(N)}_{t_j} U\big), \qquad U \in \mathcal{U}_N. \tag{29.8}$$

On a sequence of sides $(N_K)_K$ we write $W^{\mathrm{lat}}_{K,\ell,\chi,t}$ and $W^{\mathrm{lat}}_{K,j}$ for these functions on $\mathcal{U}_{N_K}$.

The paths ℓ_{j,a_N} depend only on the loop and the mesh, and not on the configuration, on any parameter of the renormalization group, or on the coarse comparison side used below. By Lemma 29.10, along every sequence $N_K \to \infty$ they form admissible approximations of the loops ℓ_j, with swept areas $O(a_{N_K})$.

The Wilson flow and the holonomies of closed lattice paths are continuous and covariant under lattice gauge transformations, and a character removes the conjugation at the base point. The functions (29.7) and (29.8) are therefore continuous, in particular Borel, and invariant under all lattice gauge transformations on the whole configuration space. By unitarity, $|W^{\mathrm{lat}}_{N,\ell,\chi,t}| \le \chi(I)$, and the functions $W^{\mathrm{lat}}_{N,j}$ are real with absolute value at most one. In particular,

$$|w_j(X) - W^{\mathrm{lat}}_{N,j}(U)| \le 2 \qquad \text{for all } X \in \mathcal{X}_L,\ U \in \mathcal{U}_N. \tag{29.9}$$

The results of Section 28 allow characters of arbitrary finite-dimensional representations, including the unnormalized fundamental character. Whenever we apply Theorems 28.1 and 28.2 to the functions $W^{\mathrm{lat}}_{N,j}$, we apply them to the vector of fundamental characters and multiply its entries by $1/2$. This continuous linear map preserves joint convergence in law, and for complex source functionals it replaces the sources z_i by $z_i/2$. The limits are the corresponding joint laws of the determining coordinates w_j.

The lattice energy

Recall the physical lattice energy $\mathsf{E}_a(U) = (8/a)\sum_{p\in\mathcal{P}_N} q(U_p)$ of (2.2), $a = L/N$, in which each positive plaquette is counted once. In terms of the Wilson action S_W of Definition 4.1, which equals E_0, we have $\mathsf{E}_a = 2S_W/a$. For a lattice potential A at mesh a we write e^{aA} for the configuration with $(e^{aA})_{(x,x+ae_i)} = \exp(aA_i(x))$, and for a smooth one-form b on $\mathbb{T}^3_L$ we write $S_a b$ for its restriction to the lattice, $(S_a b)_i(x) = b_i(x)$.

Lemma 29.14. *Let $L > 0$ and $a = L/N$ with $N \ge 4$.*

1. *The function E_a is continuous on $\mathcal{U}_N$, invariant under lattice gauge transformations, and nonincreasing along the Wilson flow $\Psi^{(N)}_t = \Phi^{\mathrm{W}}_{4t/a^2}$.*
2. *For every $R > 0$ there exists $C_{L,R} < \infty$, independent of N, such that for lattice potentials A, B at mesh a with $\|A\|_{C^1_a}, \|B\|_{C^1_a} \le R$,*

$$|\mathsf{E}_a(e^{aA}) - \mathsf{E}_a(e^{aB})| \le C_{L,R}\|A - B\|_{C^1_a}, \qquad 0 \le \mathsf{E}_a(e^{aA}) \le C_{L,R}.$$

3. *For every smooth periodic one-form b we have $\mathsf{E}_a(e^{aS_a b}) \to E_L(b)$ as $a \to 0$. More precisely, if $\|b\|_{C^2} \le R$ and a is sufficiently small, then $|\mathsf{E}_a(e^{aS_a b}) - E_L(b)| \le C_{L,R}a$.*
4. *Let $\mathcal{E}_a(U) = (4/a)\sum_{p\in\mathcal{P}_N} q(U_p)$ be the normalization used in Section 24. Then $\mathsf{E}_a = 2\mathcal{E}_a$ on $\mathcal{U}_N$.*

The factor $8/a$ is chosen so that the limit in (3) is the energy E_L of (2.3), without a factor $1/2$; the exponent in (2.1) equals $\mathsf{E}_{a_N}/(2g_3^2)$. The point of (2) is that the Lipschitz constant does not depend on the mesh: a plaquette logarithm is $O(a^2)$, so a plaquette energy and its variation are $O(a^4)$, which compensates the factor a^{-1} and the $3(L/a)^3$ plaquettes.

Proof. (1) Continuity follows from the finite products and the trace. A lattice gauge transformation conjugates each plaquette matrix, which leaves $q(U_p)$ unchanged. Since E_a is a positive multiple of the Wilson action, it is nonincreasing along the negative gradient flow Φ^{W}, and the positive change of time $s = 4t/a^2$ does not affect this.

(2) We consider one plaquette $p_{ij}(x)$ and set

$$v = \big(aA_i(x),\, aA_j(x+ae_i),\, -aA_i(x+ae_j),\, -aA_j(x)\big).$$

For aR small, the expansion of the logarithm of a product of four exponentials in Lemma 24.2 reads

$$f_A = \operatorname{Log} U_{p_{ij}(x)} = \sum_{k=1}^{4} v_k + \frac{1}{2}\sum_{k<l}[v_k, v_l] + \mathcal{R}(v), \qquad |\mathcal{R}(v)| \le C|v|^3, \quad \|D\mathcal{R}(v)\| \le C|v|^2.$$

The bound on $D\mathcal{R}$ follows from Taylor's integral formula for the analytic logarithm of a word of fixed length: the remainder has vanishing Taylor coefficients up to order two, and its third derivative is bounded on a smaller fixed chart. The linear sum equals $a^2(D_i^+A_j - D_j^+A_i)(x)$. If we freeze the shifted entries at x, the quadratic sum equals $a^2[A_i(x), A_j(x)]$, and changing one entry back costs at most $C_R a^3$. We conclude that

$$a^{-2}f_A = D_i^+A_j - D_j^+A_i + [A_i, A_j] + O_R(a), \qquad |f_A| \le C_R a^2. \tag{29.10}$$

Let $\delta = \|A - B\|_{C_a^1}$. By the exact cancellation in the linear term, we have $|\sum v(A) - \sum v(B)| \le Ca^2\delta$, the difference of the quadratic terms is at most $C_R a^2\delta$, and the difference of the remainders is at most $C_R a^3\delta$. Thus $|f_A - f_B| \le C_R a^2\delta$. By (4.2), $q(e^f) = |f|^2/8 + O(|f|^4)$, and the differential of $f \mapsto q(e^f)$ has norm at most $C|f|$ on this chart. Hence the plaquette energies differ by at most $C_R a^4\delta$. There are $3(L/a)^3$ positive plaquettes, and multiplication by $8/a$ gives the bound $24L^3C_R\delta$, with no remaining power of the mesh. This proves the Lipschitz bound for $a \le a_0(L,R)$. Meshes $a > a_0$ correspond to finitely many sides $N < L/a_0$; for them, the differential of the unitary exponential and telescoping give the plaquette bound $Ca\|A - B\|_\infty$, which yields a Lipschitz constant $24CN^3 \le 24C(L/a_0)^3$. We enlarge $C_{L,R}$ to cover these meshes. Since $\mathsf{E}_a(I) = 0$, taking $B = 0$, we obtain $\mathsf{E}_a(e^{aA}) \le C_{L,R}R$, and we absorb R into the constant. Nonnegativity follows from $q \ge 0$ on $\mathrm{SU}(2)$.

(3) For $A = S_a b$, forward differences differ from derivatives by $O_R(a)$ on the ball $\|b\|_{C^2} \le R$. By (29.10) and the expansion of q,

$$\mathsf{E}_a(e^{aS_a b}) = a^3 \sum_{x\in\Lambda_N} \sum_{i<j} |F_{ij}(b)(x)|^2 + O_{L,R}(a).$$

Since the summand has bounded first derivatives on this ball, replacing the Riemann sum by the integral costs a further $O_{L,R}(a)$. Finally, since $|X|^2 = -2\,\mathrm{tr}\,X^2$ and $F_{ji} = -F_{ij}$, we have $\sum_{i,j} -\mathrm{tr}\,F_{ij}^2 = \sum_{i<j}|F_{ij}|^2$, and the limit is exactly $E_L(b)$.

(4) This is immediate from the definitions. □

Stability along the Wilson flow

We recall the setting of Sections 24 and 25. Fix $1/2 < \alpha < 2/3$ and a horizon $T_0 > 0$. For a lattice potential A_0 at mesh a, its linear and quadratic flow data are $x(t) = P_t^a A_0$ and $y = \mathcal{Q}_a(x,x)$. We measure them by the flow-data norm $\mathsf{X}_\alpha^a(x) + \mathsf{Y}_\alpha^a(y)$, with the norms of Definition 4.8 on $[0,T_0]$, including all physical first differences and shifts. For two potentials A_0, A_0' in the same gauge, with flow data (x,y) and (x',y'), we write

$$d_a = \mathsf{X}_\alpha^a(x-x') + \mathsf{Y}_\alpha^a(y-y').$$

On the smaller link coordinate domain used in Lemma 24.2, the Wilson flow has damped representatives: they are obtained by a time-dependent lattice gauge transformation and solve the gauge-fixed lattice equation of that lemma, whose linear part is the lattice heat equation. A finite reference family for a smooth solution of the Yang–Mills heat flow on a time interval $[s,T]$ consists of a finite partition of $[s,T]$, smooth solutions of the DeTurck equation on the subintervals, and fixed smooth gauge transformations at the partition times, as provided by Theorem 24.10. Each of these DeTurck solutions is a reference solution.

The first lemma transfers a small error at a positive time s to all later times up to a fixed horizon. It follows directly from the comparison with a fixed smooth reference in Lemma 25.5.

Lemma 29.15. *Let $0 < s < T$, and let b be a smooth solution of the Yang–Mills heat flow on $[s,T]$ with a finite reference family, consisting of DeTurck solutions $b^{(i)}$ on intervals I_i. For lattice meshes $a \to 0$, let V_a be configurations with representatives $V_a = e^{aA_a(s)}$ such that*

$$e_a = \|A_a(s) - S_a b(s)\|_\infty + \|D_a A_a(s) - S_a \partial b(s)\|_\infty \longrightarrow 0,$$

where D_a and ∂ denote all first differences and the corresponding derivatives. Then for all sufficiently small a, the Wilson flow $t \mapsto \Psi_{t-s}^{(N)} V_a$, $t \in [s,T]$, has representatives $A_a^{(i)}$ solving that gauge-fixed lattice equation on the intervals I_i, in the gauges of the reference family, such that

$$\max_i \sup_{t\in I_i} \|A_a^{(i)}(t) - S_a b^{(i)}(t)\|_{C_a^1} \le C(e_a + a).$$

The constant C and the smallness threshold depend only on L, the horizon $T - s$, the smooth bounds of the reference family, its gauge transformations, and its chart margins. They do not depend on the mesh, the coupling, or any probability measure, and the convergence $e_a \to 0$ may be arbitrarily slow.

Proof. We translate the initial time to zero, so that the horizon is $T - s$. By Taylor's formula in our difference conventions, $\|D_a S_a b(s) - S_a \partial b(s)\|_\infty \le Ca\|b(s)\|_{C^2}$, so

$$\eta_a = \|A_a(s) - S_a b(s)\|_{C^1_a} \le e_a + Ca\|b(s)\|_{C^2}.$$

Every reference solution of the family is smooth on its closed space-time domain, and in particular its spatial derivatives up to order five are bounded. The finitely many reference solutions and fixed smooth gauge transformations have common bounds, which are part of the data of the reference family and not bounds on higher derivatives of nearby lattice fields. The fixed-reference and finite-family parts of Lemma 25.5 choose the constants and the thresholds for the mesh and the initial error from these bounds, before the incoming error is made small. At the ith partition time, using (25.14) together with the change of gauge, we obtain a recursion

$$\eta_{i+1} \le G_i C_i(\eta_i + a) + d_i a$$

for the error η_i at the start of the ith interval, with finitely many constants G_i, C_i, d_i depending only on the reference family. Iterating it finitely many times, and taking the minimum of the resulting thresholds, we obtain

$$\max_i \sup_{t \in I_i} \|A_a^{(i)}(t) - S_a b^{(i)}(t)\|_{C^1_a} \le C(\eta_a + a) \le C'(e_a + a).$$

The same lemma keeps the representatives inside the coordinate domain of Lemma 24.2, with the required positive distance from its boundary. It also identifies the solution of the gauge-fixed lattice equation on each interval with the Wilson flow, whose time normalization $4t/a^2$ is that of Lemma 24.2. Since $e_a \to 0$ and $a \to 0$, the thresholds are eventually satisfied. □

Theorem 29.16. *Fix $L, T_0, R > 0$, $1/2 < \alpha < 2/3$, $0 < \tau \le T < \infty$, and u as in Lemma 25.9, together with finitely many characters $\chi_1, \dots, \chi_b$ and lengths $\mathfrak{l}_1, \dots, \mathfrak{l}_b > 0$. There exist $a_* > 0$ and $C < \infty$, depending only on these data, with the following property. Let $a = L/N \le a_*$, and let U, U' be the configurations of two lattice potentials at mesh a in the same gauge, whose flow data have norms at most R on $[0, T_0]$ and discrepancy d_a. Then*

$$\sup_{\tau \le t \le T} \Big(\big|\mathsf{E}_a(\Psi_t^{(N)} U) - \mathsf{E}_a(\Psi_t^{(N)} U')\big| + \sum_{i=1}^{b} \big|\chi_i(\mathrm{Hol}_{\ell_{i,a}} \Psi_t^{(N)} U) - \chi_i(\mathrm{Hol}_{\ell_{i,a}} \Psi_t^{(N)} U')\big| \Big) \le C d_a \tag{29.11}$$

for all closed lattice paths $\ell_{i,a}$ in Λ_N of physical length at most $\mathfrak{l}_i$, and

$$\sup_{\tau\le t\le T} \mathsf{E}_a(\Psi_t^{(N)}U) \le C.$$

The constants do not depend on the coupling, on any probability measure, or on the number of averaging steps. The estimate requires no convergence of the configurations as $a \to 0$, no condition on swept areas, and no bound on higher derivatives, and it has no additive error term in the mesh. This allows us to apply it to finite-scale reconstructions with a growing number of scales.

Proof. Let δ, K be the constants of Lemma 25.9. Suppose first that $d_a \le \delta$. By that lemma, the two Wilson flows have damped representatives B, B', solving the gauge-fixed lattice equation on the intervals of a common reference family. They satisfy the individual bounds $\|B(t)\|_{C_a^1}, \|B'(t)\|_{C_a^1} \le K$ and the difference bound $\|B(t) - B'(t)\|_{C_a^1} \le Cd_a$. By gauge invariance and Lemma 29.14(2), the energies differ by at most $C_{L,K}Cd_a$, and each energy is bounded on every interval. Explicitly, a plaquette logarithm is $O_K(a^2)$, the difference of two of them is $O_K(a^2\|B - B'\|_{C_a^1})$, and, since the differential of $f \mapsto q(e^f)$ is $O(|f|)$, the difference of two plaquette energies is $O_K(a^4\|B - B'\|_{C_a^1})$. The normalization cancels as

$$\frac{8}{a}\cdot 3\Big(\frac{L}{a}\Big)^3 C_K a^4 \|B - B'\|_{C_a^1} = 24L^3C_K\|B - B'\|_{C_a^1}.$$

This is the energy E_a, not $\mathcal{E}_a$. For the loops we apply Corollary 25.11 at each $t \in [\tau, T]$; its constant is uniform over the times in $[\tau, T]$ and over all paths within the length bounds. The observables are continuous in t, which joins the finitely many intervals. If $d_a > \delta$, we use the individual energy bound and $|\chi_i| \le \chi_i(I)$: the left side of (29.11) is at most $2C + 2\sum_i \chi_i(I) \le (2C + 2\sum_i \chi_i(I))d_a/\delta$, and we enlarge C accordingly. All constants were fixed before the two configurations were chosen. □

The last deterministic statement concerns a fixed compact family of smooth fields: the cardinal interpolants, in the sense of Lemma 16.3, of arrays on a fixed coarse mesh. Here the constants may depend on all derivatives of the family, unlike those of Theorem 29.16.

Lemma 29.17. *Fix a coarse mesh $h > 0$, a bound $M_h < \infty$, a finite horizon, and the cardinal basis, and let f range over the cardinal interpolants of arrays on the lattice of mesh h with supremum at most M_h, as in Lemma 28.4. Let $0 < \tau < T < \infty$, and let $\ell_1, \dots, \ell_b$ be loops with characters $\chi_1, \dots, \chi_b$ and time-independent admissible approximations $(\ell_{i,a})$, with comparison homotopies of swept area $\mathcal{A}_{i,a} \to 0$. Then, as $a \to 0$ along meshes compatible with h, the paths*

$$t \mapsto \Big(\mathsf{E}_a\big(\Psi_t^{(N)}e^{af|_a}\big),\ \big(\chi_i(\mathrm{Hol}_{\ell_{i,a}}\Psi_t^{(N)}e^{af|_a})\big)_{i\le b}\Big), \qquad t \in [\tau, T],$$

converge uniformly in $t \in [\tau, T]$, and uniformly over the family, to the paths $t \mapsto (E_L(\Phi_t[f]), (\chi_i(\mathrm{Hol}_{\ell_i}\Phi_t[f]))_{i\le b})$. More precisely, the uniform distance between these paths is at most

$$C_{h,M_h,\tau,T,\mathscr{W}}\big(a + \max_i \mathcal{A}_{i,a}\big), \tag{29.12}$$

where $\mathscr{W}$ denotes the list of loops, characters, and lengths. The limit map from arrays to $C([\tau,T];\mathbb{R}\times\mathbb{C}^b)$ is continuous.

Proof. We use the finite reference families and the consistency of the lattice flow with the sampled smooth flow in the proof of Lemma 28.4. On each reference interval the C^1_a distance between the damped representative and the sampled reference solution tends to zero uniformly over the family. The Lipschitz bound and the consistency for smooth samples in Lemma 29.14 bound the error in the energy by $C\|A_a - S_a b\|_{C^1_a} + Ca$. The reference bounds are uniform over this compact family and its finitely many reference families. The error in the loops is at most $C(a + \mathcal{A}_{i,a})$, by Lemma 29.11(1),(2) (as in the proof of Lemma 28.4), plus the propagated error in the potential. All these bounds are uniform in time, which gives (29.12). The continuity of the limit map follows from the smooth dependence of the flow on its initial datum and the continuity of the energy in C^1. □

29.3 Joint convergence under the conditioned measures

Standing assumptions. In Sections 29.3 to 29.5 we fix $L > 0$ and an odd integer $M \ge 3$, together with the integer J, the remaining parameters Θ of the small-field event, and the coupling bound $\gamma_0 \in (0,1]$ of Theorem 23.2, for which Theorem 23.9 holds. We fix $\gamma \in (0,\gamma_0]$ and $n_* \in 4\mathbb{N}$, and set $B = M^J$, $N_K = n_* B^K$, $a_K = L/N_K$, and $n_r = n_* B^r$. For $0 \le r \le K$ let

$$\nu_{K|r} = \nu_{N_K,n_r,\gamma} = \mu_{N_K,\gamma}\big(\,\cdot \mid S_{N_K,n_r,\gamma}\big), \qquad e_{K|r} = \mu_{N_K,\gamma}\big(S^c_{N_K,n_r,\gamma}\big)$$

be the conditioned Wilson measure with coarse side n_r and the corresponding small-field failure probability. Let $\mathcal{R}$ be the set of indices r for which Theorem 28.8, and hence Theorems 28.1 and 28.2, apply at the coarse side n_r; this set is infinite. By Theorem 23.9, as recorded in Theorem 28.2, for $r \in \mathcal{R}$ we have

$$e_{K|r} \le \epsilon_K + F_\gamma(n_r), \qquad \epsilon_K \to 0 \ (K\to\infty), \qquad F_\gamma(n_r) \to 0 \ (r\to\infty), \tag{29.13}$$

and one may take $\epsilon_K = 0$ and $F_\gamma(u) = C' u^3 e^{-\bar{c}u/\gamma} + C_{\mathrm{w}} u^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mu/\gamma}}$.

The conditioning is removed by the following elementary identity. If $e_{K|r} < 1$, then $\mu_{N_K,\gamma} = (1 - e_{K|r})\nu_{K|r} + e_{K|r}\rho_{K|r}$ with $\rho_{K|r} = \mu_{N_K,\gamma}(\,\cdot \mid S^c_{N_K,n_r,\gamma})$ (any probability measure if $e_{K|r} = 0$). In particular,

$$\mu_{N_K,\gamma}(\mathcal{B}) \le \nu_{K|r}(\mathcal{B}) + e_{K|r} \qquad \text{for every Borel event } \mathcal{B}, \tag{29.14}$$

and $|\mathbb{E}_{\mu_{N_K,\gamma}} F - \mathbb{E}_{\nu_{K|r}} F| \le D e_{K|r}$ for every measurable F with $0 \le F \le D$, and $\le 2 e_{K|r} \|F\|_\infty$ for every bounded complex measurable F (Lemma 5.5). We always use these bounds in the following order: first $K \to \infty$ at a fixed $r \in \mathcal{R}$, and then $r \to \infty$ in $\mathcal{R}$.

Finite-scale reconstructions. Fix $r \in \mathcal{R}$ and write $n = n_r$ and $\nu_K = \nu_{nB^K,n,\gamma}$, so that $\nu_K = \nu_{K+r|r}$. We recall the following objects from Theorem 28.8, with input horizon $T_0 = L^2$; they are all defined on the probability space $(\mathcal{U}_{nB^K}, \nu_K)$. Backward reconstruction of U with the reconstruction maps of Theorem 15.12 gives arrays A_j, $0 \le j \le K$, on the lattices of mesh $a_j = (L/n)B^{-j}$, and the configuration $e^{a_K A_K}$ is a gauge representative of U. For $0 \le q \le K$, the finite-scale reconstruction from the first q renormalization group steps from the coarse side is the fine configuration $U_K^{[q]} = \exp(a_K I_{a_q \to a_K} A_q)$, where $I_{a_q \to a_K}$ is the cardinal interpolation of Lemma 16.3. Its flow data at mesh a_K are $x_q = P^{a_K} I_{a_q \to a_K} A_q$ and $y_q = \mathcal{Q}_{a_K}(x_q, x_q)$, and those of U are x_K, y_K. We set

$$\mathsf{R}_K = \mathsf{X}_\alpha^{a_K}(x_K) + \mathsf{Y}_\alpha^{a_K}(y_K), \qquad \rho(R) = \sup_{K \ge 0} \nu_K\{\mathsf{R}_K > R\},$$
$$D_{K,q} = \mathsf{X}_\alpha^{a_K}(x_K - x_q) + \mathsf{Y}_\alpha^{a_K}(y_K - y_q).$$

By Theorem 28.8, we have $\rho(R) \to 0$ as $R \to \infty$ and

$$\lim_{q \to \infty} \sup_{K \ge q} \nu_K\{D_{K,q} > \eta\} = 0 \qquad \text{for every } \eta > 0. \tag{29.15}$$

For each fixed q, there exists a compact set $\mathcal{C}_q$ of arrays, independent of $K \ge q$, that supports the law of A_q under every ν_K. These laws converge weakly as $K \to \infty$ to a law supported on $\mathcal{C}_q$ (Theorem 15.13). Let f_q be the cardinal interpolant of A_q on the torus, a one-form, and let $\lambda_q = \lambda_{r,q}$ be the law of the trajectory $t \mapsto \Phi_t[f_q]$ when A_q has this limiting law.

Theorem 29.18. *Assume the standing assumptions, and let $r \in \mathcal{R}$. There exists a Borel probability measure λ_r on $\mathcal{X}_L$, written $\lambda_{r,\gamma}$ when the coupling is displayed, with the following properties.*

1. *As $q \to \infty$, every finite vector of energies $E_L(X(v))$, $v > 0$, and functions $W_{\ell,\chi,t}$ under $X \sim \lambda_q$ converges in law to the same vector under $X \sim \lambda_r$, and $(i^{1,2})_\# \lambda_q \to (i^{1,2})_\# \lambda_r$ against bounded $\mathcal{T}_{1,2}$-continuous functions.*
2. *Let $v_1, \dots, v_p > 0$. For $h \le b$ let ℓ_h be loops with admissible approximations $(\ell_{h,K})_K$ along $(N_K)_K$, let χ_h be characters, let $t_h > 0$, and write $W_{K,h}^{\mathrm{lat}} = \chi_h(\mathrm{Hol}_{\ell_{h,K}} \Psi_{t_h}^{(N_K)} U)$. Then, under $\nu_{K|r}$, as $K \to \infty$,*

$$\Big(\big(\mathsf{E}_{a_K}(\Psi_{v_i}^{(N_K)} U)\big)_{i \le p}, \big(W_{K,h}^{\mathrm{lat}}\big)_{h \le b} \Big) \Longrightarrow \Big(\big(E_L(X(v_i))\big)_{i \le p}, \big(W_{\ell_h,\chi_h,t_h}(X)\big)_{h \le b} \Big),$$

where $X \sim \lambda_r$.

3. *Suppose that the paths $\ell_{h,K}$ do not depend on the time, and let $0 < \tau < T < \infty$. Then, under $\nu_{K|r}$, the processes*

$$t \mapsto \Big(\mathsf{E}_{a_K}(\Psi_t^{(N_K)}U), \big(\chi_h(\mathrm{Hol}_{\ell_{h,K}}\Psi_t^{(N_K)}U)\big)_{h\le b}\Big), \qquad t \in [\tau, T],$$

converge in law in $C([\tau,T];\mathbb{R}\times\mathbb{C}^b)$ to $t \mapsto (E_L(X(t)), (W_{\ell_h,\chi_h,t}(X))_{h\le b})$ with $X \sim \lambda_r$. If $(\ell'_{h,K})_K$ are other time-independent admissible approximations of the same loops, then

$$\lim_{K\to\infty} \mathbb{E}_{\nu_{K|r}} \sup_{\tau\le t\le T} \max_{h\le b} \big|\chi_h(\mathrm{Hol}_{\ell_{h,K}}\Psi_t^{(N_K)}U) - \chi_h(\mathrm{Hol}_{\ell'_{h,K}}\Psi_t^{(N_K)}U)\big| = 0.$$

4. *For admissible approximations with swept areas $O(a_K)$, in particular those of Definition 29.13, the limit laws of the loop vectors in (2) are those of Theorem 28.1.*
5. *For every $t > 0$,*

$$\lim_{A\to\infty} \sup_{K\ge r} \nu_{K|r}\big\{\mathsf{E}_{a_K}(\Psi_t^{(N_K)}U) > A\big\} = 0, \qquad \lim_{A\to\infty} \sup_{K\ge 0} \mu_{N_K,\gamma}\big\{\mathsf{E}_{a_K}(\Psi_t^{(N_K)}U) > A\big\} = 0.$$

All convergence moduli are at the fixed coupling γ and, for the conditioned measures, at the fixed index r.

Proof. We fix $r \in \mathcal{R}$ and use the reindexed measures ν_K and the notation introduced above; the statements for $\nu_{K|r}$ follow by the shift $K \mapsto K + r$. We first construct the laws λ_q and show that the lattice observables of U are close in law to those of the finite-scale reconstructions, whose limits are continuum observables under λ_q; this produces joint limits of the lattice observables. We then prove that the energies under λ_q are tight, extract a limit λ_r using the compactness theorem of Cao and Chatterjee for Sobolev trajectories, identify λ_r by its Wilson loops, and use the continuity of energies after a positive time (Lemma 29.7) to identify the joint limits of energies and loops.

Step 1: the laws λ_q. The map from arrays A_q to the initial datum f_q is linear and continuous in every smooth norm, and by Theorem 24.10 the smooth flow depends continuously on its initial datum on every finite horizon. Hence every determining coordinate w_j of the trajectory $t \mapsto \Phi_t[f_q]$ is a continuous function of the array. Since the Borel σ-algebra of $\mathcal{X}_L$ is generated by the w_j (Theorem 29.3), the map from arrays to trajectories is measurable, and λ_q is a Borel probability measure on $\mathcal{X}_L$. Its image $(i^{1,2})_\#\lambda_q$ is a Borel probability measure on $\mathcal{X}_L^{1,2}$, by Step 4 of the proof of Theorem 29.3.

Step 2: approximation by finite-scale reconstructions. Fix a finite list as in (2), respectively a time-independent list and an interval $[\tau, T]$ as in (3). Let Z_K be the corresponding finite vector, respectively path, of observables of U, with values in the complete separable metric space $E = \mathbb{R}^p \times \mathbb{C}^b$, respectively $E = C([\tau,T];\mathbb{R}\times\mathbb{C}^b)$, which we equip with the

bounded metric $d = \min(2, \|\cdot\|_\infty)$. Let $Z_K^{[q]}$ be the same observables of the finite-scale reconstruction $U_K^{[q]}$, on the same probability space $(\mathcal{U}_{nB^K}, \nu_K)$. Since $e^{a_K A_K}$ is a gauge representative of U and the observables are gauge invariant, Z_K is the observable of the conditioned configuration itself, not merely a random variable with the same law.

On the event $\{\mathsf{R}_K \le R,\ D_{K,q} \le \eta\}$ with $\eta \le 1$, both flow data have norm at most $R+1$, and the two potentials are in the same gauge. By Theorem 29.16 at radius $R+1$, applied on an interval containing all times of the list, we have $d(Z_K, Z_K^{[q]}) \le C_R \eta$ whenever $a_K \le a_*(R+1)$. We conclude that, for every test function ϕ on E bounded by one and with Lipschitz constant at most one,

$$\left|\mathbb{E}_{\nu_K}\phi(Z_K) - \mathbb{E}_{\nu_K}\phi(Z_K^{[q]})\right| \le C_R\eta + 2\rho(R) + 2\nu_K\{D_{K,q} > \eta\} \tag{29.16}$$

for all K with $a_K \le a_*(R+1)$. This threshold does not depend on q. By (29.15), the right side of (29.16) tends to zero, uniformly in $K \ge q$, if we choose first R large, then η small, and then q large, as in the proof of Theorem 28.1.

Fix q, and let G be the map that sends a trajectory to the continuum energies and Wilson loops of the list. By Lemma 29.17, applied with the coarse mesh a_q and the compact set $\mathcal{C}_q$, the observables of $U_K^{[q]}$ converge as $K \to \infty$, uniformly for $A_q \in \mathcal{C}_q$, to the continuous function $A_q \mapsto G(t \mapsto \Phi_t[f_q])$. Combining this with the weak convergence of the laws of A_q, which are all supported on $\mathcal{C}_q$, we obtain $Z_K^{[q]} \Rightarrow G_\# \lambda_q$. The observable maps converge uniformly on $\mathcal{C}_q$ to a continuous map, and each fixed-K map is continuous on $\mathcal{C}_q$. By uniform convergence, compactness of $\mathcal{C}_q$, and completeness of E, the union of their images has compact closure, and so does the union of the supports of the laws of $Z_K^{[q]}$, $K \ge q$. Each Z_K has compact support, since the compact configuration space is mapped continuously into E by the finite-dimensional Wilson flow. By Lemma 28.9, a version of the converging-together principle [28, Theorem 3.2] that also constructs the limit, the laws of Z_K converge to a probability measure ρ_G on E. Letting $K \to \infty$ at fixed q in (29.16), we find that $G_\#\lambda_q \to \rho_G$ as $q \to \infty$. The argument applies to every finite list, and in particular to the union of any two lists. The limits are therefore consistent under unions and projections, and we never combine separately obtained marginal limits.

Step 3: tightness of the energies under λ_q. Let $t > 0$ and $\varepsilon > 0$. Fix R with $\rho(R) < \varepsilon$. By (29.15), for all sufficiently large q we have $\sup_{K \ge q} \nu_K\{D_{K,q} > 1\} < \varepsilon$, and we may also assume $a_q \le a_*(R+1)$, so that $a_K \le a_*(R+1)$ for all $K \ge q$. On the event $\{\mathsf{R}_K \le R,\ D_{K,q} \le 1\}$ the flow data of $U_K^{[q]}$ have norm at most $R+1$, and by the individual bound in Theorem 29.16 we have $\mathsf{E}_{a_K}(\Psi_t^{(nB^K)} U_K^{[q]}) \le C_{R,t}$ for a deterministic $C_{R,t}$. Let ϕ be continuous, with $\phi = 0$ on $(-\infty, C_{R,t}]$, $\phi = 1$ on $[C_{R,t}+1, \infty)$, and $0 \le \phi \le 1$. Then $\mathbb{E}_{\nu_K}\phi(\mathsf{E}_{a_K}(\Psi_t^{(nB^K)} U_K^{[q]})) \le 2\varepsilon$ for $K \ge q$. Letting $K \to \infty$, by Lemma 29.17 and the

convergence of the law of A_q, we obtain

$$\lambda_q\{E_L(X(t)) > C_{R,t} + 1\} \leq \mathbb{E}_{\lambda_q}\phi\big(E_L(X(t))\big) \leq 2\varepsilon.$$

The finitely many smaller q have laws supported on compact sets of smooth initial data, and their energies at time t are bounded. We conclude that the energies at time t are tight under $\{\lambda_q\}_{q\geq 0}$, for every $t > 0$.

Step 4: the limit λ_r. The compactness theorem for Sobolev trajectories [43, Theorem 3.73, pp. 41–42] applies to Borel $\mathcal{X}_L^{1,2}$-valued random variables whose energy laws at each positive time are tight, which we have just verified for $(i^{1,2})_\#\lambda_q$. For fixed L we use the rescaling of Lemma 29.2. We obtain a subsequence along which $(i^{1,2})_\#\lambda_q$ converges, against bounded $\mathcal{T}_{1,2}$-continuous functions, to a Borel probability measure η on $\mathcal{X}_L^{1,2}$. We set $\lambda_r = (j^{1,2})_\#\eta$, a Borel probability measure on $\mathcal{X}_L$. By Lemma 29.2(6),(7), $j^{1,2}$ preserves the functions $W_{\ell,\chi,t}$, and these are continuous on $\mathcal{X}_L^{1,2}$. Hence the finite joint laws of the functions $W_{\ell,\chi,t}$ under λ_r are the limits of those under λ_q along the subsequence. By Step 2, these are the marginals of the limits ρ_G, so they do not depend on the subsequence. By Theorem 29.3(4), λ_r does not depend on the subsequence. Since $i^{1,2}j^{1,2} = \mathrm{Id}$, we have $\eta = (i^{1,2})_\#\lambda_r$, so the limit η is unique. The whole sequence $(i^{1,2})_\#\lambda_q$ therefore converges to $(i^{1,2})_\#\lambda_r$: otherwise a subsequence would stay away from it, and a further subsequence would converge to $(i^{1,2})_\#\lambda_r$, a contradiction.

Step 5: identification of the energies. By Lemma 29.7, for every $v > 0$ the function $Z \mapsto E_L(Z(v))$ is continuous on $(\mathcal{X}_L^{1,2}, \mathcal{T}_{1,2})$; one factors the evaluation at time v through an earlier time $s \in (0, v)$. The functions $W_{\ell,\chi,t} \circ j^{1,2}$ are continuous as well. Applying bounded continuous functions to the whole vector, we see from Step 4 that every finite vector of energies and Wilson loops under λ_q converges in law to the same vector under λ_r. This proves (1). By Step 2 applied to finite vectors, the same vectors under λ_q converge to the limit law ρ_G of the lattice observables. We conclude that ρ_G is the law of the continuum vector under λ_r, which proves (2). This step uses the continuity of the energy after a positive time; measurability of the energy, or convergence of the energy marginals separately, would not suffice.

Step 6: paths and comparison of approximations. In the setting of (3), the limit ρ_G is a probability measure on continuous paths, and by Step 5 its finite-dimensional distributions at rational times coincide with those of $G_\#\lambda_r$. Evaluations at rational times generate the Borel σ-algebra of $C([\tau, T]; \mathbb{R} \times \mathbb{C}^b)$ and determine probability measures on it, and the continuum path map G is Borel for the same reason. This implies that $\rho_G = G_\#\lambda_r$. For two time-independent admissible approximations, we apply this to the union of the two lists. In the limit, the corresponding loop paths coincide. The supremum over $[\tau, T]$ of their maximal difference is a continuous function of the joint path, bounded by

$2\max_h \chi_h(I)$. It converges in law to zero, and since it is bounded, its expectation tends to zero. This proves (3).

For approximations with swept areas $O(a_K)$ and lists consisting only of loops, Step 2 is the argument of Theorem 28.1, and both limits are the limits as $q \to \infty$ of the laws $G_\# \lambda_q$; this proves (4).

Step 7: tails of the lattice energies. The tails under the conditioned measures follow from the tightness of R_K and the individual energy bound of Theorem 29.16, applied with $U' = U$. The finitely many meshes above the threshold a_* are covered by the deterministic bound $\mathsf{E}_a(U) \le (8/a) \cdot 3N^3 \cdot 2 = 48N^3/a$, since $0 \le q \le 2$. For the Wilson measures we use (29.14) and (29.13):

$$\mu_{N_K,\gamma}\{\mathsf{E}_{a_K}(\Psi_t^{(N_K)}U) > A\} \le \nu_{K|r}\{\mathsf{E}_{a_K}(\Psi_t^{(N_K)}U) > A\} + \epsilon_K + F_\gamma(n_r).$$

We take the limit superior as $K \to \infty$, then let $A \to \infty$ at fixed r, and finally let $r \to \infty$ in $\mathcal{R}$. This shows that $\lim_{A\to\infty} \limsup_{K\to\infty} \mu_{N_K,\gamma}\{\mathsf{E}_{a_K}(\Psi_t^{(N_K)}U) > A\} = 0$. The finitely many remaining sides N_K have the deterministic bound $48N_K^3/a_K$, which proves (5). □

29.4 Measurable approximation by smooth trajectories

We now construct Borel maps π_K that approximate the lattice Wilson loop coordinates by smooth trajectories, subject to one-sided energy bounds. The maps choose from the countable family of trajectories X_q of Lemma 29.8, so no measurable choice of gauges is needed. The energy bounds transfer the tightness of the lattice energies to the trajectories $\pi_K(U)$. The map π_K is an auxiliary measurable approximation, not a canonical continuum interpolation of a lattice configuration.

Theorem 29.19. *Assume the standing assumptions of Section 29.3. Let $(X_q)_{q\ge1}$ be the trajectories of Lemma 29.8, let w_j and $W^{\mathrm{lat}}_{K,j}$ be as in Theorem 29.3 and Definition 29.13, and set $s_i = L^2 2^{-i}$ and $\varepsilon_m = 2^{-m}$. For $m \ge 1$, $K \ge 0$, and $U \in \mathcal{U}_{N_K}$, we say that q satisfies the level-m conditions at U if*

$$\begin{aligned} |w_j(X_q) - W^{\mathrm{lat}}_{K,j}(U)| &< \varepsilon_m && (j \le m),\\ E_L(X_q(s_i)) &< \mathsf{E}_{a_K}(\Psi_{s_i}^{(N_K)}U) + \varepsilon_m && (i \le m). \end{aligned} \tag{29.17}$$

Let $\pi_{K,m}(U) = X_q$ for the least q satisfying the level-m conditions at U, let $\pi_{K,m}(U) = X_1$, the zero trajectory, if there is no such q, and let $\pi_{K,0} = X_1$. Then the following statements hold.

1. *Each map $\pi_{K,m} : \mathcal{U}_{N_K} \to \mathcal{X}_L$ is Borel and invariant under all lattice gauge transformations.*
2. *For each fixed $m \ge 1$, the probability that no q satisfies the level-m conditions tends to zero as $K \to \infty$, both under $\nu_{K|r}$ for every $r \in \mathcal{R}$ and under $\mu_{N_K,\gamma}$.*

3. *There exists a nondecreasing sequence of integers $m(K) \to \infty$, depending only on the data fixed in the standing assumptions and not on U, such that the maps $\pi_K = \pi_{K,m(K)}$ satisfy, for every $r \in \mathcal{R}$, every $j \geq 1$, and every $t > 0$,*

$$\lim_{K\to\infty} \mathbb{E}_{\nu_{K|r}} |w_j(\pi_K(U)) - W^{\mathrm{lat}}_{K,j}(U)| = 0, \qquad \lim_{R\to\infty} \sup_{K\geq r} \nu_{K|r}\big\{E_L(\pi_K(U)(t)) > R\big\} = 0,$$

and such that the image measures $(\pi_K)_{\#}\nu_{K|r}$ converge to λ_r against every bounded $\mathcal{T}_W$-continuous function and weakly with respect to d_c.

4. *Let $\mathscr{W}$ be a finite list of loops with admissible approximations, characters, and positive times as in Theorem 29.18(2), with lattice vector $\mathscr{W}^{\mathrm{lat}}_K(U)$ and continuum vector $\mathscr{W}(X)$. Then for every bounded continuous function f of this vector and every $r \in \mathcal{R}$,*

$$\lim_{K\to\infty} \mathbb{E}_{\nu_{K|r}} \big| f(\mathscr{W}(\pi_K(U))) - f(\mathscr{W}^{\mathrm{lat}}_K(U)) \big| = 0.$$

The sequence $m(K)$ may depend on L, γ, M, J, Θ, n_*, the enumeration (b_q), the loops and times (ℓ_j, t_j), and the convergence moduli in (2) for the countably many indices $r \in \mathcal{R}$. The maps π_K do not depend on the index r that is later used to study their laws.

Proof. We prove (1) directly from the definition, (2) from the joint convergence of Theorem 29.18 and an open-set argument, and then choose $m(K)$ by a diagonal argument. The energy constraint gives the tails in (3), the compactness of energy sublevel sets and the determining property of the w_j identify the limits, and an approximation by functions of finitely many coordinates gives (4).

Step 1: measurability and invariance. Each condition in (29.17) is a strict inequality between continuous gauge-invariant functions of U. Then the set $F_{K,m,q}$ of configurations at which q satisfies the level-m conditions is open, in particular Borel, and invariant under lattice gauge transformations. The event that q is the least such index is $F_{K,m,q} \setminus \bigcup_{q'<q} F_{K,m,q'}$, and the event that no index satisfies the conditions is the complement of $\mathcal{S}_{K,m} = \bigcup_q F_{K,m,q}$. For a Borel set $\mathcal{B} \subset \mathcal{X}_L$, the preimage $\pi^{-1}_{K,m}(\mathcal{B})$ is the countable union of the events that q is the least index, over those q with $X_q \in \mathcal{B}$, together with the failure event if $X_1 \in \mathcal{B}$. This proves that $\pi_{K,m}$ is Borel. Gauge invariance holds event by event.

Step 2: success at a fixed level. Fix $m \geq 1$. Let $\mathcal{O}_m \subset \mathbb{R}^{2m}$ be the union over q of the sets

$$\big\{(u,v) \in \mathbb{R}^m \times \mathbb{R}^m : \ |w_j(X_q) - u_j| < \varepsilon_m,\ E_L(X_q(s_i)) < v_i + \varepsilon_m \ (i,j \leq m)\big\}.$$

It is open, and by Lemma 29.8 it contains the vector $((w_j(X))_{j\leq m}, (E_L(X(s_i)))_{i\leq m})$ for every $X \in \mathcal{X}_L$. By Theorem 29.18(2), applied to the joint vector of the first m lattice coordinates and the lattice energies at the times $s_1, \dots, s_m$, and by the portmanteau theorem for open sets [28, Theorem 2.1],

$$\liminf_{K\to\infty} \nu_{K|r}(\mathcal{S}_{K,m}) \geq \lambda_r\big\{\big((w_j(X))_{j\leq m}, (E_L(X(s_i)))_{i\leq m}\big) \in \mathcal{O}_m\big\} = 1.$$

This uses the joint convergence of energies and loops on the same configuration. By (29.14) and (29.13),

$$\limsup_{K\to\infty} \mu_{N_K,\gamma}(\mathcal{S}^c_{K,m}) \le F_\gamma(n_r),$$

and letting $r \to \infty$ in $\mathcal{R}$, we obtain (2) for the Wilson measures.

Step 3: the choice of $m(K)$ and the coordinates. We enumerate $\mathcal{R}$ as $r(1), r(2), \dots$. We choose strictly increasing integers $K_m \ge \max\{m, r(1), \dots, r(m)\}$ such that for every $K \ge K_m$ the probability of $\mathcal{S}^c_{K,m}$ is at most 2^{-m}, under $\mu_{N_K,\gamma}$ and under each of $\nu_{K|r(1)}, \dots, \nu_{K|r(m)}$. This is possible by Step 2, since each K_m involves only finitely many requirements. We set $m(K) = \max\{m : K_m \le K\}$, and $m(K) = 0$ if this set is empty. This is a single deterministic definition along the sequence N_K. Fix $j \ge 1$ and $r = r(l) \in \mathcal{R}$. For all sufficiently large K we have $m(K) \ge \max(j, l)$, and then, both under $\nu_{K|r}$ and under $\mu_{N_K,\gamma}$,

$$\mathbb{E}|w_j(\pi_K(U)) - W^{\mathrm{lat}}_{K,j}(U)| \le 2^{-m(K)} + 2\,\mathbb{P}(\mathcal{S}^c_{K,m(K)}) \le 3 \cdot 2^{-m(K)}. \tag{29.18}$$

Here we used the conditions (29.17) with $j \le m(K)$ on the event $\mathcal{S}_{K,m(K)}$, and (29.9) on its complement.

Step 4: energies. Let $i \le m(K)$. On the event $\mathcal{S}_{K,m(K)}$ the energy condition in (29.17) holds, and on its complement the zero trajectory has energy zero. We conclude that for every configuration $U \in \mathcal{U}_{N_K}$,

$$E_L(\pi_K(U)(s_i)) \le \mathsf{E}_{a_K}(\Psi^{(N_K)}_{s_i} U) + 2^{-m(K)} \qquad (i \le m(K)). \tag{29.19}$$

Fix i. By Theorem 29.18(5), the lattice energies at time s_i have tails that are uniform in $K \ge r$ under $\nu_{K|r}$ and uniform in $K \ge 0$ under $\mu_{N_K,\gamma}$. By (29.19) the same holds for $E_L(\pi_K(U)(s_i))$ for all K with $m(K) \ge i$. For each of the finitely many other K, every output $\pi_K(U)$ is one of the smooth trajectories X_q. Then $E_L(\pi_K(U)(s_i))$ is a finite measurable function of U, and its tail probabilities tend to zero by continuity from above of the measure. Combining the two cases, we find that for every i the energies $E_L(\pi_K(U)(s_i))$ have tails that are uniform in $K \ge r$ under $\nu_{K|r}$ and uniform in $K \ge 0$ under $\mu_{N_K,\gamma}$. For an arbitrary $t > 0$ we choose $s_i \le t$ and use the monotonicity of the continuum energy. This proves the tail bound in (3).

Step 5: convergence of the image measures. Fix $r \in \mathcal{R}$. By Step 4 and Theorem 29.6, the image measures $(\pi_K)_\# \nu_{K|r}$ have compact containment, and every subsequence has a further subsequence converging against bounded $\mathcal{T}_W$-continuous functions and weakly for d_c. By Theorem 29.18(2), the finite vectors $(W^{\mathrm{lat}}_{K,j})_{j\le b}$ converge in law under $\nu_{K|r}$ to $(w_j)_{j\le b}$ under λ_r. By (29.18), Markov's inequality, and uniform continuity of bounded continuous functions on the cube $[-1,1]^b$, the vectors $(w_j(\pi_K(U)))_{j\le b}$ have the same

limit laws. Then every subsequential limit of the image measures has the same finite joint laws of the w_j as λ_r, and by Theorem 29.3(4) it equals λ_r. Since every subsequence has a further subsequence with this limit, every bounded $\mathcal{T}_W$-continuous function converges along the whole sequence. A bounded d_c-continuous function is $\mathcal{T}_W$-continuous, which gives the weak convergence for d_c. This completes the proof of (3).

Step 6: additional lists. We now prove (4); the argument uses only compact sets and does not require the functions $W_{\ell,\chi,t}$ of the list to be d_c-continuous. It suffices to treat real f; for complex f we apply the result to the real and imaginary parts. Let $h(X) = f(\mathscr{W}(X))$ and $D = \|f\|_\infty$; only the values of f on the compact range of the character vector matter. Let $\eta > 0$. By Step 4, Theorem 29.6, and the finiteness of the energies under λ_r, there exists a compact set $\mathcal{C} = \mathcal{K}(R)$ with mass at least $1 - \eta$ under every image measure $(\pi_K)_\# \nu_{K|r}$ and under λ_r. Let $\delta > 0$. By Lemma 29.9 there exist b and a continuous $G : [-1,1]^b \to [-D, D]$ with $|h - G \circ p_b| < \delta$ on $\mathcal{C}$, where $p_b X = (w_j(X))_{j \le b}$. Then

$$\mathbb{E}_{\nu_{K|r}} |h(\pi_K(U)) - G(p_b \pi_K(U))| \le \delta + 2D\eta.$$

By (3) and the uniform continuity of G, $\mathbb{E}_{\nu_{K|r}} |G(p_b \pi_K(U)) - G((W^{\mathrm{lat}}_{K,j}(U))_{j \le b})| \to 0$. Next we apply Theorem 29.18(2) to the single joint list consisting of the first b coordinates and the whole list $\mathscr{W}$. Its limit is the corresponding vector under λ_r, and applying the bounded continuous function $|G(u) - f(v)|$ to the joint vector, we obtain

$$\lim_{K \to \infty} \mathbb{E}_{\nu_{K|r}} \big| G\big((W^{\mathrm{lat}}_{K,j}(U))_{j \le b}\big) - f(\mathscr{W}^{\mathrm{lat}}_K(U)) \big| = \mathbb{E}_{\lambda_r} |G(p_b X) - h(X)| \le \delta + 2D\eta.$$

By the triangle inequality, the limit superior in (4) is at most $2\delta + 4D\eta$, and we let $\delta, \eta \to 0$. □

29.5 Removal of the conditioning

Theorem 29.20. *Assume the standing assumptions of Section 29.3, and let π_K be the maps of Theorem 29.19. Then the following statements hold.*

1. *For every $t > 0$,*
$$\lim_{R \to \infty} \sup_{K \ge 0} \mu_{N_K,\gamma} \big\{ E_L(\pi_K(U)(t)) > R \big\} = 0.$$
2. *The image measures $(\pi_K)_\# \mu_{N_K,\gamma}$ have compact containment, and they converge, against every bounded $\mathcal{T}_W$-continuous function and weakly with respect to d_c, to a Borel probability measure $\lambda_{L,\gamma,[n_*]}$ on $\mathcal{X}_L$.*
3. *For every $j \ge 1$, $\lim_{K \to \infty} \mathbb{E}_{\mu_{N_K,\gamma}} |w_j(\pi_K(U)) - W^{\mathrm{lat}}_{K,j}(U)| = 0$.*

4. *For every finite list $\mathscr{W}$ as in Theorem 29.19(4) and every bounded continuous function f of its vector,*

$$\lim_{K\to\infty} \mathbb{E}_{\mu_{N_K,\gamma}} f\big(\mathscr{W}_K^{\mathrm{lat}}(U)\big) = \int f(\mathscr{W}(X))\, d\lambda_{L,\gamma,[n_*]}(X),$$
$$\lim_{K\to\infty} \mathbb{E}_{\mu_{N_K,\gamma}} \big|f(\mathscr{W}(\pi_K(U))) - f(\mathscr{W}_K^{\mathrm{lat}}(U))\big| = 0.$$

All statements concern the whole sequence $N_K = n_* B^K$ at the fixed coupling γ, and the convergence moduli and $m(K)$ may depend on γ and on this sequence.

Proof. Statement (1) and the bound (29.18) under $\mu_{N_K,\gamma}$, which gives (3), were proved in Steps 3 and 4 of the proof of Theorem 29.19. By (1) and Theorem 29.6, the image measures have compact containment, and every subsequence has a further subsequence converging against bounded $\mathcal{T}_W$-continuous functions and weakly for d_c. By Theorem 28.2, applied to the fundamental characters and multiplied by $1/2$, every finite vector $(W_{K,j}^{\mathrm{lat}})_{j\le b}$ converges in law under $\mu_{N_K,\gamma}$ along the whole sequence. By (3), every subsequential limit of the image measures has these limits as the finite joint laws of the w_j, and by Theorem 29.3(4) all subsequential limits coincide. Applying the compactness to a subsequence that stays away from this common limit gives a contradiction, which proves (2).

Fix a finite list $\mathscr{W}$ and a bounded continuous f. By Theorem 29.19(4), the nonnegative discrepancy

$$D_K = \big|f(\mathscr{W}(\pi_K(U))) - f(\mathscr{W}_K^{\mathrm{lat}}(U))\big| \le 2\|f\|_\infty$$

satisfies $\mathbb{E}_{\nu_{K|r}} D_K \to 0$ for every $r \in \mathcal{R}$. By Lemma 5.5 and (29.13), for every $r \in \mathcal{R}$,

$$\limsup_{K\to\infty} \mathbb{E}_{\mu_{N_K,\gamma}} D_K \le 2\|f\|_\infty F_\gamma(n_r),$$

and letting $r \to \infty$ shows that the expected absolute discrepancy tends to zero. Since $f \circ \mathscr{W}$ is bounded and $\mathcal{T}_W$-continuous, by (2) we have $\mathbb{E}_{\mu_{N_K,\gamma}} f(\mathscr{W}(\pi_K(U))) \to \int f(\mathscr{W}(X))\, d\lambda_{L,\gamma,[n_*]}(X)$, and the first assertion of (4) follows. This argument covers every finite list of loops with admissible approximations, since Theorem 29.18 and Theorem 29.19(4) apply to such lists; no comparison of paths under the Wilson measures is needed. □

29.6 Couplings below a fixed bound

Sections 29.3 to 29.5 use the parameters of Theorem 23.2, which are adapted to small couplings $\gamma \le \gamma_0$. For an arbitrary fixed coupling we use instead the parameters of Theorem 23.5, which are chosen for all couplings below a given bound Γ. In this subsection we check that the construction carries over, and we collect the statements about general admissible approximations of loops.

The setting below a coupling bound. Fix $0 < \Gamma < \infty$, $L > 0$, and an odd integer $M \geq 3$. Let J, the parameters Θ, and the minimum coarse side $n_\Gamma \in 4\mathbb{N}$ be as in Theorem 23.5; they are chosen before the coupling, and Theorem 23.10 holds for all $\gamma \in (0, \Gamma]$, $u \in 4\mathbb{N}$ with $u \geq n_\Gamma$, and $K \geq 0$. Fix $\gamma \in (0, \Gamma]$ and $n_* \in 4\mathbb{N}$, and define B, N_K, a_K, n_r, $\nu_{K|r}$, and $e_{K|r}$ as in the standing assumptions of Section 29.3. Let $\mathcal{R}$ be an infinite set of indices r for which Lemma 28.11 applies at the coarse side n_r. By Theorem 23.10, the bound (29.13) holds for $r \in \mathcal{R}$, with $\epsilon_K = 0$ and $F_\gamma(u)$ equal to the right side of (23.13). We refer to these assumptions as the setting below the coupling bound Γ.

Theorem 29.21. *Assume the setting below the coupling bound Γ. Then all conclusions of Theorems 29.18 to 29.20 hold in this setting, with the same lattice energy E_a, the same trajectories X_q, the same level-m conditions, and the zero trajectory when no index satisfies them. In particular, there exist Borel maps $\pi_K : \mathcal{U}_{N_K} \to \mathcal{X}_L$, invariant under all lattice gauge transformations and independent of r, and Borel probability measures λ_r, $r \in \mathcal{R}$, and $\lambda_{L,\gamma,[n_*]}$ on $\mathcal{X}_L$, with the following properties.*

1. *For every $r \in \mathcal{R}$, the joint limits of lattice energies and loops under $\nu_{K|r}$ in Theorem 29.18(2),(3) are the laws of the corresponding continuum vectors under λ_r, and the image measures $(\pi_K)_\# \nu_{K|r}$ converge to λ_r, with tight energies at positive times and L^1 convergence of the coordinates $w_j(\pi_K(U)) - W_{K,j}^{\mathrm{lat}}(U) \to 0$.*
2. *Under $\mu_{N_K,\gamma}$, the image measures $(\pi_K)_\# \mu_{N_K,\gamma}$ converge to $\lambda_{L,\gamma,[n_*]}$, the energies of $\pi_K(U)$ at every positive time have tails that are uniform in $K \geq 0$, the coordinates converge in L^1, and every finite list of loops with admissible approximations, characters, and positive times converges in law to its continuum vector under $\lambda_{L,\gamma,[n_*]}$.*

These are statements at each fixed coupling; the success probabilities at a fixed level and the sequence $m(K)$ may depend on γ.

Proof. We fix γ after J, Θ, and n_Γ, and we go through the proofs of the three theorems. The results of Sections 29.1 and 29.2 do not involve the coupling.

The proof of Theorem 29.18 used the following stochastic inputs: the reconstruction arrays, the gauge representative property, the tightness $\rho(R) \to 0$, the tail bound (29.15), and the convergence of the laws of the arrays A_q, all from Theorem 28.8; the argument of Theorem 28.1; and Lemma 28.4. In the present setting, Lemma 28.11 provides all of them, for the same conditional fluctuation kernels, reconstruction maps, and configurations, with constants depending on the fixed coupling. Steps 1–6 of that proof therefore apply without change and construct the measures λ_r with properties (1)–(4) of Theorem 29.18. Step 7 used Theorem 23.9 only through (29.13), which holds here by Theorem 23.10; property (5) therefore holds as well.

In the proof of Theorem 29.19, Step 1 involves neither the coupling nor a measure. In Step 2, the set $\mathcal{O}_m$ is defined by the trajectories X_q, which do not depend on γ. It

contains the vector of every trajectory, and in particular of λ_r-almost every one. By the joint convergence just established, we have $\nu_{K|r}(\mathcal{S}^c_{K,m}) \to 0$ for every fixed m and $r \in \mathcal{R}$, and (29.14) with (29.13) implies that $\limsup_K \mu_{N_K,\gamma}(\mathcal{S}^c_{K,m}) \le F_\gamma(n_r)$, which tends to zero as $r \to \infty$. The choice of K_m and $m(K)$ in Step 3 is the same; it may now depend on the fixed coupling, and (29.18) holds under $\nu_{K|r}$ and under $\mu_{N_K,\gamma}$. The bound (29.19) holds on every configuration. Step 4 then gives the energy tails under both measures, using property (5) for the lattice energies and the finiteness of the energies of the finitely many other outputs. Steps 5 and 6 use only these facts and the measures λ_r constructed above.

In the proof of Theorem 29.20, compact containment follows from the energy tails. The whole-sequence limits of the finite vectors $(W^{\mathrm{lat}}_{K,j})_{j\le b}$ under $\mu_{N_K,\gamma}$ are given by Theorem 28.2, which holds in this setting by Lemma 28.11. The identification of all subsequential limits of the image measures with one measure $\lambda_{L,\gamma,[n_*]}$ is then the same. So is the treatment of additional lists: the discrepancy $D_K \le 2\|f\|_\infty$ has conditioned expectations tending to zero, which gives $\limsup_K \mathbb{E}_{\mu_{N_K,\gamma}} D_K \le 2\|f\|_\infty F_\gamma(n_r)$ for every $r \in \mathcal{R}$, and we let $r \to \infty$. □

The next lemma records the role of the deterministic estimates of Lemma 29.11 for general admissible approximations of loops, below a coupling bound.

Lemma 29.22. *The following statements hold.*

1. *The estimates of Lemma 29.11 hold with constants that do not depend on the coupling or on any probability measure.*
2. *On every compact family of cardinal interpolants as in Lemma 29.17, they give the bound* (29.12) *for every finite list of loops with time-independent admissible approximations.*
3. *Assume the setting below a coupling bound* Γ*, and let* $r \in \mathcal{R}$*. For every finite list of positive energy times and of loops with admissible approximations, characters, and positive times, the lattice vector converges in law under* $\nu_{K|r}$ *to the corresponding continuum vector under the measure* λ_r *of Theorem 29.21. For time-independent admissible approximations, the corresponding processes converge in law in* $C([\tau,T];\mathbb{R}\times\mathbb{C}^b)$ *for every* $0<\tau<T<\infty$*.*

Proof. Statement (1) is Lemma 29.11, whose proof is purely geometric. For (2), at a fixed coarse mesh the family of cardinal interpolants is compact with bounds on all derivatives. The comparison of the lattice flow with the sampled smooth flow, together with (1), then gives Lemma 29.17, including general admissible approximations. Statement (3) is Theorem 29.18(2),(3) in the setting below the coupling bound, which holds by Theorem 29.21. There is no circularity: the proof of Theorem 29.18 uses (2) through Lemma 29.17, which rests on (1) and on Lemma 28.4, and neither of these uses (3). □

Theorem 29.23. *Let* ℓ *be a piecewise* C^1 *loop in* $\mathbb{T}^3_L$*, let* $a_K \to 0$*, and let* (ℓ_K) *be an admissible approximation of* ℓ *along these meshes:* $\sup_K \mathrm{length}(\ell_K) \le \mathfrak{l} < \infty$*, and for all sufficiently*

large K there exist comparison homotopies H_K between ℓ and ℓ_K, with connectors c_K, such that $A_K = \mathrm{Area}(H_K) \to 0$.

1. *For every smooth connection A we have $\|\mathrm{Hol}_\ell A - (\mathrm{Hol}_{c_K} A)(\mathrm{Hol}_{\ell_K} A)(\mathrm{Hol}_{c_K} A)^{-1}\|_{\mathrm{op}} \le C\|F_A\|_\infty A_K$. If $\|A\|_{C^1} \le R$, then $|\chi(\mathrm{Hol}_\ell A) - \chi(\mathrm{Hol}_{\ell_K} A)| \le C_\chi(R + R^2)A_K$, and replacing the exact transports along the edges of ℓ_K by $\exp(a_K A_i(x))$ changes $\chi(\mathrm{Hol}_{\ell_K} A)$ by at most $C_{\chi,R}\,a_K$. These constants do not depend on the coupling or on K.*
2. *Assume the setting below a coupling bound Γ, with $a_K = L/N_K$. Every finite list of loops with admissible approximations, characters, and positive times converges in law under $\nu_{K|r}$, $r \in \mathcal{R}$, to its continuum vector under λ_r, and under $\mu_{N_K,\gamma}$ to its continuum vector under the measure $\lambda_{L,\gamma,[n_*]}$ of Theorem 29.21.*
3. *In the setting of (2), let $(\ell_{h,K})$ and $(\ell'_{h,K})$, $h \le b$, be two admissible approximations of the same loops, with lattice vectors $\mathscr{W}_K^{\mathrm{lat}}$ and $\mathscr{W}_K'^{\mathrm{lat}}$ for fixed characters and times. Then $\mathbb{E}_{\mu_{N_K,\gamma}}|\mathscr{W}_K^{\mathrm{lat}}(U) - \mathscr{W}_K'^{\mathrm{lat}}(U)| \to 0$, and $\mathbb{E}_{\mu_{N_K,\gamma}}|f(\mathscr{W}_K^{\mathrm{lat}}(U)) - f(\mathscr{W}_K'^{\mathrm{lat}}(U))| \to 0$ for every bounded continuous f.*
4. *In the setting of (2), for every $R < \infty$,*

$$\lim_{K\to\infty} \sup_{\sum_h |z_h| \le R} \Big| \mathbb{E}_{\mu_{N_K,\gamma}} \exp\Big(\sum_h z_h W_{K,h}^{\mathrm{lat}}\Big) - \int \exp\Big(\sum_h z_h W_{\ell_h,\chi_h,t_h}(X)\Big)\, d\lambda_{L,\gamma,[n_*]}(X) \Big| = 0.$$

5. *In the setting of (2), for time-independent admissible approximations the path convergence of Theorem 29.18(3) under $\nu_{K|r}$ holds on every interval $[\tau, T] \subset (0,\infty)$, and for two such approximations*

$$\lim_{K\to\infty} \mathbb{E}_{\mu_{N_K,\gamma}} \sup_{\tau \le t \le T} \max_{h \le b} \big| \chi_h(\mathrm{Hol}_{\ell_{h,K}} \Psi_t^{(N_K)} U) - \chi_h(\mathrm{Hol}_{\ell'_{h,K}} \Psi_t^{(N_K)} U) \big| = 0.$$

6. *A sequence of closed lattice paths of bounded physical length that converges uniformly to ℓ, as parametrized loops, is an admissible approximation of ℓ.*

Proof. Statements (1) and (6) are Lemma 29.11, and the convergence under $\nu_{K|r}$ in (2) and (5) is Lemma 29.22(3). The convergence under $\mu_{N_K,\gamma}$ in (2) is Theorem 29.21(2). We give the comparison argument, which also proves (3)–(5). Let $D = \max_h \chi_h(I)$ for a nonempty list, and let $G_K = |\mathscr{W}_K^{\mathrm{lat}}(U) - \mathscr{W}_K'^{\mathrm{lat}}(U)|_\infty$, so that $0 \le G_K \le 2D$. By Lemma 29.22(3), applied to the union of the two lists, the two vectors converge jointly under $\nu_{K|r}$ to the same continuum vector, and $\mathbb{E}_{\nu_{K|r}} G_K \to 0$. By Lemma 5.5 and (29.13),

$$\limsup_{K\to\infty} \mathbb{E}_{\mu_{N_K,\gamma}} G_K \le 2D F_\gamma(n_r).$$

We take the limit in K first at this fixed r, and then let $r \to \infty$ in $\mathcal{R}$; the right side tends to zero. This proves the first assertion of (3) for the maximum norm, hence for any norm. Taking for $(\ell'_{h,K})$ the lattice paths of Lemma 29.10, whose limit under $\mu_{N_K,\gamma}$ is identified

by Theorem 29.20 in the setting of Theorem 29.21, we obtain the limit in (2) for every admissible approximation. The second assertion of (3) follows from uniform continuity of f on the compact range of the character vectors and Markov's inequality. For (4), the vectors are bounded by D, and for $\sum_h |z_h| \le R$,

$$\left|e^{z\cdot v} - e^{z\cdot v'}\right| \le R e^{DR} \max_h |v_h - v'_h|.$$

Then (3) transfers the uniform convergence of source functionals for the paths of Lemma 29.10, which holds by Theorem 28.2 (in this setting by Lemma 28.11), to every admissible approximation, and (2) identifies the limit. For the supremum in (5), we apply Theorem 29.18(3), in the setting below the coupling bound, to the two time-independent approximations simultaneously. Their joint limit has identical loop paths, and the supremum of the difference is bounded by $2D$, so its conditioned expectation tends to zero. The bound of Lemma 5.5 at the same lattice side, followed by the limit $r \to \infty$, gives the conclusion under $\mu_{N_K,\gamma}$. Two arbitrary time-independent approximations are compared through the paths of Lemma 29.10, which do not depend on time. □

29.7 The continuum limit along the sequences $n_* M^{JK}$

Theorem 29.24. *Let $0 < \Gamma < \infty$, $L > 0$, and $M \ge 3$ odd. There exist $J \in \mathbb{N}$, parameters Θ, and $n_\Gamma \in 4\mathbb{N}$, chosen before the coupling, such that the following holds for every $\gamma \in (0, \Gamma]$ and every $n_* \in 4\mathbb{N}$ with $n_* \ge n_\Gamma$. Let $B = M^J$ and $N_K = n_* B^K$, and write $\mu_K = \mu_{N_K,\gamma}$. Then, as $K \to \infty$:*

1. *For loops $\ell_1, \dots, \ell_m$ with admissible approximations $(\ell_{i,K})_K$, characters $\chi_1, \dots, \chi_m$ of finite-dimensional representations of $\mathrm{SU}(2)$, and times $t_1, \dots, t_m > 0$, the vector $(\chi_i(\mathrm{Hol}_{\ell_{i,K}} \Psi_{t_i}^{(N_K)} U))_{i \le m}$ converges in law under μ_K, and for every $R < \infty$ the expectations $\mathbb{E}_{\mu_K} \exp(\sum_i z_i \chi_i(\mathrm{Hol}_{\ell_{i,K}} \Psi_{t_i}^{(N_K)} U))$ converge uniformly in $z \in \mathbb{C}^m$ with $\sum_i |z_i| \le R$.*
2. *There exist Borel maps $\pi_K : \mathcal{U}_{N_K} \to \mathcal{X}_L$, invariant under all lattice gauge transformations, such that the image measures $(\pi_K)_\# \mu_K$ have compact containment and converge, against every bounded $\mathcal{T}_W$-continuous function and weakly with respect to d_c, to a Borel probability measure $\lambda_{L,\gamma,[n_*]}$ on $\mathcal{X}_L$.*
3. *For every $t > 0$ and every $j \ge 1$,*

$$\lim_{R\to\infty} \sup_{K \ge 0} \mu_K\{E_L(\pi_K(U)(t)) > R\} = 0, \qquad \lim_{K\to\infty} \mathbb{E}_{\mu_K} |w_j(\pi_K(U)) - W_{K,j}^{\mathrm{lat}}(U)| = 0,$$

   and the limit law in (1) is the law of $(W_{\ell_i,\chi_i,t_i}(X))_{i \le m}$ under $X \sim \lambda_{L,\gamma,[n_*]}$.
4. *The limits in (1) do not depend on the choice of the admissible approximations, and for two admissible approximations of the same loops the difference of the vectors in (1) tends to zero in $L^1(\mu_K)$.*

Here the Wilson flow runs for the lattice time $4t/a_{N_K}^2$, and the characters need not be normalized; they are bounded by the dimensions of the representations. The convergence moduli, the maps π_K, and the measure may depend on γ, on the sequence N_K, and on the observables. Every fixed $\gamma > 0$ lies below some bound Γ, so the theorem applies to every $\gamma > 0$. By Corollary 29.26 below, its conclusions hold for every $n_* \in 4\mathbb{N}$, not only for $n_* \geq n_\Gamma$.

Proof. Let J, Θ, and n_Γ be given by Theorems 23.5 and 23.10; they are chosen before the coupling. Fix $\gamma \in (0, \Gamma]$ and $n_* \geq n_\Gamma$. By Lemma 28.11, the conditioned estimates of Section 28 hold at all coarse sides n_r with r in an infinite set $\mathcal{R}$. The minimum coarse sides there, the bounds on the flow data, and the convergence moduli may depend on the fixed coupling. We are therefore in the setting below the coupling bound Γ of Section 29.6. Theorem 29.21 gives (2) and (3), including the energy tails with supremum over all $K \geq 0$ and the identification of every finite list of loops with admissible approximations under the same measure $\lambda_{L,\gamma,[n_*]}$. By Theorem 29.23(2)–(4), we obtain (1) and (4), including the uniform convergence of the source functionals. The maps π_K are defined on the configuration spaces of all sides N_K, $K \geq 0$. For the finitely many K with $m(K) = 0$ their value is the zero trajectory, which adds a single compact point and does not affect compact containment, the energy tails, or any limit. If the conditioned estimates require coarse sides larger than a bound depending on γ, we use only indices $r \in \mathcal{R}$ above it. No parameter of the hierarchy is chosen again. □

The case $\Gamma = 1$ is used in the weak-coupling analysis, where the parameters of Theorem 23.2 enter. We state it separately, with the quantifiers in the form in which it is used.

Theorem 29.25. *Let $L > 0$ and $M \geq 3$ odd. There exist $J \in \mathbb{N}$ and parameters Θ, chosen before the coupling, the lattice sides, and the number of steps, such that for every $\gamma \in (0, 1]$ there exists $n_0 < \infty$, which may depend on L, γ, M, J, and Θ, with the following property. For every $n_* \in 4\mathbb{N}$ with $n_* \geq n_0$, with $B = M^J$ and $N_K = n_* B^K$, the conclusions (1)–(4) of Theorem 29.24 hold along the whole sequence $K \to \infty$, for the Wilson measures $\mu_{N_K,\gamma}$ of Definition 4.1.*

All bounds that are uniform in the lattice side range over every $K \geq 0$.

Proof. Fix L and M, and choose the bound $\Gamma = 1$ in Theorems 23.5 and 23.10; the construction there keeps the parameters of Theorem 23.2 and provides the corresponding minimum side. The proof of Theorem 29.24 establishes conclusions (1)–(4) directly from Lemma 28.11 and Theorems 29.21 and 29.23, without using the present theorem. Specializing it to $\Gamma = 1$, with $n_0 = n_1$, we obtain the theorem; in fact n_0 can be chosen independently of γ, and larger minimum sides depending on γ are also allowed. No choice of $m(K)$ uniform in γ is claimed. □

The next corollary removes the lower bound on the base side and records how the limit is used when a comparison side is fixed before the coupling, as in Sections 34 to 36.

Corollary 29.26. *Let $0 < \Gamma < \infty$, $L > 0$, and $M \geq 3$ odd, let J, Θ, and n_Γ be as in Theorem 29.24, and set $B = M^J$. Fix $n_* \in 4\mathbb{N}$ before the coupling.*

1. *Let $\gamma \in (0, \Gamma]$, and let $a_\gamma \geq 0$ be an integer with $n_* B^{a_\gamma} \geq n_\Gamma$. The measure given by Theorem 29.24 for the base side $n_* B^{a_\gamma}$ does not depend on the choice of a_γ; we denote it by $\lambda_{L,\gamma,[n_*]}$. Let π'_K be the maps of that theorem for the base side $n_* B^{a_\gamma}$, and set $\pi_K = \pi'_{K-a_\gamma}$ for $K \geq a_\gamma$ and $\pi_K = X_1$, the zero trajectory, for $K < a_\gamma$. Then the conclusions (1)–(4) of Theorem 29.24 hold along the sequence $N_K = n_* B^K$, $K \geq 0$, for these maps and this measure, including the energy tails with supremum over all $K \geq 0$.*
2. *Let $n = n_* B^a$ be a comparison side, fixed before the coupling, with $n \geq n_\Gamma$, and possibly subject to further side conditions used in later sections, such as the margin* (23.52) *for the flat connections and the conditions on the analytic radius. Then the bound of Theorem 23.10 on $\mu_{nB^k,\gamma}(S^c_{nB^k,n,\gamma})$ holds uniformly in $\gamma \in (0, \Gamma]$ and $k \geq 0$. Moreover, for each fixed $\gamma \in (0, \Gamma]$, the limits along $N = nB^k$ of the expectations of bounded continuous functions of finite loop vectors as in Theorem 29.24(1) are the corresponding expectations under $\lambda_{L,\gamma,[n_*]}$, also when $a_\gamma > a$.*

In (2), every further estimate at the side n keeps its own range of couplings, and neither the side n nor a fixed number of scales used in a later weak-coupling estimate is replaced by a side depending on γ. The coupling bound γ_0 of Theorem 23.2 is not changed. We claim no choice of $m(K)$ independent of γ, no interchange of the limits $K \to \infty$ and $\gamma \to 0$, and no comparison between different classes $[n]_M$.

Proof. We fix Γ, the parameters, and n_Γ first, and then n_*, before the coupling. Since $B > 1$, there exists an integer $a_\gamma \geq 0$ with $n_* B^{a_\gamma} \geq n_\Gamma$. For fixed $\gamma \in (0, \Gamma]$ we apply Theorem 29.24 with the base side $u = n_* B^{a_\gamma}$. That theorem allows further minimum sides depending on γ internally, and it gives its conclusions along the sequence $uB^K = N_{K+a_\gamma}$, $K \geq 0$. This sequence is a tail of the sequence $(N_K)_K$, with the same configuration spaces, Wilson measures, Wilson flow, and lattice paths. Hence every finite loop vector, and every expectation of a bounded continuous function of it, has the same limit along $(N_K)_K$. Two choices of a_γ give sequences that share a common tail. The finite joint laws of the limits of the coordinates $W^{\mathrm{lat}}_{K,j}$ therefore coincide, and by Theorem 29.3(4) the two measures coincide.

The maps π_K are Borel and gauge invariant. Changing finitely many terms of a sequence does not affect convergence or the L^1 convergence of the coordinates. Adding the zero trajectory to a compact set does not affect compactness in either topology, so compact containment is preserved. The added image measures have zero energy at

every positive time, and the energy tails with supremum over all $K \geq 0$ are therefore unchanged. This proves (1).

For (2), the uniform bound on the small-field failure probability follows from Theorem 23.10, since $n \geq n_\Gamma$. The reindexing in (1) does not change any measure, event, or observable at the side n. For fixed γ, all sufficiently large sides nB^k belong to the tail $(uB^K)_K$ used above, so the expectations of bounded continuous functions of finite loop vectors converge to the expectations under $\lambda_{L,\gamma,[n_*]}$, also when $a_\gamma > a$. Every further estimate at the side n keeps its own range of couplings, and no parameter of the comparison side or bound on the coupling was changed. □

29.8 The sequence nM^k

The results of Section 29.7 give convergence along the subsequences n_*M^{JK} for one fixed J. To obtain convergence along the full sequence nM^k, we use two consecutive values J and $J+1$, both of which are available by Corollary 23.15. Each residue class of k modulo J shares infinitely many lattice sides with the sequence of depth $J+1$, and at a common lattice side the Wilson measures and the lattice observables are identical. This identifies the limits along all residue classes.

Lemma 29.27. *Let $J \geq 1$, $n \in \mathbb{N}$, and $r \in \{0, \dots, J-1\}$. For every integer $s \geq 0$ let $K = r + (J+1)s$ and $K' = r + Js$. Then $r + JK = (J+1)K'$, so that*

$$nM^{r+JK} = nM^{(J+1)K'}, \tag{29.20}$$

and $K, K' \to \infty$ as $s \to \infty$.

Proof. We have $r + J(r + (J+1)s) = (J+1)r + J(J+1)s = (J+1)(r+Js)$. □

Theorem 29.28. *Let $0 < \Gamma < \infty$, $L > 0$, $M \geq 3$ odd, and $n \in 4\mathbb{N}$. There exist two choices of the parameters of Theorem 23.5, with consecutive numbers J and $J+1$ of averaging steps per renormalization group step, made before the coupling, such that for every $\gamma \in (0, \Gamma]$ the following statements hold, with $N_k = nM^k$ and $a_k = L/N_k$.*

1. *For loops $\ell_1, \dots, \ell_m$ with admissible approximations $(\ell_{i,k})_k$ along $(N_k)_k$, characters $\chi_1, \dots, \chi_m$, and times $t_1, \dots, t_m > 0$, the vector $(\chi_i(\mathrm{Hol}_{\ell_{i,k}} \Psi_{t_i}^{(N_k)} U))_{i \leq m}$ converges in law under $\mu_{N_k,\gamma}$ as $k \to \infty$, and for every $R < \infty$ its source functionals $\mathbb{E}_{\mu_{N_k,\gamma}} \exp(\sum_i z_i \chi_i(\mathrm{Hol}_{\ell_{i,k}} \Psi_{t_i}^{(N_k)} U))$ converge uniformly in $z \in \mathbb{C}^m$ with $\sum_i |z_i| \leq R$.*
2. *There exist Borel maps $\pi_k : \mathcal{U}_{N_k} \to \mathcal{X}_L$, invariant under all lattice gauge transformations, such that the image measures $(\pi_k)_\# \mu_{N_k,\gamma}$ have compact containment and converge, against every bounded $\mathcal{T}_W$-continuous function and weakly with respect to d_c, to a Borel probability measure $\lambda_{L,\gamma,[n]_M}$ on $\mathcal{X}_L$. Here $[n]_M$ is the class of n for the relation*

$$n \sim_M n' \quad \Longleftrightarrow \quad nM^a = n'M^b \text{ for some integers } a, b \geq 0.$$

3. *For every $t > 0$ and every $j \geq 1$,*

$$\lim_{R\to\infty} \sup_{k\geq 0} \mu_{N_k,\gamma}\{E_L(\pi_k(U)(t)) > R\} = 0, \qquad \lim_{k\to\infty} \mathbb{E}_{\mu_{N_k,\gamma}} |w_j(\pi_k(U)) - W^{\mathrm{lat}}_{N_k,j}(U)| = 0,$$

   and the limit law in (1) is the law of $(W_{\ell_i,\chi_i,t_i}(X))_{i\leq m}$ under $X \sim \lambda_{L,\gamma,[n]_M}$.
4. *The measure $\lambda_{L,\gamma,[n]_M}$ depends only on L, γ, and $[n]_M$: for every $n' \in [n]_M$, every bound $\Gamma' \geq \gamma$, and every choice of the parameters of Theorem 23.5 for Γ', the measures obtained from n' and these parameters in Corollary 29.26 and in (2) coincide with $\lambda_{L,\gamma,[n]_M}$. For two admissible approximations of the same loops, the difference of the vectors in (1) tends to zero in $L^1(\mu_{N_k,\gamma})$.*
5. *The conclusions of Theorems 30.4 to 30.6 (convergence of the processes of lattice energies and loops on compact intervals of positive times, agreement of time-independent admissible approximations in expected supremum, convergence of the images in the Sobolev trajectory space, and invariance under spatial isometries and center symmetries) hold along the full sequence $N_k = nM^k$, for the maps π_k and the measure $\lambda_{L,\gamma,[n]_M}$.*

Since M is odd and $4 \mid n$, every $n' \in [n]_M$ is also divisible by four. The maps and convergence moduli may depend on the fixed coupling, on n, and on the two parameter choices. The proof of (5), which applies the arguments of Section 30 on each residue class and then the assembly below, is given in Section 30.

Remark 29.29. The theorem identifies the limit within one class $[n]_M$. It does not compare the measures for different classes or for different odd integers M. It gives no rate of convergence, no convergence of moments of the energy, and no uniformity as $\gamma \to 0$, as $\Gamma \to \infty$, or in J. The statements about conditioned measures remain statements along the sequences $n_* B^K$ at fixed coarse sides; we do not identify the limits of the conditioned measures along different residue classes. Likewise, the bounds on the small-field failure probability refer to the sequences uB^K and the coarse sides u for which they are stated.

Proof of Theorem 29.28(1)–(4). We prove the convergence along each residue class modulo J by Corollary 29.26, identify the limits through the common lattice sides of Lemma 29.27, and then interlace the maps.

Step 1: the two parameter choices. By Corollary 23.15 there exists J_0 such that for every $J \geq J_0$ there exist parameters Θ_J and a minimum side, fixed before the coupling, with all conclusions of Theorems 23.5 and 23.10 for $0 < \gamma \leq \Gamma$. We fix such choices for two consecutive values J and $J + 1$. This use of the corollary is not circular. Its proof first applies Lemma 23.14 with the bound one and then the construction of Theorem 23.5, which changes only the constants in the failure bound and the minimum sides and keeps J and the structural parameters. Now fix $\gamma \in (0, \Gamma]$. For each of the two depths, Theorem 29.24, with Lemma 28.11 and Theorem 29.21, provides maps with all the stated

properties along the corresponding sequences. These maps choose among the trajectories X_q, with value X_1 when no index satisfies the conditions and with a sequence $m(K)$ depending on the fixed coupling, and the energy constraint uses the lattice energy of Lemma 29.14. The additional minimum side depending on γ is finite and does not change J or the parameters. No modulus of convergence and no sequence $m(K)$ is claimed to be uniform in the coupling or in J.

Step 2: the residue classes. For each $r \in \{0, \dots, J-1\}$ we apply Corollary 29.26(1) with depth J and base side nM^r. This is allowed even if nM^r is below the minimum side, since the corollary provides a finite shift and the zero trajectory for the finitely many omitted sides. Let $\lambda^{(r)}$ be the resulting measure and $\pi_K^{(r)}$ the resulting maps along the sequence $nM^rB^K = nM^{r+JK}$. We also apply the corollary with depth $J+1$ and base side n, and let λ' be the resulting measure along the sequence $nM^{(J+1)K'}$.

Step 3: identification of the limits. For the comparison we use the lattice paths of Lemma 29.10, which depend only on the loop and the mesh and not on the parameters of the hierarchy. By Lemma 29.27, for every r the sequences nM^{r+JK} and $nM^{(J+1)K'}$ have infinitely many common terms. At each common side N, the Wilson measure $\mu_{N,\gamma}$, the Wilson flow, the times, and the lattice loop vectors are identical. The two whole-sequence limits of every finite vector $(W^{\mathrm{lat}}_{N,j})_{j\le b}$ therefore agree. By Theorem 29.3(4), $\lambda^{(r)} = \lambda'$ for every r; we write $\lambda_{L,\gamma,[n]_M}$ for this common measure. No conditioned measure, density, or reconstruction has been compared.

Step 4: interlacing. For $k = r + JK$ with $r \in \{0, \dots, J-1\}$ and $K \ge 0$, set $\pi_k = \pi_K^{(r)}$. Since each side N_k belongs to exactly one residue class, these maps are Borel and gauge invariant. For every bounded $\mathcal{T}_W$-continuous function, the expectations along each of the J residue sequences converge to its expectation under $\lambda_{L,\gamma,[n]_M}$. Taking the largest of the finitely many thresholds, we obtain convergence along the whole sequence. The same argument gives the weak convergence for d_c and the L^1 convergence of the coordinates. If $\mathcal{K}(R^{(r)})$ has mass at least $1-\eta$ under all image measures of residue r, then $\mathcal{K}(R)$ with $R_j = \max_r R_j^{(r)}$ contains all these sets and has mass at least $1-\eta$ for all k. Moreover,

$$\sup_{k\ge 0} \mu_{N_k,\gamma}\{E_L(\pi_k(U)(t)) > R\} \le \max_{0\le r<J} \sup_{K\ge 0} \mu_{nM^{r+JK},\gamma}\{E_L(\pi_K^{(r)}(U)(t)) > R\},$$

which tends to zero as $R \to \infty$. The convergence of finite loop vectors, the uniform convergence of the source functionals, and the agreement of admissible approximations follow by the same finite argument from Corollary 29.26(1) on each residue class, with the limit identified by Step 3. This assembly uses different sequences $m(K)$ on the finitely many residue classes; it never identifies their values, the indices q chosen, or the conditioned measures.

Step 5: dependence only on the class. Let $n' \in [n]_M$ with $nM^a = n'M^b$, and consider a construction as in Corollary 29.26 with base side n', depth J', and parameters for a bound $\Gamma' \geq \gamma$. Its sides satisfy $n'M^{J'K} = nM^{a-b+J'K}$ for all sufficiently large K, so they form a subsequence of a tail of $(nM^k)_k$. Its loop limits therefore coincide with those along the full sequence, and Theorem 29.3(4) identifies its measure with $\lambda_{L,\gamma,[n]_M}$. The full sequence $n'M^k = nM^{a-b+k}$, $k \geq b - a$, is a shifted tail of the full sequence nM^k, and the measure obtained in (2) from n' is the same. In particular, constructions with two different bounds $\Gamma, \Gamma' \geq \gamma$ give the same measure. This proves (4) and completes the proof of (1)–(4). □

Proof of Theorem 2.3. Let $L > 0$, $\gamma > 0$, $M \geq 3$ odd, and $n \in 4\mathbb{N}$, and apply Theorem 29.28 with any bound $\Gamma \geq \gamma$. Part (1) of Theorem 2.3 is Theorem 29.28(1); the independence of the limit from the admissible approximations follows from the L^1 agreement in Theorem 29.28(4). For part (2), Theorem 29.28(3) shows that every limit law in part (1) is the law of the corresponding continuum vector under $\lambda = \lambda_{L,\gamma,[n]_M}$, and uniqueness follows from Theorem 29.3(4). Part (3) is Theorem 29.28(2),(3) for the paths of Definition 29.13; for any other fixed admissible approximation $(\ell_{j,k})_k$ of ℓ_j it follows from the L^1 agreement in Theorem 29.28(4) and the triangle inequality. Part (4) is the energy bound in Theorem 29.28(3), and part (5) is Theorem 29.28(4).

SECTION 30

Further properties of the continuum measure

In this section, we prove the properties of the continuum measure stated in Theorems 2.5 and 2.6. In Section 29, we constructed the measure $\lambda = \lambda_{L,\gamma,[n]_M}$ on the trajectory space $\mathcal{X}_L$ at each fixed $\gamma > 0$, together with Borel, gauge-invariant maps π_k from lattice configurations to $\mathcal{X}_L$, and showed that every finite family of flowed lattice Wilson loops converges in law to the corresponding regularized Wilson loops under λ (Theorem 29.28). We prove the following further properties.

1. The measures on tori of different side lengths are related by an exact dilation (Theorem 30.1).
2. The joint processes of lattice energy and flowed Wilson loops converge in distribution on every compact time interval in $(0, \infty)$, in the uniform topology (Theorem 30.4). A deterministic input is a uniform Lipschitz bound in time for these processes (Lemma 30.3).
3. The image laws also converge in the finer Sobolev topology of Cao and Chatterjee (Theorem 30.5).
4. The measure is invariant under the isometries $x \mapsto Qx + y$ of $\mathbb{T}_L^3$, with Q a signed permutation matrix, and under the center symmetries; in particular, products of Wilson loops with odd total winding have mean zero (Theorem 30.6).
5. These conclusions hold along the full sequence of lattice sides nM^k (Section 30.6).
6. The map $\gamma \mapsto \lambda_{L,\gamma,[n]_M}$ is weakly continuous. On every compact interval $I \subset (0, \infty)$, each fixed finite vector of flowed lattice Wilson loops converges uniformly in the bounded-Lipschitz distance. The approximating maps can be chosen independently of $\gamma \in I$, with uniform convergence against each bounded Wilson-continuous test and in the bounded-Lipschitz distance for d_c, and with uniform tails of the energies of the image trajectories (Theorem 30.10). Uniformity in γ is not asserted for the path laws or for the laws in the Sobolev topology.
7. At each fixed $0 < \gamma \leq 1$, along the sequence $N_K = n_* B^K$ of Theorem 29.25, replacing the Wilson flow by the gradient flow of $\sum_p [q(U_p) + cq(U_p)^2]$, with $0 \leq c \leq C_0 < \infty$, preserves the limits of finite vectors of Wilson loops and the limits of the joint processes of energies and Wilson loops at positive times (Theorems 30.13 and 30.15).

The inputs are the results of Section 29 on the trajectory space, the energy, the joint limits under conditioned measures, and the approximating maps; the deterministic

estimates for the Wilson flow and its modifications in Sections 24 and 25; the finite-mesh control of the linear and quadratic flow data in Section 28; and the bound on the small-field failure probability in Section 23. The convergence of the energy and loop processes is used in Sections 34 and 36, and the convergence in the Sobolev topology in Sections 32 and 34.

Most proofs below have the same structure. Fix a coarse side $n_r = n_* B^r$. Under the conditioned Wilson measure $\nu_{N_K, n_r, \gamma}$, the configuration is, up to a gauge transformation, the field built by the reconstruction maps of Section 15, and the norm of its linear and quadratic flow data is tight in K (Theorem 28.8). On the event that this norm is at most R, the deterministic flow estimates of Sections 24 and 25 apply. We then remove the conditioning using the elementary inequality (30.2) below, taking first the limit $K \to \infty$ at fixed r and then $r \to \infty$. Since the lattice energy is unbounded, only bounded functions of it, such as indicators of tail events or bounded continuous path tests, are transferred in this way. No convergence of moments of the energy is claimed in this section.

30.1 Setting and notation

Fix $L > 0$, an odd integer $M \geq 3$, and $0 < \Gamma < \infty$. Before the coupling is chosen, we fix the integer J, the parameter tuple Θ, and the minimum coarse side n_Γ of Theorem 29.24, that is, of Theorem 23.5. Then fix $0 < \gamma \leq \Gamma$ and $n_* \in 4\mathbb{N}$, and set

$$B = M^J, \qquad N_K = n_* B^K, \qquad a_K = L/N_K.$$

If $n_* < n_\Gamma$, we use the convention of Corollary 29.26: the results are applied to the shifted base $n_* B^{a_\gamma} \geq n_\Gamma$, and at the finitely many cutoffs $K < a_\gamma$ the maps are the stationary zero trajectory. We write $\lambda = \lambda_{L,\gamma,[n_*]}$ for the continuum measure along $(N_K)_{K \geq 0}$, and π_K for the maps of Theorem 29.21. For the full sequence $N_k = nM^k$ of Theorem 29.28, the maps are instead those of that theorem, which are obtained by interlacing finitely many sequences of the previous form, and the measure is $\lambda_{L,\gamma,[n]_M}$. By part (4) of that theorem, $\lambda = \lambda_{L,\gamma,[n_*]_M}$. The two consecutive values J and $J+1$ and their parameter tuples are given by Corollary 23.15, and no constant uniform in J is used. Every assertion in Sections 30.2 to 30.6 is made at one fixed coupling; Section 30.7 treats compact intervals of couplings.

All gauge transformations are periodic, and all homotopy classes are included. Deterministic constants have the dependence described in item (7) of Definition 4.14. They may depend on the stated bounds on the flow data, the waiting times and horizons, the lengths of the lattice paths, the representations, and the margins of the smooth reference solutions, but not on the coupling, the cutoff, the depth of the hierarchy, or the law. Stochastic constants and convergence moduli may in addition depend on γ, on the coarse side, and on the parameters. No estimate is uniform as the waiting time or the coupling tends to zero.

By Lemma 28.11, the results of Section 28 that we use hold at each fixed $0 < \gamma \le \Gamma$, with Theorem 23.10 as the bound on the small-field failure probability. These are the finite-mesh control of the flow data (Theorem 28.8), the consistency estimate for a fixed finite-scale reconstruction (Lemma 28.4), and the removal of conditioning (Theorem 28.2). By Theorem 29.21, the conclusions of Theorems 29.18 to 29.20 hold in the present setting, with their fixed-coupling dependence.

Conditioned measures. For an integer $r \ge 0$ and $K \ge r$ write

$$n_r = n_* B^r, \qquad \nu_{K|r} = \nu_{N_K,n_r,\gamma} = \mu_{N_K,\gamma}(\,\cdot \mid S_{N_K,n_r,\gamma}), \qquad e_{K|r} = \mu_{N_K,\gamma}(S^c_{N_K,n_r,\gamma}).$$

For all sufficiently large r, by Theorems 23.10 and 28.2, we have

$$e_{K|r} \le \epsilon_K^{\mathrm{sf}} + F_\gamma(n_r), \qquad \epsilon_K^{\mathrm{sf}} \longrightarrow 0, \qquad F_\gamma(u) = C' u^3 e^{-\bar{c}u/\gamma} + C_{\mathrm{w}} u^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mu/\gamma}}, \tag{30.1}$$

and $F_\gamma(n_r) \to 0$ as $r \to \infty$ at fixed $\gamma > 0$; here ϵ_K^{sf} is the remainder denoted by ϵ_K in (29.13). Let r_0 be so large that, for every $r \ge r_0$, we have $n_r \ge n_\Gamma$, all additional thresholds on the coarse side in Lemma 28.11 are satisfied for the fixed coupling and input horizon, and (30.1) holds. All conditioned trajectory laws and conditioned estimates below are used only for these indices. We write λ_r for the trajectory law of Theorem 29.18, which is the limit of the flowed observables under $\nu_{K|r}$ as $K \to \infty$, and Y^r for the identity map of $\mathcal{X}_L$ under λ_r. Since $\nu_{K|r}$ is $\mu_{N_K,\gamma}$ conditioned on an event of probability $1 - e_{K|r}$, there exists a probability measure $\rho_{K|r}$ (arbitrary if $e_{K|r} = 0$) such that $\mu_{N_K,\gamma} = (1 - e_{K|r})\nu_{K|r} + e_{K|r}\rho_{K|r}$. This implies that, for every bounded complex Borel function F, every Borel function $0 \le G \le D$, and every Borel event A,

$$\begin{gathered} \bigl|\mathbb{E}_{\mu_{N_K,\gamma}} F - \mathbb{E}_{\nu_{K|r}} F\bigr| \le 2 e_{K|r} \|F\|_\infty, \\ \mathbb{E}_{\mu_{N_K,\gamma}} G \le \mathbb{E}_{\nu_{K|r}} G + D e_{K|r}, \qquad \mu_{N_K,\gamma}(A) \le \nu_{K|r}(A) + e_{K|r}. \end{gathered} \tag{30.2}$$

This is Lemma 5.5; the last inequality is (29.14).

Observables. For a mesh $a = L/N$ we use the lattice energy

$$\mathsf{E}_a(U) = \frac{8}{a} \sum_{p \in \mathcal{P}_N} q(U_p)$$

of (2.2) and Lemma 29.14, with each positive plaquette counted once. Its smooth limit is the energy E_L of (2.3). For a closed lattice path ℓ_a and a character χ, the flowed lattice Wilson loop is $\chi(\mathrm{Hol}_{\ell_a} \Psi_t^{(N)} U)$, where $\Psi_t^{(N)}$ is the Wilson flow run for the lattice time $4t/a^2$. We use the determining coordinates $w_j(X) = (1/2) \operatorname{tr} \mathrm{Hol}_{\ell_j} X(t_j)$ and the metric d_c of Theorem 29.3, and their lattice counterparts $W_{K,j}^{\mathrm{lat}}$ of Definition 29.13. On lattice one-forms, $\|A\|_{C_a^1} = \|A\|_\infty + \max_{j,\epsilon} \|D_{a,j}^\epsilon A\|_\infty$ is the supremum norm plus the maximum of the forward and backward differences divided by a, and $S_a b$ denotes the sampling of a smooth one-form b at the lattice vertices.

Admissible approximations. Throughout this section, the lattice paths approximating a loop ℓ form an admissible approximation in the sense of Definition 2.1. That is, they are closed lattice paths ℓ_K in Λ_{N_K}, fixed in time and of uniformly bounded physical length, such that for all sufficiently large K there exists a based piecewise C^1 homotopy between ℓ_K and ℓ, together with a connecting path between the basepoints when these differ, whose swept area A_K, counted with multiplicity, tends to zero. No homotopy is required at finitely many initial indices, and all comparisons below are made on the tail. This is the class of Theorem 29.23, and it contains the paths of Lemma 29.10.

Flow data and reference solutions. For an initial potential A_0 on mesh a, its linear and quadratic flow data are the linear heat evolution $x_a(t) = P_t^a A_0$ and the quadratic Picard term $y_a = \mathcal{Q}_a(x_a, x_a)$. We measure them on a horizon $[0, T_0]$ by the norm $\mathsf{X}_\alpha^a(x_a) + \mathsf{Y}_\alpha^a(y_a)$ of Definitions 24.3 and 4.8, which includes the difference components. Under $\nu_{K|r}$, we write $\mathsf{R}_{K|r}$ for this norm of the flow data of the gauge representative of U given by the reconstruction maps (Theorem 15.13). By Theorem 28.8, we have

$$\lim_{R\to\infty} \sup_{K\geq r} \nu_{K|r}\{\mathsf{R}_{K|r} > R\} = 0 \tag{30.3}$$

for every fixed $r \geq r_0$. By Theorem 24.10, every smooth trajectory has, on a finite horizon, a finite reference family: smooth solutions of the Yang–Mills heat equation in DeTurck gauge, that is, of the gauge-fixed equation of that theorem, on consecutive time intervals, together with fixed smooth gauge transformations at the transition times. We call each of these solutions a reference solution. On the lattice, after a time-dependent gauge transformation that adds a damping term of the same kind, the Wilson flow is represented by the solution of a damped lattice equation whose linear part is the lattice heat equation (Lemma 24.2). As in Section 25, we call these solutions damped representatives and say that they are in the damped gauge. We compare them with the reference solutions using Lemma 25.5.

30.2 Exact dilation

Once the lattice sites are indexed by $(\mathbb{Z}/N\mathbb{Z})^3$, the Wilson measure (2.1) does not depend on L: the side length enters only through the physical units of time and length. The following theorem transfers this to the continuum measures. We write $\mathcal{X}_1$ for the trajectory space of the unit torus.

Theorem 30.1. *Fix an odd integer $M \geq 3$, an equivalence class $[n]_M$, and $\gamma > 0$, and let $\lambda_{L,\gamma,[n]_M}$ be the measure of Theorem 29.28, constructed with any $\Gamma \geq \gamma$. For $L > 0$ define $D_L : \mathcal{X}_1 \to \mathcal{X}_L$ on representatives by*

$$(D_L A)(t, x) = L^{-1} A(t/L^2, x/L).$$

Then D_L is a bijection, a homeomorphism for the Wilson topologies, and a Borel isomorphism. The measures satisfy

$$\lambda_{L,\gamma,[n]_M} = (D_L)_{\#}\lambda_{1,\gamma,[n]_M}. \tag{30.4}$$

For every $X \in \mathcal{X}_1$ and $t > 0$,

$$LE_L((D_L X)(t)) = E_1(X(t/L^2)). \tag{30.5}$$

In particular, for loops ℓ_i on the unit torus, characters χ_i, and times $\theta_i > 0$, the joint law under $\lambda_{L,\gamma,[n]_M}$ of the Wilson loops $W_{L\ell_i,\chi_i,L^2\theta_i}$ and the energies $LE_L(X(L^2\theta_i))$ does not depend on L.

This independence holds exactly at every finite cutoff for the flowed lattice Wilson loops on the dilated lattice paths. Let $\pi_{k,1}$ be the maps of Theorem 29.28 on the unit torus, and set $\pi_{k,L} = D_L \circ \pi_{k,1}$. These maps are Borel and invariant under lattice gauge transformations on the full configuration spaces of side L, and at every cutoff they have the same dimensionless energy tails and the same coordinate errors $\mathbb{E}|w_j(\pi_{k,L}) - W^{\mathrm{lat}}_{k,j}|$ as on the unit torus, when the determining family on side L is the dilation of that on the unit torus. Consequently, the convergence errors are uniform in $L > 0$ for each fixed bounded Wilson-continuous or bounded d_c-continuous test transported from the unit torus, and for each fixed bounded continuous test of a finite vector of flowed lattice Wilson loops. For other bounded Borel tests the transported errors equal the unit-side errors, and they tend to zero only if the unit-side errors do. No convergence of the energy laws of the maps $\pi_{k,L}$ is asserted, and no uniformity in γ, or for parameters chosen independently at different L, is asserted.

Proof. We first prove the identities at a finite cutoff, then check that D_L is a well-defined map of trajectory spaces that transforms energies and Wilson loops as stated, and then identify the limiting measures. Finally, we construct the maps $\pi_{k,L}$.

Step 1: identities at a finite cutoff. We index the sites by $(\mathbb{Z}/N\mathbb{Z})^3$ and the links by a site and a direction. Under this identification, the finite measures, including their normalizing constants, are identical for all L, since the product Haar measure and the exponent $-4N\gamma^{-1}\sum_p q(U_p)$ in (2.1) do not involve L. The Wilson flow is the gradient flow of $\sum_p q(U_p)$ for the product bi-invariant metric, which does not involve L either. By the definition $\Psi_t^{(N)} = \Phi^{\mathrm{W}}_{4t/a_N^2}$, the physical time t on side L corresponds to the lattice time $4tN^2/L^2$; at $t = L^2\theta$, this is the lattice time $4\theta N^2$ of the physical time θ on the unit torus. Dilation by L sends each edge of the lattice in the unit torus to the corresponding edge of the lattice in $\mathbb{T}_L^3$ and preserves the order of the edges in a path. We conclude that every joint identity for the flowed lattice Wilson loops stated in the theorem holds configuration by configuration, before any expectation is taken.

Step 2: the continuum dilation. The map is well defined on gauge orbits. If k is a periodic gauge transformation of the unit torus, then $k_L(x) = k(x/L)$ is periodic on side

L, and direct differentiation gives $(D_L A)^{k_L} = D_L(A^k)$ at each time. Further,

$$F_{ij}(D_L A)(t,x) = L^{-2} F_{ij}(A)(t/L^2, x/L), \qquad \partial_t (D_L A)(t,x) = L^{-3}(\partial_t A)(t/L^2, x/L),$$

and the covariant divergence $\sum_j D_j F_{ji}$ of the curvature scales in the same way as $\partial_t A$, with the factor L^{-3}. Thus D_L maps solutions of the Yang–Mills heat flow to solutions and preserves the compatibility relation $X(t) = \Phi_{t-s} X(s)$. By the uniqueness of smooth covariant solutions (Theorem 24.10), D_L is a map of trajectory spaces; its inverse is $X \mapsto ((t,y) \mapsto LX(L^2 t, Ly))$. Parallel transport along $u \mapsto L\ell(u)$ has coefficient $L^{-1} A(\ell(u)) \cdot L\dot{\ell}(u) = A(\ell(u)) \cdot \dot{\ell}(u)$, so

$$W_{L\ell,\chi,L^2\theta}(D_L X) = W_{\ell,\chi,\theta}(X). \tag{30.6}$$

Composition with the dilation therefore permutes bijectively the regularized Wilson loops, which generate the Wilson topologies, so D_L is a homeomorphism for these topologies. By Theorem 29.3, it is a Borel isomorphism. Squaring the curvature and changing variables $x = Ly$, we obtain $E_L(D_L A) = L^{-1} E_1(A)$, which is (30.5).

Step 3: identification of the measures. We use the same sequence $N_k = nM^k$ and the dilated lattice paths in the identities of Step 1. Since dilation multiplies lengths by L and swept areas by L^2, for each fixed L the dilation of an admissible approximation is an admissible approximation; the same holds for the paths of Lemma 29.10. Theorem 29.28 identifies the limiting joint laws of finitely many Wilson loops on both tori. By (30.6) and the determination of probabilities by these laws (Theorem 29.3), we obtain (30.4).

Step 4: a simultaneous choice of maps. We identify the finite link spaces as in Step 1 and set $\pi_{k,L} = D_L \circ \pi_{k,1}$. These maps are Borel and gauge invariant on the full configuration spaces. Since continuous images of compact sets are compact, the image laws have compact containment for each L, and they converge to $(D_L)_{\#}\lambda_{1,\gamma,[n]_M}$. We choose the determining family on side L by dilating the loops of the unit family by L and its rational times by L^2. Then $d_{c,L}(D_L X, D_L Y) = d_{c,1}(X,Y)$, and the coordinate errors at each cutoff agree exactly. Further, for every $\theta > 0$ and R,

$$\mu_{N_k,\gamma}\{LE_L(\pi_{k,L}(L^2\theta)) > R\} = \mu_{N_k,\gamma}\{E_1(\pi_{k,1}(\theta)) > R\}.$$

For a fixed bounded test F on $\mathcal{X}_1$, let $F_L = F \circ D_L^{-1}$ on $\mathcal{X}_L$. Its error at each cutoff, against the limiting measure, is exactly the unit-side error of F. By Theorem 29.28, this error tends to zero for bounded Wilson-continuous F and for bounded d_c-continuous F. The same identity and the same convergence hold for a fixed bounded continuous test of a finite vector of flowed lattice Wilson loops. Finally, the joint identities for energies and Wilson loops under the limiting measures follow from (30.4), (30.5), and (30.6), which do not involve the convergence of lattice energies. □

Remark 30.2. At fixed γ, the continuum coupling $g_3^2 = \gamma/L$ changes with L. At fixed $g_3^2 > 0$, the dimensionless coupling $\gamma = g_3^2 L$ eventually exceeds any fixed Γ as $L \to \infty$, and Theorem 29.24 gives no uniformity as $\Gamma \to \infty$. Thus Theorem 30.1 is not a statement about large volumes: it yields no infinite-volume limit, no mass gap, no uniform bound on the unscaled energies, and no comparison between different equivalence classes $[n]_M$. The continuity in L at fixed g_3^2 is Corollary 30.12.

30.3 Energy and loop processes at positive times

In this section, we prove that the processes $t \mapsto \mathsf{E}_{a_K}(\Psi_t^{(N_K)} U)$ and $t \mapsto \chi_i(\mathrm{Hol}_{\ell_{i,K}} \Psi_t^{(N_K)} U)$ converge jointly, on every compact interval $[\tau, T] \subset (0, \infty)$ and in the uniform topology, to the corresponding processes under λ. The main difficulty is the energy. The function $X \mapsto E_L(X(t))$ is Borel, but it is not known to be continuous for d_c or for the Wilson topology. The convergence of the image laws $(\pi_K)_\# \mu_{N_K,\gamma}$ therefore does not by itself identify the limit of the lattice energies. We use instead the joint convergence under the conditioned measures in Theorem 29.18, whose proof identifies the energies through the Sobolev topology (Lemma 29.7), together with a comparison of the conditioned and unconditioned limits that holds for all bounded Borel tests.

Lemma 30.3. *Fix $L, T_0, R > 0$, $1/2 < \alpha < 2/3$, $0 < \tau < T < \infty$, finitely many characters χ_i, and lengths $\ell_i^* > 0$. For a mesh $a = L/N$ let $\ell_{i,a}$ be closed lattice paths of physical length at most ℓ_i^*, fixed in time. Let $U \in \mathcal{U}_N$ have a gauge representative whose flow data on $[0, T_0]$ have norm at most R, and set $U(t) = \Psi_t^{(N)} U$. There are $a_0 > 0$ and $C < \infty$ such that, for all $a \le a_0$ and $t, u \in [\tau, T]$,*

$$\begin{aligned} \sup_{\tau \le t \le T} \mathsf{E}_a(U(t)) &\le C, \\ \big|\mathsf{E}_a(U(t)) - \mathsf{E}_a(U(u))\big| + \sum_i \big|\chi_i(\mathrm{Hol}_{\ell_{i,a}} U(t)) - \chi_i(\mathrm{Hol}_{\ell_{i,a}} U(u))\big| &\le C|t-u|. \end{aligned} \tag{30.7}$$

The constants may depend on $L, T_0, R, \alpha, \tau, T$, the characters, the lengths ℓ_i^*, the fixed difference stencil and interpolations, and the margins of the reference solutions used in the proof, but not on the coupling, the cutoff, the depth of the hierarchy, or the particular configuration.

Suppose in addition that, along a sequence $a \to 0$, the paths $\ell_{i,a}$ form admissible approximations of loops ℓ_i, and that at a fixed time $s < \tau$ a smooth one-form b and the reference solutions of its trajectory are given, such that a representative $A_a(s)$ of $U(s)$, in the gauge of the first reference solution, satisfies $e_a = \|A_a(s) - S_a b\|_{C_a^1} \to 0$. Then $\mathsf{E}_a(U(t))$ and $\chi_i(\mathrm{Hol}_{\ell_{i,a}} U(t))$ converge, uniformly for $t \in [\tau, T]$, to the energy and the Wilson loops at time $t - s$ of the continuum trajectory started at b.

Proof. At a small positive time s, the lattice solutions have bounded differences of every order, so they lie close to samples of a compact family of smooth fields. Finitely many

reference solutions for this compact family control the lattice flow up to time T with uniform bounds on three differences. The equation of the flow then bounds the time derivative in C^1_a, and the energy and the loops inherit a Lipschitz bound.

Step 1: smoothing at a small positive time. Let T_R be the existence time of Theorem 24.5 for flow data of norm at most R, and fix $0 < s < \min(T_R, T_0, \tau/4)$, with a positive waiting interval before s. The local solution in the damped gauge and its identification with the Wilson flow follow from Theorem 24.5 and Lemma 24.2. By the first part of Theorem 25.7, every fixed order of differences at time s is bounded, uniformly over the configurations in the statement.

These bounds produce a compact family of smooth limiting fields, uniformly over the configurations. We interpolate each value array and each difference array by piecewise multilinear interpolation. A bound on the next difference bounds the modulus of continuity, also across the cells of the lattice. Then the Arzelà–Ascoli theorem and a diagonal extraction give uniform limits of all these arrays along every sequence of meshes tending to zero. Discrete summation by parts identifies the limit of $D^\nu_a A_a$ with the corresponding distributional derivative of the limit of the value arrays, so the limits are smooth. Their bounds at every order imply that the set of all such limiting fields is compact in each fixed C^q norm and consists of smooth fields; closedness follows from a diagonal sequence of approximating lattice fields. Further, as $a \to 0$, the lattice fields at time s are uniformly close, in value and first differences, to samples of fields in this compact family. Otherwise, an offending sequence and the preceding extraction would give a contradiction.

Step 2: continuation to the time T. We apply Theorem 24.10, with a regularity index at least six, to this compact family of smooth fields. We use the open neighborhood given there, not a claim that families with finitely many bounded derivatives have smooth closure. By the part of Lemma 25.5 on compact families of reference solutions, the restarted lattice solutions in the damped gauge satisfy a uniform C^1_a bound. The compact set in that lemma is the family just constructed, which is compact in C^3 and in every higher norm, and its thresholds and its finitely many reference solutions are fixed before the configuration or the mesh is chosen. For a quantitative comparison with a given smooth limiting trajectory, we apply the fixed-reference estimate of the same lemma on each time interval; the regularity index six provides the five derivatives that it requires. The incoming error in Lemma 29.15 is measured with sampled first derivatives. By Taylor's formula, we have $\|D_a S_a b - S_a \partial b\|_\infty \le Ca\|b\|_{C^2}$, so this error differs from the C^1_a error by $O(a)$. Thus Lemma 29.15 is an instance of Lemma 25.5. Only after the C^1_a bound is available do we apply the second part of Theorem 25.7, which gives uniform bounds on three differences.

The waiting times leave no gap at the transition times. By the local existence statement in C^6 of Theorem 24.10, each reference solution extends a fixed positive amount beyond

the right endpoint of its interval. Since the finitely many families of endpoints are bounded, we can choose a common extension time. The comparison in a common gauge extends the lattice representative over this overlap. We choose the waiting time on the next interval shorter than the overlap, so that the bounds of the second part of Theorem 25.7 on the next interval overlap those on the preceding one, and the first waiting interval ends before τ. We obtain finitely many overlapping representations in the damped gauge that cover $[\tau, T]$, each with uniform bounds on three differences. The fixed gauge transformations at the transition times preserve each of these difference bounds. Indeed, for a smooth gauge transformation k, the function $a^{-1}\operatorname{Log}(k(x)e^{aZ}k(x+ae_i)^{-1})$ extends smoothly to $a = 0$, and the exact product rule gives the bound at each order, using finitely many derivatives of k. These derivatives are part of the data of the reference family.

Step 3: the time derivative. In each of these representations, the equation of the flow is exactly

$$\partial_t A_a = \Delta_a A_a + \mathcal{N}_a(A_a, A_a) + a^{-3} R_3(aA_a),$$

by Lemma 24.2. One difference of the Laplacian uses at most three differences of A_a, and one difference of the quadratic term uses at most two. A term of degree $d \geq 3$ in the last summand carries the factor a^{d-3}. Using the absolute convergence of the analytic series and the shifted product rule, we have

$$\|\partial_t A_a\|_{C^1_a} \leq C \tag{30.8}$$

on the bounds of Step 2, with no inverse power of the mesh. In particular, the time derivative of a link variable $e^{aA_{a,i}}$ has norm at most $Ca\|\partial_t A_{a,i}\|_\infty$. Differentiating a path with n_i links and using unitarity, we find that the time derivative of its character is at most $C_{\chi_i} a n_i \|\partial_t A_a\|_\infty \leq C_{\chi_i} \ell_i^* C$, since $an_i \leq \ell_i^*$. By the Lipschitz estimate of Lemma 29.14 and (30.8), the energy difference is at most $C|t-u|$, and the same lemma bounds the energy itself. Both observables are invariant under the damping gauge transformations and under the fixed gauge transformations at the transition times. Since the lattice flow is continuous in time, the finitely many estimates on the intervals concatenate with the largest constant. This proves (30.7).

Step 4: comparison with a given smooth trajectory. The last assertion uses the given incoming error e_a rather than recovering a limiting field from the flow data. Applying the fixed-reference estimate of Lemma 25.5 on the consecutive intervals of the reference solutions, we find the error $C(e_a + a)$ in C^1_a up to time T, as in Lemma 29.15. By Lemma 29.14, the energy error is bounded in the same way. For the loops, comparing exact edge transports with sampled link variables and using the curvature-area estimate of Theorem 29.23, we obtain the error $C(e_a + a + A_{i,a})$, where $A_{i,a}$ is the swept area of the comparison homotopy for $\ell_{i,a}$. These errors tend to zero uniformly in $t \in [\tau, T]$. □

Theorem 30.4. *Work in the setting of Section 30.1: fix $0 < \gamma \le \Gamma$, the sequence $N_K = n_* B^K$, the maps π_K of Theorem 29.21, and the measure λ. Let $0 < \tau < T < \infty$, let $\ell_1, \dots, \ell_m$ be loops, $\chi_1, \dots, \chi_m$ characters of finite-dimensional representations of $\mathrm{SU}(2)$, and $(\ell_{i,K})_K$ admissible approximations of ℓ_i. Then, under $\mu_{N_K,\gamma}$,*

$$\Big(t \mapsto \big(\mathsf{E}_{a_K}(\Psi_t^{(N_K)} U), (\chi_i(\mathrm{Hol}_{\ell_{i,K}} \Psi_t^{(N_K)} U))_{i=1}^m\big)\Big) \\ \Longrightarrow \Big(t \mapsto \big(E_L(X(t)), (W_{\ell_i,\chi_i,t}(X))_{i=1}^m\big)\Big), \qquad X \sim \lambda,$$

in distribution in $C([\tau,T]; \mathbb{R} \times \mathbb{C}^m)$ with the uniform norm. If $(\ell_{i,K}^{(1)})_K$ and $(\ell_{i,K}^{(2)})_K$ are two admissible approximations of the same loops, with flowed lattice Wilson loops $W_{K,i}^{(1)}(t)$ and $W_{K,i}^{(2)}(t)$, then

$$\lim_{K\to\infty} \mathbb{E}_{\mu_{N_K,\gamma}} \sup_{\tau \le t \le T} \max_i \big| W_{K,i}^{(1)}(t) - W_{K,i}^{(2)}(t) \big| = 0.$$

In particular, every finite joint vector of lattice energies and flowed lattice Wilson loops at times in $(0,\infty)$ converges in law to the corresponding vector under λ. The same path convergence and the same comparison of two admissible approximations hold along the full sequence $N_k = nM^k$, for the maps and the measure $\lambda_{L,\gamma,[n]_M}$ of Theorem 29.28; this is proved in Section 30.6.

The convergence is tested only by bounded continuous functions on the path space. In particular, the theorem gives no moment bound for time derivatives under the Wilson measure.

Proof. We first recall that the joint path convergence holds under the conditioned measures, with limit λ_r. Then we show that λ_r and λ are close for all bounded Borel tests, which lets us pass to the Wilson measure. The comparison of two approximations is a consequence.

Step 1: conditioned measures. Let $r \ge r_0$, so that (30.1) holds. At fixed r, by Theorem 29.18, the energy and loop paths under $\nu_{K|r}$ converge jointly to the image of λ_r under the continuum path map. The proof of that theorem compares the lattice flows of the full field and of a finite-scale reconstruction, identifies the energies through the Sobolev topology, and uses Theorem 28.8 for the bounds on the flow data; no limiting initial potential is constructed. That theorem applies to every finite union of admissible approximations, so two approximations of the same loops have identical limiting loop paths.

Step 2: comparison of the limits for Borel tests. We now identify the limit of the lattice energies under the Wilson measure with the same λ; this does not follow from the agreement of the loop marginals alone. By Theorems 29.19 and 29.20, the same maps π_K

have image limit λ_r under $\nu_{K|r}$ and image limit λ under $\mu_{N_K,\gamma}$, for bounded d_c-continuous tests. We claim that

$$\left| \int f \, d\lambda_r - \int f \, d\lambda \right| \le 2\|f\|_\infty F_\gamma(n_r) \tag{30.9}$$

for every bounded Borel function f on $\mathcal{X}_L$. For bounded d_c-continuous f, this follows by applying (30.2) to $f(\pi_K)$ at the same cutoff, using (30.1), and passing to the two image limits. By Theorems 29.3 and 29.6, both limits are tight probability measures on the separable metric space $(\mathcal{X}_L, d_c)$, and in particular inner regular. A bounded Borel function on a metric space can then be approximated in $L^1(\lambda + \lambda_r)$ by bounded continuous functions with the same bound on the supremum. Indeed, we first approximate it uniformly by a simple function $\sum_k c_k \mathbf{1}_{A_k}$ with disjoint A_k and $|c_k| \le \|f\|_\infty$. We then choose disjoint compact sets $K_k \subset A_k$ that carry all but an arbitrarily small part of the mass of $\lambda + \lambda_r$, then disjoint open neighborhoods $O_k \supset K_k$ of arbitrarily small additional mass, and continuous functions $0 \le \phi_k \le 1$ equal to one on K_k and supported in O_k. The function $\sum_k c_k \phi_k$ has the required bound and approximation property. This proves (30.9) for every bounded Borel f, without any continuity of the energy for d_c.

Step 3: the Wilson measure. Let $G(X)$ be the continuum path $t \mapsto (E_L(X(t)), (W_{\ell_i,\chi_i,t}(X))_i)$ on $[\tau, T]$, and $G_K(U)$ the corresponding lattice path. The map G is Borel into $C([\tau, T]; \mathbb{R} \times \mathbb{C}^m)$. Indeed, its Wilson-loop coordinates at rational times are Borel by Theorem 29.3, its energy coordinates are Borel by Theorem 29.6, each trajectory gives continuous paths because the flow is smooth, and evaluations at rational times generate the Borel σ-algebra of the path space. Then (30.9) applies to $f \circ G$ for every bounded continuous path test f. Using (30.2) at the cutoff N_K and then Step 1, we obtain

$$\limsup_{K\to\infty} \left| \mathbb{E}_{\mu_{N_K,\gamma}} f(G_K(U)) - \int f(G(X)) \, d\lambda(X) \right| \le 4\|f\|_\infty F_\gamma(n_r).$$

Letting $r \to \infty$ proves the convergence along the whole sequence. The tightness of the lattice paths under the Wilson measure can also be seen directly. By Lemma 30.3, on the event $\{\mathsf{R}_{K|r} \le R\}$, the paths lie, for small meshes, in a compact set of the path space given by the Arzelà–Ascoli theorem. We first make $F_\gamma(n_r)$ small, then the probability in (30.3) small, and then take K large. By (30.2), the complement of the compact set has Wilson probability at most its conditioned probability plus $e_{K|r}$. The finitely many remaining cutoffs have compact path images.

The source functionals of admissible approximations also converge locally uniformly. Indeed, path convergence implies the convergence of every finite joint vector of Wilson loops, and the vector is bounded by the dimensions of the representations. On each ball $\{\sum_i |z_i| \le R'\}$, the functions $e^{\sum_i z_i w_i}$ are bounded and have a common Lipschitz constant in z, so a finite net of the ball gives uniform convergence.

Step 4: two approximations. Applying Theorem 29.18 to the union of the two approximations, we find that the limiting joint path has identical loop paths. Let Δ be the supremum over $t \in [\tau, T]$ of the maximal loop discrepancy; it is continuous in the uniform topology. If the list of loops is empty, there is nothing to prove; otherwise, let $D = \max_i \chi_i(I)$. The bounded continuous test $\min(2D, \Delta)$ equals Δ on all lattice and limiting paths of characters, and it vanishes under the limiting law. Its expectation under $\nu_{K|r}$ then tends to zero. Applying (30.2) at the same cutoff and then letting $r \to \infty$, we obtain the conclusion under the Wilson measure. □

30.4 Convergence in the Sobolev topology

In [43], Cao and Chatterjee also consider trajectories of Sobolev gauge orbits. Recall from Definition 29.1 that $\mathcal{H}_L = H^1(\mathbb{T}^3_L; \mathfrak{su}(2)^3)/\mathcal{G}^{2,2}_L$ carries the sequential weak quotient topology $\mathcal{T}_q$, that $\mathcal{X}^{1,2}_L$ is the space of trajectories $Z : (0, \infty) \to \mathcal{H}_L$ with $Z(t) = \Phi^{1,2}_{t-s} Z(s)$ for $0 < s < t$, with the topology $\mathcal{T}_{1,2}$ of pointwise evaluation [43, Definition 3.70, p. 41], and that $i^{1,2} : \mathcal{X}_L \to \mathcal{X}^{1,2}_L$ sends a smooth orbit at each time to its Sobolev orbit. The compactness behind this topology is the weak compactness of gauge orbits with bounded energy, which goes back to Uhlenbeck [151]; we use it only through the results of Cao and Chatterjee cited below. We consider $\mathcal{T}_{1,2}$ because, for each $t > 0$, the energy $Z \mapsto E_L(Z(t))$ is continuous for it (Lemma 29.7); the energy is not known to be continuous for the Wilson topology. Convergence in $\mathcal{T}_{1,2}$ therefore carries the convergence of the energies of the approximating trajectories.

Theorem 30.5. *Work in the setting of Section 30.1. The maps $i^{1,2} \circ \pi_K$ are Borel on the full configuration spaces, and*

$$(i^{1,2} \circ \pi_K)_\# \mu_{N_K,\gamma} \Longrightarrow (i^{1,2})_\# \lambda$$

against every bounded $\mathcal{T}_{1,2}$-continuous real function. The topology on $\mathcal{X}_L$ pulled back by $i^{1,2}$ is finer than $\mathcal{T}_W$ and has the same Borel σ-algebra. For each fixed $r \geq r_0$, the same conclusion holds under the conditioned measures $\nu_{K|r}$, with limit $(i^{1,2})_\# \lambda_r$. The conclusion under the Wilson measures also holds for the maps of Theorem 29.28 along $N_k = nM^k$, with limit $(i^{1,2})_\# \lambda_{L,\gamma,[n]_M}$. The conclusion under conditioned measures is asserted only along the sequences $(n_* B^K)_K$; no sequence of conditioned measures along nM^k is considered, and no conditioned limits along different residue classes are compared. In each case, every finite joint vector of energies at positive times and Wilson loops of the image trajectories converges in distribution.

More generally, let X_K, $K \geq 0$, be Borel $\mathcal{X}_L$-valued random variables such that, for every $t > 0$, the laws of $E_L(X_K(t))$ are tight, and such that the finite joint laws of the Wilson loops of X_K converge to those of a Borel probability λ' on $\mathcal{X}_L$. Then the laws of $i^{1,2}(X_K)$ converge to $(i^{1,2})_\# \lambda'$ against every bounded $\mathcal{T}_{1,2}$-continuous real function.

Each assertion has exactly the uniformity of its input convergence: the theorem adds no uniformity in the coupling and no rate.

Proof. We first show that $i^{1,2}$ is a Borel bijection with a Borel inverse that preserves Wilson loops, then prove the general assertion by compactness, and finally check its hypotheses for the maps π_K.

By [43, Lemma 3.84, pp. 47–48], $i^{1,2}$ is Borel. Every trajectory in $\mathcal{X}_L^{1,2}$ has a smooth representative at every positive time [43, Lemma 3.85, p. 48], and choosing its smooth orbit defines a map $j^{1,2} : \mathcal{X}_L^{1,2} \to \mathcal{X}_L$ [43, Definition 3.86, p. 48]; a Sobolev gauge transformation between two smooth connections is smooth [43, Lemma 3.10, p. 24], so this choice is unambiguous. We have $j^{1,2} \circ i^{1,2} = \mathrm{Id}$ [43, Lemma 3.87, p. 48], and $i^{1,2} \circ j^{1,2} = \mathrm{Id}$ directly at each time. By [43, Lemmas 3.88–3.89, pp. 48–49], $j^{1,2}$ preserves all Wilson loops and is continuous into $\mathcal{T}_W$. Thus $i^{1,2}$ and $j^{1,2}$ are inverse Borel bijections. Since $j^{1,2}$ is continuous, every $\mathcal{T}_W$-open set $V = (j^{1,2} \circ i^{1,2})^{-1}(V)$ is open for the pulled-back topology, which is therefore finer than $\mathcal{T}_W$. The measurability of $i^{1,2}$ gives the reverse inclusion of Borel σ-algebras; the continuity of $i^{1,2}$ is not used.

We now consider the general sequence. The variables $i^{1,2}(X_K)$ are measurable $\mathcal{X}_L^{1,2}$-valued, and their energies at every positive time have tight laws, since passing to the Sobolev orbit does not change the energy. These are the hypotheses of [43, Theorem 3.73, pp. 41–42]. Applying this theorem to an arbitrary subsequence, we obtain a further subsequence converging against all bounded $\mathcal{T}_{1,2}$-continuous functions to a Borel probability measure η on $\mathcal{X}_L^{1,2}$. The regularized Wilson loops on $\mathcal{X}_L^{1,2}$ are bounded and continuous [43, Definition 3.82, p. 47], and they become the usual Wilson loops at positive times after applying $j^{1,2}$ [43, Lemma 3.88, p. 48]. Hence every finite joint law of the Wilson loops under $j^{1,2}_{\#}\eta$ equals that under λ'. Since these laws determine probability measures (Theorem 29.3), we have $j^{1,2}_{\#}\eta = \lambda'$. Applying the inverse Borel map $i^{1,2}$, we find $\eta = (i^{1,2})_{\#}\lambda'$, independently of the subsequence. If the expectations of a bounded continuous test did not converge to the claimed limit, some subsequence would stay at a positive distance from it, which contradicts what we just proved. This proves the general assertion.

For the image laws under the Wilson measures, the hypotheses are the energy tails and the convergence of the finite joint laws of the Wilson loops in Theorems 29.20 and 29.21, which hold in the present setting. For the conditioned measures, they are the corresponding conditioned statements in Theorem 29.19. For the maps along $N_k = nM^k$, they are the convergence of the image laws and the energy tails at every positive time asserted in Theorem 29.28. No other property of the construction of π_K is used. The convergence of finite joint vectors of energies of the image trajectories follows from Lemma 29.7, and the Wilson loops are continuous for $\mathcal{T}_{1,2}$ by the preceding paragraph. The rescaling to side L and all measurability statements are those of Theorem 29.3. □

30.5 Spatial isometries and center symmetry

Two groups act on the trajectory space. The first consists of the isometries $f(x) = Qx + y$ of $\mathbb{T}_L^3$ with $Q \in O(3,\mathbb{Z})$, the signed permutation matrices, and $y \in \mathbb{T}_L^3$; they act at every time by pullback of one-forms, and then on gauge orbits. The second is the group $\{\pm I\}^3$ of center symmetries. On the lattice, a center symmetry multiplies the link variables crossing one coordinate plane by a central element; this is the familiar center symmetry of pure gauge theories on a torus (compare 't Hooft [149]). Both groups preserve the Wilson measure and commute with the Wilson flow, and we pass these exact identities to the limit. For a loop ℓ whose lift to $\mathbb{R}^3$ runs from x to $x + Lw(\ell)$, the vector $w(\ell) \in \mathbb{Z}^3$ is its winding vector; the winding vector of a closed lattice path is defined in the same way. This is the vector denoted by $\nu(\ell)$ in Theorem 2.5; it is distinct from the determining coordinates w_j.

Theorem 30.6. *Work in the setting of Section 30.1. The measure λ is invariant under the pullback f^* by every isometry $f(x) = Qx + y$ with $Q \in O(3,\mathbb{Z})$ and $y \in \mathbb{T}_L^3$. It is also invariant under the following action of $\{\pm I\}^3$. For $z = (z_1, z_2, z_3) \in \{\pm I\}^3$ choose a smooth map $h_z : \mathbb{R}^3 \to \mathrm{SU}(2)$ with $h_z(x + Le_i) = z_i h_z(x)$, and set*

$$C_z[A] = [A^{h_z}], \qquad A^{h_z} = h_z A h_z^{-1} - (dh_z)h_z^{-1}.$$

The connection A^{h_z} is periodic, the class $C_z[A]$ does not depend on the choice of h_z or of the representative A modulo periodic smooth gauge transformations, and C_z defines a group action on $\mathcal{A}_L/\mathcal{G}_L$ that commutes with the Yang–Mills heat flow, hence an action on $\mathcal{X}_L$. The spatial and center maps are homeomorphisms for the Wilson topology and Borel automorphisms, and they preserve the energy.

For normalized fundamental Wilson loops $W_{\ell,t}(X) = (1/2)\,\mathrm{tr}\,\mathrm{Hol}_\ell X(t)$, integers $b_1, \dots, b_m \geq 0$, and times $t_1, \dots, t_m > 0$,

$$\mathbb{E}_\lambda \prod_{j=1}^m W_{\ell_j,t_j}^{b_j} = 0 \qquad \text{if} \qquad \sum_{j=1}^m b_j w(\ell_j) \neq 0 \text{ in } (\mathbb{Z}/2\mathbb{Z})^3.$$

For characters of the irreducible representations of highest weights n_j, the same holds with b_j replaced by $b_j n_j$ in the parity condition. The corresponding selection rule holds at every finite cutoff, with the winding vectors of the lattice paths. All these conclusions also hold for the measure $\lambda_{L,\gamma,[n]_M}$ of Theorem 29.28.

The center symmetry acts on periodic gauge orbits; it is not an additional identification in the quotient by periodic gauge transformations, since h_z is not periodic when $z \neq (I, I, I)$.

Proof. We first prove exact identities on the lattice, then construct the continuum actions and compute their effect on Wilson loops, and finally pass to the limit.

Step 1: lattice symmetries. A lattice translation or a signed permutation of the coordinates relabels the directed edges, inverting a link variable when the orientation of its edge is reversed. It preserves the product Haar measure and the product bi-invariant Riemannian metric. A plaquette path is mapped to a plaquette path, up to cyclic permutation and inversion. Since $q(V) = q(V^{-1})$ and q is a class function, the Wilson action, and hence the Wilson measure (2.1), are preserved. The invariance of Haar measure under inversion also follows from Lemma 5.1 and the uniqueness of the Haar probability measure.

Let $c_e \in \{\pm I\}$, with $c_{\bar{e}} = c_e^{-1}$, be a center-valued function on links such that $\prod_{e \in \partial p} c_e = I$ for every plaquette p. The map $U_e \mapsto c_e U_e$ preserves the product Haar measure, the product metric, and the trace of every plaquette variable, so it preserves the Wilson measure. An explicit choice with monodromy z is $c_e = z_i$ on the positive direction-i links from the plane $x_i = L - a$ to the plane $x_i = 0$, and $c_e = I$ on all other links. Its product around every plaquette is I, and for a closed lattice path ℓ_a,

$$c(\ell_a) = \prod_{i=1}^{3} z_i^{w_i(\ell_a)}, \qquad \mathrm{Hol}_{\ell_a}(cU) = c(\ell_a)\,\mathrm{Hol}_{\ell_a}(U). \tag{30.10}$$

Every such flat center-valued function acts, modulo lattice gauge transformations, as one of these explicit choices. Indeed, we lift the lattice to $a\mathbb{Z}^3$. On the lift, the product of a flat function along a path with fixed endpoints does not depend on the path, since any closed lattice path can be reduced to the trivial path by cancellations and by moves across elementary squares. Thus the lifted function is the lattice differential of a center-valued function on the vertices of $a\mathbb{Z}^3$, whose three monodromies under the periods Le_i are the z_i. For two flat functions with the same monodromies, the ratio of these vertex functions is periodic, so their actions on periodic lattice gauge orbits agree.

An isometry that preserves a smooth function maps its Riemannian gradient to its gradient. All the maps above are isometries of $\mathcal{U}_N$ that preserve the Wilson action, so they commute with the Wilson flow, which exists and is unique globally on the compact configuration space; the rescaling of time by $4/a^2$ preserves this commutation. We conclude that the exact identities of joint laws, and (30.10), hold simultaneously for any finite list of lattice paths, characters, and positive times, without conditioning and without choosing representatives.

Step 2: the continuum actions. Write $z_i = (-I)^{\varepsilon_i}$ with $\varepsilon_i \in \{0, 1\}$, and let

$$h_z(x) = \exp\Big(\frac{2\pi}{L}\tau_3 \sum_i \varepsilon_i x_i\Big),$$

where $\tau_3 = -i\sigma_3/2$. Since $e^{2\pi\tau_3} = -I$, this map has the required monodromy. Since the z_i are central, A^{h_z} is periodic and smooth whenever A is. If A is replaced by A^k with k

periodic, then $(A^k)^{h_z} = (A^{h_z})^{h_z k h_z^{-1}}$, and $h_z k h_z^{-1}$ is periodic. If h_z' has the same monodromy as h_z, then $h_z' h_z^{-1}$ is periodic and $A^{h_z'} = (A^{h_z})^{h_z' h_z^{-1}}$. This proves both independence claims, for gauge transformations in all homotopy classes. The product $h_z h_{z'}$ has monodromy zz', so the induced maps on orbits form a group action.

The curvature transforms as $F(A^{h_z}) = h_z F(A) h_z^{-1}$, so the energy is preserved. The Yang–Mills heat equation is covariant under the time-independent smooth gauge transformation h_z on $\mathbb{R}^3$, and both the transformed initial datum and the transformed solution are periodic. By the uniqueness of periodic smooth solutions (Theorem 24.10), C_z commutes with the flow. The same facts for the pullback f^* follow from the chain rule, the orthogonality of Q, the invariance of volume, and the same uniqueness. Hence both kinds of maps act on trajectories.

For a loop ℓ whose lift runs from x to $x + Lw(\ell)$, the transformation rule $H^k(s) = k(\ell(0))H(s)k(\ell(s))^{-1}$ for parallel transport gives

$$\mathrm{Hol}_\ell(A^{h_z}) = h_z(x)\,\mathrm{Hol}_\ell(A) h_z(x + Lw(\ell))^{-1} = \Big(\prod_i z_i^{w_i(\ell)}\Big) h_z(x)\,\mathrm{Hol}_\ell(A) h_z(x)^{-1}. \tag{30.11}$$

For $f(x) = Qx + y$, parallel transport gives $W_{\ell,\chi,t}(f^*X) = W_{f\ell,\chi,t}(X)$. The character of the irreducible representation of highest weight n satisfies $\chi_n(-H) = (-1)^n \chi_n(H)$, since $-I$ acts as $(-1)^n$ on the nth symmetric power of the fundamental representation. For a general finite-dimensional representation ρ, the two eigenspaces of the involution $\rho(-I)$ are invariant subrepresentations, and the transformed character is the difference of their characters. It follows that every Wilson loop composed with either kind of map is a finite linear combination of Wilson loops. Since $\mathcal{T}_W$ is the initial topology of the Wilson loops, both kinds of maps and their inverses are continuous, and by Theorem 29.3 they are Borel.

Step 3: spatial invariance. Fix $y \in \mathbb{T}_L^3$ and $Q \in O(3,\mathbb{Z})$. Let y_K be lattice translations with $d(y_K, y) \le \sqrt{3}a_K/2$, and set $f_K(x) = Qx + y_K$, which maps the lattice to itself. The exact identity of Step 1 for f_K applies to a finite list of admissible approximations $(\ell_{i,K})_K$. The transformed paths have the same lengths, and the comparison homotopies transformed by f_K connect them to $f_K\ell_i$ with the same swept areas, which tend to zero. We append the translation strip between $f_K\ell_i$ and $f\ell_i$, together with a connecting path between their basepoints. On the universal cover, its swept area is at most $|y_K - y|\,\mathrm{length}(\ell_i)$, and the same bound holds after projection to the torus, for the swept area counted with multiplicity. Thus the transformed paths form an admissible approximation of $f\ell_i$, with swept areas $A_{i,K} + O(a_K) \to 0$. Using the identification of the limiting finite joint laws of the Wilson loops in Theorem 29.20 (along nM^k, in Theorem 29.28) together with Theorem 29.23, we pass the exact identities to every finite joint law of the Wilson loops of f^*X and of X under λ. By Theorem 29.3, we have $(f^*)_\# \lambda = \lambda$. This proves invariance under continuous as well as lattice translations.

Step 4: center invariance and the selection rule. We now use the exact center identity of Step 1. Since a based homotopy preserves the integer winding vector, for large K the central sign in (30.10) for $\ell_{i,K}$ is the sign in (30.11) for ℓ_i. By the convergence of joint loop laws, the identity passes to every finite joint vector under λ. Since these laws determine probability measures, we have $(C_z)_{\#}\lambda = \lambda$. For a product of normalized fundamental Wilson loops raised to the powers b_j, this invariance multiplies the expectation by $\prod_i z_i^{\sum_j b_j w_i(\ell_j)}$. If the vector $\sum_j b_j w(\ell_j)$ has a nonzero component modulo two, we choose $z_i = -I$ at such a component and $z_i = I$ elsewhere. Then the multiplier is -1, so the expectation equals its negative and vanishes; the variables are bounded, so no integrability issue arises. The rule for irreducible characters follows in the same way, with the additional parities n_j, and the rule at a finite cutoff follows directly from the exact identities of Step 1. For the measure $\lambda_{L,\gamma,[n]_M}$ along the full sequence, see Section 30.6. □

30.6 Collected conclusions and the full sequence

We collect the conclusions of Sections 30.3 to 30.5 in the setting of Theorem 29.21, and then prove their extension to the full sequence $N_k = nM^k$.

Corollary 30.7. *At every fixed $0 < \gamma \leq \Gamma$, in the setting of Theorem 29.21, all conclusions of Theorems 30.4 to 30.6 hold, with admissible approximations fixed in time. In particular, the joint processes of lattice energies E_a and flowed lattice Wilson loops converge in distribution in the uniform topology on $[\tau, T]$ to the corresponding processes under the same measure λ, and the expected supremum of the loop discrepancy between two admissible approximations tends to zero. The image laws of the maps π_K in the Sobolev topology converge, together with every finite joint vector of energies and Wilson loops of the image trajectories. The measure λ is invariant under the spatial and center symmetries, and the winding selection rules hold. These conclusions hold at each fixed coupling; no modulus of convergence for the paths or in the Sobolev topology is uniform in the coupling.*

Proof. Theorems 30.4 to 30.6 are formulated and proved at every fixed $0 < \gamma \leq \Gamma$, for the maps and the measure of Theorem 29.21, and their inputs have no further restriction on γ. The deterministic Lemma 30.3 uses Theorems 24.5 and 25.7 and Lemma 25.5, which have no restriction on the coupling, together with the energy estimates of Lemma 29.14; its Lipschitz bound in time uses only the lengths of the paths. The bounds on the flow data are tight by Lemma 28.11. The joint loop limits used in the proof of Theorem 30.6 are given by Theorems 29.21 and 29.23; the strip added when a continuous translation is approximated by lattice translations has vanishing swept area and is covered by Theorem 29.23. The Sobolev assertion requires only the energy tails and the convergence of the finite joint laws of the Wilson loops, which are part of Theorem 29.21.

We also record a second proof of the convergence of the conditioned path laws used in Step 1 of the proof of Theorem 30.4. By Lemma 30.3, on each event $\{\mathsf{R}_{K|r} \le R\}$ and for small meshes, the joint energy and loop paths are bounded and Lipschitz in time with constants depending on R, and the consistency of the loop paths for admissible approximations follows from (29.12). By (30.3) and the Arzelà–Ascoli theorem, the conditioned path laws are tight. By Theorems 29.21 and 29.23, their joint laws at rational times are those of the paths under λ_r, and these laws determine a probability measure on the continuous path space. Hence the conditioned path laws converge to the image of λ_r under the continuum path map, which is Borel because its coordinates at rational times are Borel and its paths are continuous. This argument does not require the energy to be continuous in the Wilson topology. The passage to the Wilson measure is then Steps 2 and 3 of the proof of Theorem 30.4. □

We now prove the assertions on the full sequence $N_k = nM^k$ in Theorems 30.4 to 30.6, which are also the additional assertions of Theorem 29.28 on paths, the Sobolev topology, and symmetries.

Proof of the assertions on the full sequence. We take the consecutive integers $J, J+1$ of Corollary 23.15 and the maps used in Theorem 29.28. In this paragraph, $r \in \{0, \dots, J-1\}$ denotes a residue index. For each residue r, the subsequence nM^{r+Jl}, $l \ge 0$, is a sequence of the form n_*B^l with base $nM^r \in 4\mathbb{N}$, and the maps of Theorem 29.28 on it are those of Corollary 29.26.

On every such residue-class subsequence, Theorem 30.4, applied through Theorem 29.21, yields the convergence of the energy and loop paths and the comparison of two admissible approximations. By Theorem 29.28, the limiting measure is the same $\lambda_{L,\gamma,[n]_M}$ for every residue. The continuum path map is Borel: its energy coordinates at fixed times are Borel by Theorem 29.6, its Wilson-loop coordinates are Borel by Theorem 29.3, its paths are continuous, and the Borel σ-algebra of the uniform path space is generated by the evaluations at a countable dense set of times. Hence the limiting path law is the same for every residue. For a bounded continuous path test, the expectations converge along each of the finitely many residue classes, and taking the largest of the finitely many thresholds proves the convergence along the whole sequence. The same finite maximum proves the comparison of two admissible approximations.

For the Sobolev assertion, the general part of Theorem 30.5 applies directly to the interlaced maps, since Theorem 29.28 gives the tightness of the energies of the image trajectories at every positive time and the convergence of all joint laws of determining coordinates. Alternatively, the Sobolev limit along each residue class is the same Borel image $(i^{1,2})_{\#}\lambda_{L,\gamma,[n]_M}$, and the finite maximum argument above applies to every bounded continuous test for $\mathcal{T}_{1,2}$. Lemma 29.7 identifies the finite joint vectors of energies and Wilson loops of the image trajectories.

Finally, the limiting measure equals, for example, the measure along the sequence $n(M^{J+1})^I$ used in the proof of Theorem 29.28. Theorem 30.6 for that sequence therefore gives the spatial and center invariance of this measure, and the selection rule is an identity for this measure. The proof uses only fixed couplings and finitely many values of J, so no uniformity in the coupling, in Γ, or in J is involved. □

30.7 Continuity and uniform convergence in the coupling

In this section, the coupling varies in a compact interval $I = [\gamma_-, \gamma_+] \subset (0, \infty)$, $\gamma_- > 0$. We show that the convergence statements for finite vectors of Wilson loops and for the image laws specified in Theorem 30.10 hold uniformly for $\gamma \in I$, with approximating maps that do not depend on γ, and that $\gamma \mapsto \lambda_{L,\gamma,[n]_M}$ is weakly continuous. The main point is the order of the choices: the parameters, the minimum coarse side, and the sequence $m(K)$ that determines the maps must be fixed before $\gamma \in I$ is chosen. To that end, we first prove, for each fixed number of constraints, that the probability that no element of the countable family of Lemma 29.8 satisfies the constraints tends to zero uniformly in $\gamma \in I$. Only then do we choose $m(K)$.

Constants with a subscript I may depend on both endpoints $\gamma_\pm$, on the coarse side, on L, M, J, Θ, on the analytic radii, the exponents, and the moment orders, and on the stated lists of times and observables. They do not depend on $\gamma \in I$, on the depth of the hierarchy, or on the finer mesh; that is, they have the dependence described in item (7) of Definition 4.14, with the additional dependence on I. Lattice paths are admissible approximations as in Section 30.1; they and their swept areas do not depend on γ. The first of two lemmas restates the deterministic comparison of Theorem 29.16 at finitely many observation times.

Lemma 30.8. *Fix $L, T_0, R > 0$, $1/2 < \alpha < 2/3$, $0 < \tau \le T < \infty$, and a finite list $(\ell_{h,a}, \chi_h, t_h)$ of closed lattice paths, characters, and times $t_h \in [\tau, T]$, where the paths have physical lengths bounded by fixed numbers. For $n = L/a \in \mathbb{N}$ set*

$$W_h^{\mathrm{lat}}(U) = \chi_h\big(\mathrm{Hol}_{\ell_{h,a}} \Psi_{t_h}^{(n)} U\big).$$

Consider two flow data (x_a, y_a) and (x'_a, y'_a) on the same lattice and in the same gauge, of initial configurations U and U', with norms on $[0, T_0]$ at most R, and set $d_a = \mathsf{X}_\alpha^a(x_a - x'_a) + \mathsf{Y}_\alpha^a(y_a - y'_a)$, where both norms include their difference components. There are $a_* > 0$, $d_* > 0$, and $C_R < \infty$, depending only on the displayed deterministic data, such that $d_a \le d_*$ and $a \le a_*$ imply

$$\sup_{\tau \le t \le T} \big|\mathsf{E}_a(\Psi_t^{(n)} U) - \mathsf{E}_a(\Psi_t^{(n)} U')\big| + \max_h \big|W_h^{\mathrm{lat}}(U) - W_h^{\mathrm{lat}}(U')\big| \le C_R d_a,$$

and each of these energies is at most C_R on $[\tau, T]$. The constants do not depend on the coupling, the law, the cutoff, the depth of the hierarchy, the index of a finite-scale reconstruction, or the

derivatives of its arrays. For a fixed finite-scale reconstruction, interpolated by the cardinal interpolation of Lemma 16.3, the joint vector of lattice energies and flowed lattice Wilson loops converges, uniformly over the bounded set of its arrays on the coarse mesh, to the corresponding vector of the continuum flow from the interpolated field, for admissible approximations.

Proof. We work in the common gauge in which d_a is measured and apply Theorem 29.16 with the window $[\tau, T]$ and the given length bounds. After enlarging the constant, the supremum over time in that theorem bounds the discrepancy of each loop at its own time t_h, as well as the energy discrepancy, and its bound on the individual energies gives the bound C_R. We take d_* below the threshold for the discrepancy in Lemma 25.9. These are deterministic results with no restriction on the coupling. For the bounded set of coarse arrays, the uniform consistency of the joint energy and loop paths in Lemma 29.17 implies the stated consistency of the finite vector. Only this consistency constant may depend on the derivatives of the arrays of the fixed finite-scale reconstruction. □

For the second lemma, fix a coarse side n and write $a_q = (L/n)B^{-q}$. Under $\nu_{nB^k,n,\gamma}$, let $\widehat{\theta}_q$ be the link logarithms of the field reconstructed at scale q by the reconstruction maps (Theorem 15.13), and let $f_q = I_{a_q \to 0}(\widehat{\theta}_q / a_q)$ be its cardinal interpolation to a smooth one-form on $\mathbb{T}_L^3$ (Lemma 16.3). We write $X^{[q]}$ for the continuum trajectory started at f_q, and $d_{k,q}$ for the norm of the difference between the flow data of the fields reconstructed at scales k and q, computed on the lattice of mesh a_k, as in Lemma 28.10.

Lemma 30.9. *Fix $L > 0$, $I = [\gamma_-, \gamma_+] \subset (0, \infty)$, $\Gamma \geq \gamma_+$, the parameters of Theorem 23.5, and a coarse side n above the common threshold of Lemma 28.10. Fix a finite list of energies at positive times and of admissible approximations of loops with characters and positive times. Under $\nu_{nB^k,n,\gamma}$, let $Z_{k,\gamma}$ be the joint vector of lattice energies and flowed lattice Wilson loops, and let $Z_{k,\gamma}^{[q]}$ be the joint vector of continuum energies and Wilson loops of $X^{[q]}$, computed on the same sample. Then*

$$\lim_{q \to \infty} \limsup_{k \to \infty} \sup_{\gamma \in I} \mathbb{E}_{\nu_{nB^k,n,\gamma}} \min\bigl(1, |Z_{k,\gamma} - Z_{k,\gamma}^{[q]}|\bigr) = 0. \tag{30.12}$$

For each fixed q, the laws of $Z_{k,\gamma}^{[q]}$ converge as $k \to \infty$, uniformly in $\gamma \in I$, to laws that depend continuously on γ and have a common compact support. For each fixed $t > 0$, the tails of the lattice energy at time t under $\nu_{nB^k,n,\gamma}$ are uniform over $\gamma \in I$ and over all cutoffs.

Proof. For fixed q, the array on the coarse mesh lies in a fixed compact set, and the continuum vector is a continuous function of this array by Theorem 24.10. The assertion about the laws at fixed q, including the continuity in γ and the compact support, then follows from Theorem 15.16.

Let $\rho_I(R)$ be the tail of the norm of the flow data in (28.18), and let $d_*(R+1)$ be the threshold for the discrepancy in Lemma 30.8 at the radius $R+1$. Fix $0 < \delta \leq$

$\min\{1, d_*(R+1)\}$. On the event that the flow data of the full field have norm at most R and $d_{k,q} \le \delta$, the flow data of the full field and of the field reconstructed at scale q both have norm at most $R+1$, and the hypotheses of Lemma 30.8 hold for all sufficiently small meshes. Applying that lemma, followed by its consistency statement for the fixed scale q, we obtain

$$|Z_{k,\gamma} - Z_{k,\gamma}^{[q]}| \le C_R\delta + \omega_q(a_k), \qquad \omega_q(a_k) \longrightarrow 0,$$

uniformly over the bounded set of coarse arrays and over γ; the mesh threshold for the first comparison does not depend on q. This implies that the expectation in (30.12) is at most

$$\rho_I(R) + \sup_{\gamma\in I} \nu_{nB^k,n,\gamma}\{d_{k,q} > \delta\} + C_R\delta + \omega_q(a_k).$$

With R and δ fixed, we first take the limit superior in k at fixed q, then let $q \to \infty$ using (28.17), then let $\delta \to 0$, and finally let $R \to \infty$. This proves (30.12). The energy tails follow from the uniform tail $\rho_I(R)$ and the deterministic bound on the energy for flow data of norm at most R in Lemma 30.8. The finitely many coarse cutoffs below the mesh threshold are included by the bound $\mathsf{E}_a \le 48N^3/a$, which holds because $0 \le q(U_p) \le 2$ for every plaquette and there are $3N^3$ positive plaquettes. This yields the supremum over all cutoffs. □

Theorem 30.10. *Fix $L > 0$, an odd integer $M \ge 3$, and $I = [\gamma_-, \gamma_+] \subset (0,\infty)$ with $\gamma_- > 0$. Choose $\Gamma \ge \gamma_+$ and the parameters of Theorem 23.5. There is a minimum coarse side n_I such that, on every sequence $N_K = n_* B^K$ with $n_* \in 4\mathbb{N}$, after a finite shift of the base, common to all $\gamma \in I$, if $n_* < n_I$, the following statements hold, with $\lambda_\gamma = \lambda_{L,\gamma,[n_*]_M}$.*

1. *For every fixed finite vector of flowed lattice Wilson loops on admissible approximations, the laws under $\mu_{N_K,\gamma}$ converge to the corresponding law under λ_γ in the bounded-Lipschitz distance, uniformly for $\gamma \in I$. The complex source functionals and each of their fixed derivatives converge uniformly for $\gamma \in I$ and z in each fixed finite ball.*
2. *There are Borel maps π_K on the full configuration spaces, invariant under periodic lattice gauge transformations and independent of γ and of any coarse side chosen afterwards, such that for each fixed j and $t > 0$,*

$$\sup_{\gamma\in I} \mathbb{E}_{\mu_{N_K,\gamma}} |w_j(\pi_K) - W_{K,j}^{\mathrm{lat}}| \longrightarrow 0, \qquad \lim_{R\to\infty} \sup_{K\ge 0,\, \gamma\in I} \mu_{N_K,\gamma}\{E_L(\pi_K(t)) > R\} = 0.$$

For every further fixed finite vector $\mathscr{W}$ of Wilson loops on admissible approximations, with lattice counterpart $\mathscr{W}_K^{\mathrm{lat}}$, and every bounded continuous test f of that vector,

$$\sup_{\gamma\in I} \mathbb{E}_{\mu_{N_K,\gamma}} \big| f(\mathscr{W}(\pi_K)) - f(\mathscr{W}_K^{\mathrm{lat}}) \big| \longrightarrow 0.$$

The same statements on determining coordinates and energy tails hold uniformly in $\gamma \in I$ under every fixed conditioned measure $\nu_{N_K,n_r,\gamma}$ with $n_r = n_* B^r \ge n_I$.

3. *For every bounded $\mathcal{T}_W$-continuous function F on $\mathcal{X}_L$,*

$$\sup_{\gamma\in I}\left|\mathbb{E}_{\mu_{N_K,\gamma}}F(\pi_K)-\lambda_\gamma(F)\right|\longrightarrow 0.$$

   The convergence is also uniform in the bounded-Lipschitz distance of $(\mathcal{X}_L,d_c)$. The image laws and the limiting measures have common compact containment in the Wilson topology and in d_c.
4. *The map $\gamma\mapsto\lambda_\gamma$ is weakly continuous on I for both topologies, and the law of every fixed finite vector of Wilson loops and its source functional depend continuously on γ. These statements hold on all of $(0,\infty)$, by covering it with compact intervals.*

The same conclusions under the Wilson measures hold along the full sequence $N_k=n_*M^k$. The parameters, n_I, and the sequence $m(K)$ defining the maps are fixed before $\gamma\in I$ is chosen; the constants may depend on I and on the sequence.

Remark 30.11. The constants may diverge as $\gamma_-\to 0$ or $\gamma_+\to\infty$, and no rate of convergence is asserted. The uniformity concerns each fixed finite list and each fixed bounded test; it is not asserted for the path laws of Theorem 30.4, for the Sobolev laws of Theorem 30.5, or for the energy laws of the image trajectories, whose convergence at each fixed γ follows from Theorem 30.5. The maps chosen for two overlapping intervals may differ, but their limiting measures agree on the overlap, since these are determined by the joint laws of Wilson loops. Finally, if $I\subset(0,\gamma_0]$ for the coupling bound $\gamma_0\le 1$ of Theorem 23.2, one may take $\Gamma=\gamma_0$; by the clause of Theorem 23.5 that retains a prescribed J, the parameter tuple of Theorem 23.2 can then be kept, with one common enlargement of the minimum coarse side.

Proof of Theorem 30.10. The proof has six steps. We fix the parameters and n_I, and then prove uniform convergence of finite vectors of Wilson loops. Next, we prove that the failure probability at each fixed level tends to zero uniformly, choose the maps by a diagonal argument, and treat the early cutoffs. Finally, we deduce the convergence of the image laws, the continuity in γ, and the statement along the full sequence.

Step 1: parameters. Theorem 23.5 gives the common parameter tuple. We fix the horizon $T_0=L^2$ and the exponents of the norms of the flow data before any list of observables is chosen. All later lists use this horizon; their positive waiting times and later horizons affect the deterministic flow constants and the mesh thresholds, but not the minimum coarse side. Let $t_*>0$ be so small that the finitely many smallness conditions of Lemma 28.10 on the largest effective coupling $t_1=(\gamma/(Mn))^{1/2}$ hold whenever $t_1\le t_*$, and take $n_I\ge\max(n_\Gamma,\gamma_+/(Mt_*^2))$, rounded up to an element of $4\mathbb{N}$; then $t_1\le t_*$ for all $\gamma\in I$ and $n\ge n_I$. All other conditions are already included in n_Γ. No local constant is chosen using n_I or a later failure-probability constant, and every coarse side $n\ge n_I$ in the sequence is allowed with the same tuple.

Step 2: finite vectors of Wilson loops. At a fixed coarse side, the Wilson loops lie in a fixed compact box, since each is bounded by the dimension of its representation. By Lemma 30.9, the approximation errors are uniformly small, and for fixed q the approximating laws converge uniformly and depend continuously on γ. For a test function f with $\max(\|f\|_\infty, \operatorname{Lip} f) \le 1$, that is, with bounded-Lipschitz norm at most one, the triangle inequality between two cutoffs shows that the expectations under the conditioned measures form a Cauchy sequence uniformly in $\gamma \in I$; passing to a common finer cutoff, we find that the same holds for the limiting approximating laws at two indices q, q'. The probability measures on the compact box form a compact, hence complete, space for the bounded-Lipschitz distance. To see this, we partition the box into nested finite families of half-open cubes with diameters tending to zero, assigning the outer boundary to the last cells. From any sequence of laws, we extract by a diagonal argument a subsequence along which the mass of every cell converges. The limiting weights are consistent under refinement and sum to one. We subdivide $[0,1]$ into nested intervals with these lengths, so that the intervals of the children partition that of the parent. Apart from the countably many endpoints of these intervals, each point of $[0,1]$ selects a nested chain of cells, whose closures determine one point of the box. This map is measurable as a limit of step functions, and its image of Lebesgue measure is a probability measure on the box. At each level of the partition, the integral of a test with bounded-Lipschitz norm at most one against either the laws of the subsequence or this law differs from the corresponding weighted sum of values at fixed representatives of the cells by at most the largest cell diameter. Since the cell masses converge, the subsequence converges to this law in the bounded-Lipschitz distance. Hence for each coarse index r, the laws of the vector under the conditioned measures have a unique limit P^r_γ, and the convergence is uniform on I. The same approximation shows that P^r_γ is continuous in γ, as a uniform limit of the continuous laws at fixed q. The limits for different finite lists are compatible, since the laws at each cutoff are.

We write $n_r = n_* B^r$ and $\nu_{K|r,\gamma} = \nu_{N_K,n_r,\gamma}$. For $u \ge n_\Gamma$, the right side of (23.13) is nondecreasing in $\gamma \in (0,\Gamma]$, since $Mu/\gamma \ge Mn_\Gamma/\Gamma > 1$. Let $F_\Gamma(u)$ denote its value at $\gamma = \Gamma$. By Theorem 23.10, we have

$$\sup_{K \ge r,\, \gamma \in I} \mu_{N_K,\gamma}(S^c_{N_K,n_r,\gamma}) \le F_\Gamma(n_r), \qquad F_\Gamma(n_r) \longrightarrow 0 \quad (r \to \infty).$$

By (30.2), at each cutoff, the expectation of a test with bounded-Lipschitz norm at most one under the Wilson measure differs from that under the conditioned measure by at most $2F_\Gamma(n_r)$. Taking the uniform limit in K at fixed r, and then letting $r \to \infty$, we obtain uniform convergence of the vector laws under the Wilson measures. By Theorems 29.23 and 29.24, their pointwise limit is the law of the vector under λ_γ. The continuity in γ follows from the continuity of the conditioned limits and the same uniform error. For the source functionals, since the coordinates are bounded, the exponentials and

their fixed derivatives in z are uniformly bounded and uniformly continuous on a fixed complex ball; a finite net of the ball gives the stated uniformity. In particular, fixed moments and cumulants converge uniformly and depend continuously on γ. On a common small ball of sources, the logarithm with value zero at the origin is defined, since $|Z(z) - 1| \le e^{D \sum_h |z_h|} - 1 < 1/2$ there, where D bounds the dimensions of the representations. The uniform convergence of the fixed derivatives then implies the convergence of the derivatives of the logarithms of the source functionals at the origin, with no additional nonvanishing hypothesis.

The tails of the lattice energy under the Wilson measures are also uniform. At fixed r, the conditioned tail is uniform by Lemma 30.9, and by (30.2), the Wilson probability of a tail event is at most its conditioned probability plus $F_\Gamma(n_r)$. We take first the limits in the cutoff and in the size of the tail at fixed r, and then let $r \to \infty$. The finitely many earlier cutoffs are included by the bound $\mathsf{E}_a \le 48N^3/a$.

Step 3: uniform feasibility at a fixed level. Let $(X_b)_{b \ge 1}$ be the countable family of continuum trajectories of Lemma 29.8, started at the trigonometric polynomials with rational coefficients, with $X_1 = 0$; it does not depend on γ. Set $s_i = L^2 2^{-i}$ and $\epsilon_m = 2^{-m}$, and let $\pi_{K,m}(U)$ be the first X_b that satisfies

$$\begin{aligned} \big|w_j(X_b) - W^{\mathrm{lat}}_{K,j}(U)\big| &< \epsilon_m \qquad (j \le m), \\ E_L(X_b(s_i)) &< \mathsf{E}_{a_K}(\Psi^{(N_K)}_{s_i} U) + \epsilon_m \qquad (i \le m), \end{aligned} \tag{30.13}$$

and the zero trajectory if there is no such b; this is the construction of Theorem 29.19. We say that level m fails at U if no b satisfies (30.13).

Fix m, a coarse index r with $n_r \ge n_I$, and $\eta > 0$. By Lemma 30.9, applied to the m determining coordinates and the m energies in (30.13), there exists a fixed q such that, for all sufficiently large K and uniformly in $\gamma \in I$, the lattice vector differs from the continuum vector of $X^{[q]}$ on the same sample by less than $\epsilon_m/4$ with conditioned probability at least $1 - \eta$. To deduce this from the truncated expectation in (30.12), we apply Markov's inequality with the threshold $\min(1, \epsilon_m/4)$ and make that expectation smaller than $\eta \min(1, \epsilon_m/4)$. By Lemma 29.8, for every realization of $X^{[q]}$, there exists an element of the countable family whose joint vector differs from that of $X^{[q]}$ by less than $\epsilon_m/4$. Then the strict inequalities (30.13) hold, since every loop error is less than $\epsilon_m/2$ and every energy of the family element is less than the lattice energy plus $\epsilon_m/2$. Thus the conditioned probability that level m fails is at most η, uniformly in $\gamma \in I$. No measurable choice of the approximating element is needed, since its existence places the configuration in the countable union of the sets where (30.13) holds. This proves uniform feasibility at each fixed level directly, without a limiting initial potential and without using the compactness of I to make a pointwise statement uniform.

For the failure event under the Wilson measure, (30.2) bounds the limit superior in K by $F_\Gamma(n_r)$ for every fixed r with $n_r \ge n_I$, uniformly in $\gamma \in I$. Letting $r \to \infty$ after this

limit, we find that the Wilson probability that level m fails also tends to zero uniformly. For each K and m, the conditions in (30.13) are strict inequalities between continuous gauge-invariant functions of the configuration. Therefore the events that a given b is the first to satisfy them, and the failure event, are Borel, and $\pi_{K,m}$ is Borel and invariant under periodic lattice gauge transformations. The conditions do not involve γ.

Step 4: the diagonal choice. We enumerate the coarse indices r with $n_r \geq n_I$ as $r(1), r(2), \ldots$. By Step 3, we can choose increasing integers $K_m \geq \max(m, r(1), \ldots, r(m))$ such that for every $K \geq K_m$ the probability that level m fails is at most 2^{-m}, uniformly in $\gamma \in I$, under the Wilson measure and under each of the first m conditioned measures. Set $m(K) = \max\{m : K_m \leq K\}$, or $m(K) = 0$ if this set is empty, and $\pi_K = \pi_{K,m(K)}$. When level $m(K)$ does not fail, the error of each coordinate w_j with $j \leq m(K)$ is less than $2^{-m(K)}$; when it fails, the error is at most two. Thus each fixed coordinate has error in L^1 at most $3 \cdot 2^{-m(K)}$, uniformly in $\gamma \in I$, under the Wilson measure and eventually under each fixed conditioned measure. On every configuration and for $i \leq m(K)$, we have

$$E_L(\pi_K(s_i)) \leq \mathsf{E}_{a_K}(\Psi_{s_i}^{(N_K)} U) + 2^{-m(K)}, \tag{30.14}$$

since on failure the output is the zero trajectory, whose energy is zero. Combined with the uniform tails of the lattice energies from Step 2, this yields uniform tails of the energies of the image trajectories for all sufficiently large K. By the monotonicity of the continuum energy along the flow, these tails hold at every $t > 0$.

Step 5: the early cutoffs. It remains to include the finitely many cutoffs below this threshold, uniformly in γ; the finiteness of the energy of each image trajectory, pointwise in γ, would not suffice. On a fixed finite link space, the densities of the Wilson measures with respect to Haar measure are positive and continuous on the product of the compact link space with I, hence bounded above and below by positive constants. For a fixed conditioned measure, the small-field event contains one open neighborhood of the identity configuration for all $\gamma \in I$. Indeed, its finitely many conditions on charts, constraint Jacobians, and fluctuation variables hold with strict margins at the identity, and the normalized fluctuation variables are continuous near the identity and vanish there. Further, every cutoff radius $A_{\mathrm{w}} \log(1/t_k)$ has a positive minimum over I because $t_k \leq t_* < 1$. We shrink one neighborhood O so that it satisfies all these finitely many conditions. Then $\mu_{N_K,\gamma}(S_{N_K,n_r,\gamma}) \geq c\, H_{N_K}(O) > 0$ uniformly in $\gamma \in I$, and the densities of the conditioned measures are bounded above by $C_{K,r,I}$ times Haar measure. For each configuration, $\pi_K(U)$ is an element of the countable family or the zero trajectory, and has finite energy. Its tail under Haar measure tends to zero by continuity from above, and the domination by Haar measure makes this convergence uniform in γ. Hence the finitely many early cutoffs can be included, and the energy tails hold with the supremum over

all cutoffs, without assuming a deterministic bound on the energies of all elements of the countable family.

Step 6: convergence of the image laws, continuity, and the full sequence. By Theorem 29.6, the image laws under the Wilson measures have common compact containment. At each fixed γ, the coordinate errors and the convergence of finite vectors identify every subsequential limit of the image laws with λ_γ, by the determination of probabilities in Theorems 29.3 and 29.20. The image laws therefore converge to λ_γ. By the inequality for closed sets in the portmanteau theorem, each limiting measure inherits the uniform lower bound on the mass of each closed energy sublevel set, so the family of limits has the same compact containment.

Let C be a common compact set whose complement has probability at most η under all image laws and all limits. On C, the Wilson topology and the d_c topology agree. By Lemma 29.9, a bounded Wilson-continuous F with $|F| \le D$ is approximated within δ on C by $G(w_1, \dots, w_b)$, with G continuous on $[-1,1]^b$ and $|G| \le D$. Using the coordinate errors and the uniform continuity of G, we compare the expectation of G on the image with its expectation on the lattice coordinates, uniformly in γ, and the latter converges uniformly by Step 2. The two complements of C contribute at most $4D\eta$. Therefore

$$\limsup_{K\to\infty} \sup_{\gamma\in I} \left| \mathbb{E}_{\mu_{N_K,\gamma}} F(\pi_K) - \lambda_\gamma(F) \right| \le 2\delta + 4D\eta,$$

and we let $\delta, \eta \to 0$. For the class of functions with bounded-Lipschitz norm at most one for d_c, the restrictions to C have a finite uniform net. To construct it, we take a finite fine net of C, round the values of each test at its points, and choose one test realizing each rounded list of values. The Lipschitz bound controls the error between net points. The uniform convergence for these finitely many tests and the common bound on the complements give uniform convergence in the bounded-Lipschitz distance.

For a further fixed finite vector $\mathscr{W}$ and a bounded continuous test f, the function $h = f \circ \mathscr{W}$ is bounded and Wilson-continuous; let G be its approximation on C as above, and write $p_b X = (w_j(X))_{j\le b}$ and $\mathbf{W}^{\mathrm{lat}}_{K,b} = (W^{\mathrm{lat}}_{K,j})_{j\le b}$. Then

$$\begin{aligned} \left| f(\mathscr{W}(\pi_K)) - f(\mathscr{W}^{\mathrm{lat}}_K) \right| \le{}& \left| h(\pi_K) - G(p_b \pi_K) \right| + \left| G(p_b \pi_K) - G(\mathbf{W}^{\mathrm{lat}}_{K,b}) \right| \\ &+ \left| G(\mathbf{W}^{\mathrm{lat}}_{K,b}) - f(\mathscr{W}^{\mathrm{lat}}_K) \right|. \end{aligned}$$

The expectation of the first term is at most $\delta + 2D\eta$, and that of the second tends to zero uniformly by the coordinate errors. The last term is a bounded continuous test of the single joint lattice vector consisting of the determining coordinates and $\mathscr{W}^{\mathrm{lat}}_K$. By Step 2, its expectation converges uniformly to $\mathbb{E}_{\lambda_\gamma} |G \circ p_b - h| \le \delta + 2D\eta$. This proves the statement for further vectors without combining separately given marginals. For complex tests, we apply the argument to the real and imaginary parts.

At each fixed N, the density $Z_{N,\gamma}^{-1}\exp(-4N\gamma^{-1}\sum_p q(U_p))$ of the Wilson measure is continuous in $L^1(H_N)$ as a function of $\gamma \in I$, since the numerator is bounded and jointly continuous and the normalizing constant is positive and continuous. Hence the finite measures are continuous in total variation. Since the maps π_K do not depend on γ, the expectation of every bounded Borel function of π_K is continuous in γ. Combined with the uniform convergence for bounded Wilson-continuous F, this proves the weak continuity of $\gamma \mapsto \lambda_\gamma$ for the Wilson topology. Since the identity map from the Wilson topology to d_c is continuous, we also obtain weak continuity for d_c. Similarly, the uniform convergence of the finite vectors implies the continuity of their laws and source functionals. The measures λ_γ do not depend on I, so continuity on every compact interval gives continuity on $(0,\infty)$.

In this paragraph, $r \in \{0,\dots,J-1\}$ denotes a residue index. For the full sequence n_*M^k, the statements above apply to the finitely many residue bases n_*M^r, $0 \le r < J$, with one common shift of the base. By Theorem 29.28, their pointwise limits are the same λ_γ, and the maximum of finitely many uniform errors tends to zero. Let $m_r(l)$ be the diagonal sequences of the finitely many residue classes. On the full sequence, the maps are defined by (30.13) at the level $m(k) = \min_{0\le r<J} m_r(\lfloor k/J \rfloor)$, which is a nondecreasing sequence tending to infinity. A configuration that does not fail at some level does not fail at any lower level, since there are fewer conditions with larger tolerances. Hence the failure probabilities at level $m(k)$ are bounded by those of the residue classes, and all estimates on the coordinate errors and the energies persist. The finitely many initial zero outputs affect no limit and no tail. □

Corollary 30.12. *Fix a physical coupling $c = g_3^2 > 0$, an odd integer $M \ge 3$, and an equivalence class $[n]_M$, and identify $\mathcal{X}_L$ with $\mathcal{X}_1$ by D_L^{-1}. Then the map*

$$L \longmapsto (D_L^{-1})_{\#}\lambda_{L,cL,[n]_M} = \lambda_{1,cL,[n]_M}$$

is weakly continuous on $(0,\infty)$ for both topologies on $\mathcal{X}_1$. On each compact interval of side lengths in $(0,\infty)$, the limits of the dilated finite vectors of flowed lattice Wilson loops, and the convergence of the laws of the common maps, are uniform in L. The same holds jointly in (c,L) on compact rectangles in $(0,\infty)^2$, after transporting tests and times by dilation.

Proof. The notation c is local to this corollary. The displayed identity is (30.4), and the identities of Theorem 30.1 at a finite cutoff include the measure, the lattice time, and the ordered lattice paths. A compact rectangle of pairs (c,L) is mapped by $(c,L) \mapsto cL$ onto a compact interval of couplings on the unit torus. We apply Theorem 30.10 on that interval and compose the continuous functions $\gamma \mapsto \lambda_{1,\gamma,[n]_M}(F)$ with $(c,L) \mapsto cL$. We then transport the maps on the unit torus, which do not depend on the coupling, by D_L; their dimensionless errors and energy tails are exactly those on the unit torus. No

uniformity as $L \to \infty$, or for physical observation windows that are not transported by dilation, is obtained. □

30.8 Modified smoothing flows

The flowed Wilson loops are defined with the Wilson flow, the gradient flow of $\sum_p q(U_p)$ introduced by Lüscher [128]. We now show that the limits do not change when the flow is replaced by the gradient flow of a modified plaquette function, within a bounded family. For $c \geq 0$ and $a = L/N$, let

$$\mathcal{A}_c(U) = \sum_{p \in \mathcal{P}_N} \{q(U_p) + c\, q(U_p)^2\}, \qquad \Psi_t^{(N,c)} = \Phi^{\mathcal{A}_c}_{4t/a^2},$$

where $\Phi^{\mathcal{A}_c}$ is the flow of the vector field $-\nabla \mathcal{A}_c$ for the product bi-invariant metric, as in Section 24 (see Lemma 24.11). In particular, $\Psi_t^{(N,0)} = \Psi_t^{(N)}$. Since the vector field is smooth on the compact configuration space, the flow exists for all times, and it commutes with lattice gauge transformations because $\mathcal{A}_c$ is gauge invariant and the metric is invariant. Only the smoothing changes: the measure $\mu_{N,\gamma}$, the block averaging map, and all conditional kernels are unchanged. Near the identity, $q(U_p)^2$ is quartic in the plaquette logarithm, and in the damped gauge the modification adds to the equation of the flow only terms of degree at least three in the field (Lemma 24.11).

In this section and the next we use the setting of Theorem 29.25: the parameters, the order of the quantifiers, and the sequence $N_K = n_* B^K$ are those of that theorem, so the coupling is fixed in $(0, 1]$, and $\lambda_{L,\gamma,[n_*]}$ denotes the corresponding continuum measure. We define the integer r_0 of Section 30.1 for these parameters, enlarged if necessary so that the conditioned estimates used below hold for all $r \geq r_0$.

Theorem 30.13. *Work in the setting of Theorem 29.25, and fix $0 \leq C_0 < \infty$. Under the Wilson measure $\mu_{N_K,\gamma}$ let $U_K^c(t) = \Psi_t^{(N_K,c)} U$. For loops ℓ_i with admissible approximations $(\ell_{i,K})_K$, characters χ_i, and times $t_i > 0$, $1 \leq i \leq m$, set*

$$W_{K,i}^c = \chi_i\big(\mathrm{Hol}_{\ell_{i,K}} U_K^c(t_i)\big).$$

Then

$$\lim_{K \to \infty} \mathbb{E}_{\mu_{N_K,\gamma}} \sup_{0 \leq c \leq C_0} \max_i \big|W_{K,i}^c - W_{K,i}^0\big| = 0. \tag{30.15}$$

Consequently, the laws of $(W_{K,i}^c)_i$ converge to the joint law of $(W_{\ell_i,\chi_i,t_i})_i$ under $\lambda_{L,\gamma,[n_*]}$, uniformly in $c \in [0, C_0]$ in the bounded-Lipschitz distance. For every finite Z, the complex source functionals $\mathbb{E}_{\mu_{N_K,\gamma}} \exp(\sum_i z_i W_{K,i}^c)$ converge uniformly on $[0, C_0] \times \{z : \sum_i |z_i| \leq Z\}$ to the limit of those of the Wilson flow. In particular, these conclusions hold for every bounded sequence $c = c_K \geq 0$.

The maps π_K of Theorem 29.25 can be used for every c. Their compact containment, their convergence in both topologies, their limit, and the tightness of their energies over all K are

unchanged, and for the normalized fundamental coordinates $W^c_{K,j} = (1/2)\,\mathrm{tr}\,\mathrm{Hol}_{\ell_{j,K}}\,U^c_K(t_j)$ *of the determining family,*

$$\lim_{K\to\infty} \mathbb{E}_{\mu_{N_K,\gamma}} \sup_{0\le c\le C_0} \bigl|w_j(\pi_K) - W^c_{K,j}\bigr| = 0 \qquad (j \ge 1). \tag{30.16}$$

Every finite vector of Wilson loops for the modified flows converges jointly to the corresponding vector under $\lambda_{L,\gamma,[n_*]}$*, for every choice of admissible approximations.*

The number C_0 *is chosen after the parameters and the coupling, and neither the parameter tuple nor the minimum side is changed. Deterministic mesh thresholds may depend on* C_0 *and on the bounds on the flow data; convergence moduli may in addition depend on* γ*, on the coarse side, and on the observables, as in item (7) of Definition 4.14. No uniformity as* $\gamma \to 0$ *or* $C_0 \to \infty$ *is asserted.*

Proof. If the list of loops is empty, there is nothing to prove, so we assume it is not. We first prove (30.15) under the conditioned measures, using the deterministic comparison of Lemma 25.15, then remove the conditioning, and finally deduce the remaining assertions.

Step 1: conditioned measures. Fix $r \ge r_0$, write $u_r = n_* B^r$ and $\nu_{K|r} = \mu_{N_K,\gamma}(\,\cdot \mid S_{N_K,u_r,\gamma})$. Under $\nu_{K|r}$, the field given by the reconstruction maps of Theorem 15.13 is a gauge representative of the same configuration U, and the norm $\mathsf{R}_{K|r}$ of its flow data is tight by Theorem 28.8. Since each flow $\Psi^{(N_K,c)}$ commutes with gauge transformations, the Wilson loops of the flow of U equal those of the flow of this representative, for every c, and the supremum of the discrepancies is gauge invariant.

Let $D = \max_i \chi_i(I)$ and

$$\Delta_K = \sup_{0\le c\le C_0} \max_i \bigl|W^c_{K,i} - W^0_{K,i}\bigr| \le 2D.$$

On each finite lattice, the smooth flow depends continuously on c and on the initial configuration. This follows by subtracting the integral equations for two values of the parameters and applying the Lipschitz bound of the vector field on the compact configuration space. Hence the supremum over c equals the supremum over a countable dense subset of $[0, C_0]$, and Δ_K is Borel. For fixed R, the early time interval of Theorem 24.12 for flow data of norm at most R is deterministic, and the norm of the flow data on it is at most $\mathsf{R}_{K|r}$. The admissible approximations have a common bound on their lengths. Then Lemma 25.15, which applies to any fixed finite set of characters, yields a deterministic $\omega_R(a) \to 0$ such that

$$\mathbb{E}_{\nu_{K|r}}\Delta_K \le \omega_R(a_K) + 2D\,\nu_{K|r}\{\mathsf{R}_{K|r} > R\}.$$

We let $K \to \infty$ at fixed r, R, and C_0, and then $R \to \infty$. By (30.3), we conclude that $\mathbb{E}_{\nu_{K|r}}\Delta_K \to 0$.

Step 2: the Wilson measure. At the same cutoff, by Theorem 23.9, applied with the coupling bound one as in Theorem 29.25, we have $\mu_{N_K,\gamma}(S^c_{N_K,u_r,\gamma}) \le F_\gamma(u_r)$ for all $K \ge r$, with $F_\gamma(u_r) \to 0$ as $r \to \infty$ at fixed $\gamma > 0$. The second inequality in (30.2) then implies that

$$\mathbb{E}_{\mu_{N_K,\gamma}} \Delta_K \le \mathbb{E}_{\nu_{K|r}} \Delta_K + 2DF_\gamma(u_r).$$

Letting first $K \to \infty$ and then $r \to \infty$ proves (30.15), with the same order of limits as in Theorem 28.2.

Step 3: consequences. For a test with bounded-Lipschitz norm, the difference of its expectations for the modified flow and for the Wilson flow is at most its Lipschitz constant times $\mathbb{E}\Delta_K$, uniformly in c. By Theorem 29.25, the vector for the Wilson flow converges to its law under $\lambda_{L,\gamma,[n_*]}$, which proves the uniform convergence in the bounded-Lipschitz distance. For a bounded continuous test f with modulus of continuity ϖ_f on the compact range of the vector, Markov's inequality implies that the error is at most $\varpi_f(\eta) + 2\|f\|_\infty \mathbb{E}\Delta_K/\eta$ for every $\eta > 0$. For the source functionals, we have

$$\sup_{\sum_i |z_i| \le Z} \left| e^{\sum_i z_i W^c_{K,i}} - e^{\sum_i z_i W^0_{K,i}} \right| \le Z e^{DZ} \Delta_K,$$

since both exponents are bounded by DZ in absolute value and differ by at most $Z\Delta_K$. Combined with the convergence of the source functionals of the Wilson flow in Theorem 29.25, this implies the uniform convergence. The uniformity in c covers every bounded deterministic sequence c_K.

The maps π_K are those of Theorems 29.20 and 29.25; their definition does not involve c, so their law, gauge invariance, Borel measurability, energy tails, and compact containment are unchanged. For each determining coordinate,

$$\mathbb{E} \sup_c \left| w_j(\pi_K) - W^c_{K,j} \right| \le \mathbb{E} \left| w_j(\pi_K) - W^0_{K,j} \right| + \mathbb{E} \sup_c \left| W^c_{K,j} - W^0_{K,j} \right| \longrightarrow 0,$$

which is (30.16). For every other finite list, (30.15) and the identification of the limit of the Wilson-flow vector in Theorem 29.20 identify its limit under the same $\lambda_{L,\gamma,[n_*]}$; this identifies the law of the joint vector, not only its marginals. By Theorems 29.23 and 29.25, all admissible approximations have the same limits for the Wilson flow, and applying the comparison to each of them proves the independence of the choice of approximation. □

30.9 Energy and loop processes for the modified flows

We now extend Theorem 30.4 to the modified flows, jointly in $c \in [0, C_0]$ and $t \in [\tau, T]$, including the lattice energy. The loops are controlled by Lemma 25.15; the new deterministic input is the comparison of the energies.

Lemma 30.14. *Fix $L > 0$, $1/2 < \alpha < 2/3$, $0 \le R, C_0 < \infty$, $0 < \tau < T < \infty$, finitely many characters χ_i, and lengths $\ell_i^* > 0$. Consider any initial configuration on the lattice of mesh $a = L/N$ whose flow data, on the common early time interval of Theorem 24.12, have norm at most R, and let $U_a^c(t) = \Psi_t^{(N,c)} U$ for $0 \le c \le C_0$. Let $\ell_{i,a}$ be closed lattice paths of physical length at most ℓ_i^*. There is a deterministic function $\omega_{R,C_0,\tau,T}(a) \to 0$ as $a \to 0$ such that, uniformly over all such configurations and paths,*

$$\sup_{\substack{0\le c\le C_0\\ \tau\le t\le T}} \Big\{ \big|\mathsf{E}_a(U_a^c(t)) - \mathsf{E}_a(U_a^0(t))\big| + \max_i \big|\chi_i(\mathrm{Hol}_{\ell_{i,a}} U_a^c(t)) - \chi_i(\mathrm{Hol}_{\ell_{i,a}} U_a^0(t))\big| \Big\} \le \omega_{R,C_0,\tau,T}(a).$$

The maximum over an empty family of loops is zero. The function ω and the mesh thresholds depend only on the displayed data, the representations, and the margins of the charts and of the difference stencil, and not on the coupling or the depth of the hierarchy. No rate is asserted.

Proof. The assertion for the loops is Lemma 25.15; we prove the assertion for the energy on the same configurations, uniformly in both c and t. Fix $s > 0$ smaller than τ and than the length of the common early time interval, with a positive waiting interval before s. By Theorem 24.12, we have

$$\sup_{0\le c\le C_0} \|A_a^c(s) - A_a^0(s)\|_{C_a^1} \longrightarrow 0$$

uniformly over the configurations, where A_a^c is the solution in the damped gauge for the flow with parameter c. The bootstrap of Theorem 25.7 bounds every fixed order of differences of the Wilson-flow solution on the waiting interval before s, and the equation of Lemma 24.2 bounds its time derivatives at each fixed order of differences by the next two orders.

Suppose that the assertion for the energy fails. Then there exist meshes $a_j \to 0$, configurations, parameters $c_j \in [0, C_0]$, and times $t_j \in [\tau, T]$ with a fixed positive discrepancy of the energies. We interpolate the value and difference arrays of the Wilson-flow solution at time s by piecewise multilinear interpolation. The bounds on the next differences give equicontinuity across the cells. Then the Arzelà–Ascoli theorem with a diagonal extraction gives uniform limits of the arrays of all orders, and discrete summation by parts identifies them as the derivatives of one smooth periodic one-form b_s. In particular, $\|A_{a_j}^0(s) - S_{a_j} b_s\|_{C_{a_j}^1} \to 0$, and by the early comparison, the same convergence holds for all $c \in [0, C_0]$, uniformly.

We apply Theorem 24.10 to the single field b_s up to time $T - s$, with at least five derivatives and strict chart margins. This gives a finite reference family, whose fixed gauge transformations we sample at the transition times. Next, Lemma 25.14 applies on

the consecutive intervals, for $c = 0$ and for every $c \le C_0$. If the initial errors are $\eta_j \to 0$, this lemma gives errors at most $C(\eta_j + a_j) \to 0$ in $C^1_{a_j}$ throughout the reference solutions. At a transition time, the fixed smooth gauge transformation k changes the C^1_a norm by a bounded factor on the chart, since $a^{-1}\operatorname{Log}(k(x)e^{aA_i(x)}k(x+ae_i)^{-1})$ extends smoothly to $a = 0$. Thus the errors propagate across every transition, with constants uniform in c.

On each interval, both lattice representatives have a common bound on their C^1_a norms, and their distance tends to zero. By the Lipschitz estimate of Lemma 29.14, which is uniform in the mesh, the difference of their energies is at most this distance times a fixed constant. By the gauge invariance of E_a, these are the energies of the two flows, also at the transition times. This contradicts the assumed discrepancy at t_j. Therefore the supremum over the configurations, c, and t defines a function of a that tends to zero, and combining it with the function for the loops proves the lemma. The only reference solutions used for a hypothetical offending sequence are those of its extracted smooth limit b_s, so no derivatives of finite-scale reconstructions of growing index enter the constants. □

Theorem 30.15. *Work in the setting of Theorem 30.13; in particular $\gamma \in (0,1]$ is fixed. Fix $0 \le C_0 < \infty$, $0 < \tau < T < \infty$, loops $\ell_1, \dots, \ell_m$ with admissible approximations $(\ell_{i,K})_K$ fixed in time, and characters $\chi_1, \dots, \chi_m$. Under the Wilson measure $\mu_{N_K,\gamma}$ let*

$$U^c_K(t) = \Psi_t^{(N_K,c)}U, \qquad W^c_{K,i}(t) = \chi_i\big(\operatorname{Hol}_{\ell_{i,K}} U^c_K(t)\big).$$

Then

$$D_K = \sup_{\substack{c\in[0,C_0]\\ t\in[\tau,T]}} \Big\{ \big|\mathsf{E}_{a_K}(U^c_K(t)) - \mathsf{E}_{a_K}(U^0_K(t))\big| + \max_i \big|W^c_{K,i}(t) - W^0_{K,i}(t)\big| \Big\} \longrightarrow 0 \tag{30.17}$$

in $\mu_{N_K,\gamma}$-probability. The random continuous fields $(c,t) \mapsto (\mathsf{E}_{a_K}(U^c_K(t)), (W^c_{K,i}(t))_i)$ converge in distribution in $C([0,C_0]\times[\tau,T];\mathbb{R}\times\mathbb{C}^m)$, with the uniform norm, to the field that does not depend on c and has the time path

$$t \longmapsto \big(E_L(X(t)), (W_{\ell_i,\chi_i,t}(X))_i\big), \qquad X \sim \lambda_{L,\gamma,[n_*]}.$$

Moreover $\mathbb{E}_{\mu_{N_K,\gamma}} \sup_{c,t} \max_i |W^c_{K,i}(t) - W^0_{K,i}(t)| \to 0$. The number C_0, the time interval, and the observables are fixed before $K \to \infty$, and the convergence moduli have the dependence described in item (7) of Definition 4.14, with these additional data.

The theorem asserts convergence in probability of the energy discrepancy, not convergence of its expectation: only the indicator of the event $\{D_K > \eta\}$ is transferred from the conditioned measures.

Proof. We first recall the tightness of the norm of the flow data under the conditioned measures, then apply Lemma 30.14 on the event where this norm is bounded and transfer the probability of the complementary event, and finally deduce the convergence of the fields.

Step 1: tightness of the flow data. Fix $r \geq r_0$, write $u_r = n_* B^r$ and $\nu_{K|r} = \mu_{N_K,\gamma}(\cdot \mid S_{N_K,u_r,\gamma})$. By Theorem 15.13, the field given by the reconstruction maps at the finest scale is a gauge representative of the same configuration. Let x_j be the linear heat evolutions, on the finest lattice, of the cardinal interpolations of the fields reconstructed at the scales j, and $y_j = \mathcal{Q}_{a_K}(x_j, x_j)$, as in Theorem 28.8. The tightness (30.3) of $\mathsf{R}_{K|r} = \mathsf{X}_\alpha^{a_K}(x_{K-r}) + \mathsf{Y}_\alpha^{a_K}(y_{K-r})$ is part of Theorem 28.8; we recall the argument, since it uses only finite-scale reconstructions. Lemma 26.2 gives the exact identity

$$(x_k, y_k) - (x_{h-1}, y_{h-1}) = \Big(\sum_{j=h}^{k} d_j,\ \sum_{j=h}^{k} \{ \mathcal{B}_{a_K}(x_{j-1}, d_j) + \mathcal{Q}_{a_K}(d_j, d_j) \} \Big), \qquad d_j = x_j - x_{j-1},$$

where $\mathcal{B}_a(u, v) = \mathcal{Q}_a(u, v) + \mathcal{Q}_a(v, u)$. By the estimate for the linear heat evolution in Theorem 28.6 and the two tail estimates in Theorem 28.7, this difference is small in probability as $h \to \infty$, uniformly in the remaining depth. For each fixed h, the arrays of the field reconstructed at scale $h-1$ range over a bounded finite-dimensional set, by the construction of the reconstruction maps and the cutoffs on the normalized fluctuation variables, and their cardinal interpolations have bounded derivatives of every fixed order. Using the estimates for cardinal interpolation and the heat semigroup in Lemmas 16.1 and 16.3, we bound x_{h-1} and its fixed differences on every finer lattice. The exact shifted quadratic term of Lemma 24.2, the contraction of the heat semigroup, and the Duhamel integral then bound y_{h-1} and its first difference by $C_h t$. Hence the norm of the flow data of the field reconstructed at scale $h-1$ has a deterministic bound C_h, independent of the finest mesh. We choose h so that the probability that the difference above exceeds one is less than a given $\varepsilon > 0$, and then a bound $R > C_h + 1$. The finitely many remaining depths have bounded arrays and are included by enlarging R. This proves (30.3) at the fixed r and γ. Restricting the horizon to the common early time interval does not increase the norm.

Step 2: the discrepancy. The flows are gauge equivariant and the energies and Wilson loops are gauge invariant. On the event $\{\mathsf{R}_{K|r} \leq R\}$, Lemma 30.14 implies that $D_K \leq \omega_R(a_K)$. The random variable D_K is Borel, since the finite flow and its dependence on c and on the initial configuration are continuous, so the supremum over (c, t) equals the supremum over a countable dense set. For every fixed $\eta > 0$ and all sufficiently large K, we have $\omega_R(a_K) < \eta$ and hence

$$\nu_{K|r}\{D_K > \eta\} \leq \nu_{K|r}\{\mathsf{R}_{K|r} > R\}.$$

Applying the last inequality in (30.2) to the event $\{D_K > \eta\}$, and using Theorem 23.9 with the coupling bound one, we obtain

$$\limsup_{K \to \infty} \mu_{N_K,\gamma}\{D_K > \eta\} \leq \sup_{K \geq r} \nu_{K|r}\{\mathsf{R}_{K|r} > R\} + F_\gamma(u_r), \qquad F_\gamma(u_r) \longrightarrow 0.$$

Letting first $R \to \infty$ at the fixed r and then $r \to \infty$ proves (30.17).

Step 3: convergence of the fields. The finite flow is smooth in (c, t) on its compact time interval, so each field is continuous. By Theorem 30.4, the path of the Wilson flow, $c = 0$, converges in distribution. Its image under the continuous map that sends a time path to the field that is constant in c therefore converges to the stated field. With the maximum norm on $\mathbb{R} \times \mathbb{C}^m$, the uniform distance between the field for the modified flows and this image is at most D_K. For a test f with bounded-Lipschitz norm, the difference of the two expectations is at most $\mathrm{Lip}(f)\eta + 2\|f\|_\infty \mu_{N_K,\gamma}\{D_K > \eta\}$, which proves convergence for such tests. For bounded continuous tests, we also need the compact containment of the paths of the Wilson flow. It follows from the bounds on the values and the Lipschitz bound in time of Lemma 30.3, with the same localization to $\{\mathsf{R}_{K|r} \le R\}$ and the same removal of the conditioning as in Step 2. By a finite covering argument, a bounded continuous test is uniformly continuous between the points of a compact set and all sufficiently nearby paths, and outside the compact set we use the bound on the test. This proves the convergence in distribution of the fields. Finally, the supremum of the loop discrepancy is bounded by twice the largest dimension of the representations, so its convergence to zero in probability implies the convergence of its expectation. □

Remark 30.16. The results concern parameters c in a bounded interval and fixed positive observation times. No assertion is made for unbounded c_K, for other modifications of the flow, for observation times tending to zero with the lattice spacing, or for different equivalence classes $[n]_M$, and no rate and no uniformity as $\gamma \to 0$ is asserted. Statements formulated only in terms of $\lambda_{L,\gamma,[n_*]}$, such as those in Sections 32 and 34 to 36, concern the same measure; the theorems above do not give new proofs of the estimates at finite cutoff on which those statements rest.

Proof of Theorems 2.5 and 2.6. The measure $\lambda = \lambda_{L,\gamma,[n]_M}$ and the maps π_k are those of Theorem 29.28. Part (1) of Theorem 2.5 is the assertion along the full sequence nM^k in Theorem 30.4, proved in Section 30.6. Part (2) is the assertion under the Wilson measures along nM^k in Theorem 30.5. Part (3) is Theorem 30.6, applied to $\lambda_{L,\gamma,[n]_M}$ as shown in Section 30.6; the winding vectors $w(\ell_j)$ of that theorem are the vectors $\nu(\ell_j)$ of Theorem 2.5. Part (4) is (30.4) in Theorem 30.1. Part (5) is Theorem 30.10. Items (1)–(3) of that theorem, together with its assertion along the full sequence, give the uniform convergence of finite vectors in the bounded-Lipschitz distance and the choice of maps independent of $\gamma \in I$ for which the convergence in Theorem 2.3(3) and the tightness in Theorem 2.3(4) hold uniformly. Item (4) gives the weak continuity of $\gamma \mapsto \lambda_{L,\gamma,[n]_M}$ on $(0, \infty)$ for both topologies. Theorem 2.6 is Theorems 30.13 and 30.15, along the sequence $N_K = n_* B^K$ of Theorem 29.25. □

PART X

Gaussian short-distance limits

SECTION 31

Reconstruction estimates and divergence-free currents

This section and Section 32 prove the short-distance theorem, Theorem 2.8. We study the heat-smoothed circulations defined in Definition 31.1: circulations, around small lattice loops of size ε, of the linear heat evolution of the reconstructed fine field, divided by $\sqrt{g_3^2\varepsilon}$. They are linear in the link logarithms of one fixed gauge representative; flowed Wilson loops are compared with them in Lemma 32.11.

The main result of this section is an exact decomposition of the heat-smoothed circulation $I^{K,s}$ under the conditioned Wilson measure, proved in Lemma 31.8:

$$I^{K,s} = T_s + \sum_{j=1}^{K-s} \Gamma_j(\widehat{\theta}_{j-1})(w_j - \bar{w}_j) + \mathsf{N}_{K,s}.$$

Here T_s is the contribution of the coarse field on the lattice of side n_s; the j-th summand is linear in the centered normalized fluctuation variables of the j-th RG step, so that the sum is a martingale; and $\mathsf{N}_{K,s}$ collects conditional means and nonlinear terms. For $a \le \varepsilon \le \varepsilon_0(s)$ and $\eta = g_3^2\varepsilon$, we show that

$$|T_s| + \mathbb{E}|\mathsf{N}_{K,s}| \le \frac{Cr}{g_3 H_s}\sqrt{\varepsilon} + Cg_3 D_s\sqrt{\varepsilon} + C\sqrt{\eta}\,[1+\log(1/\eta)]^2,$$

uniformly in the number K of RG steps, where $H_s = L/n_s$ is the coarse mesh and D_s is bounded uniformly in s. Theorem 31.6 identifies the covariance of the martingale increments at the zero field:

$$\sum_{j=1}^{K-s} \Gamma_j(0)\Gamma_j(0)^{\mathsf{T}} = C^{a,\varepsilon,L} \otimes I_3 - C^{\mathrm{ret}}_{s,a,\varepsilon}.$$

In the linearized Gaussian theory, $C^{a,\varepsilon,L} \otimes I_3$ is the covariance of the circulation of the lattice Maxwell Gaussian field, and $C^{\mathrm{ret}}_{s,a,\varepsilon}$ is the covariance of its conditional expectation given the linearized coarse field. As $a \to 0$ and then $\varepsilon \to 0$, with s fixed, the right side converges to $\Sigma \otimes I_3$, where Σ is the covariance in (2.6). Section 32 uses these facts to show that the martingale is asymptotically Gaussian.

The normalization by $\sqrt{g_3^2\varepsilon}$ comes from the Gaussian Maxwell field. If A has covariance $g_3^2(-\Delta)^{-1}$ in three dimensions, then $e^{\sigma\varepsilon^2\Delta}A$ has typical size $g_3\varepsilon^{-1/2}$, and its circulation around a loop of length of order ε has typical size $g_3\sqrt{\varepsilon} = \sqrt{\eta}$.

Two ideas enter the proof of the decomposition. The first concerns the zero-fluctuation reconstruction, in which every fluctuation variable is set to zero. Let $\widehat{L}_i$ be the linearization at the zero field of the i-th zero-fluctuation reconstruction map; it takes link logarithms on the lattice of mesh a_{i-1} to link logarithms on the lattice of mesh a_i. Each $\widehat{L}_i$ is a constrained minimization of the Maxwell quadratic form. By Theorem 31.3, a product of them agrees, up to a periodic gradient, with a single constrained minimization over all the averaging steps at once:

$$a^{-1}\widehat{L}_k \cdots \widehat{L}_{j+1} v = a_j^{-1} E_j^a v + d_a f_j(v).$$

The circulation around a closed lattice loop annihilates the gradient exactly, and E_j^a obeys bounds that do not depend on $k - j$. The nonlinear Taylor remainders $\widehat{\mathcal{R}}_i$ of the reconstruction maps are inserted at their own scale and then propagated to the fine lattice by the linearizations:

$$\text{mesh } a_j \xrightarrow{\widehat{P}_{i-1}\circ\cdots\circ\widehat{P}_{j+1}} \text{mesh } a_{i-1} \xrightarrow{\widehat{\mathcal{R}}_i} \text{mesh } a_i \xrightarrow{\widehat{L}_k\cdots\widehat{L}_{i+1}} \text{mesh } a.$$

Converting link logarithms at mesh a_i into a potential at the scale a_j introduces the factor $a_j/a_i = B^{i-j}$. Since $\widehat{\mathcal{R}}_i$ vanishes to second order, every monomial contains at least two inputs, each carrying a contraction factor α_* for every preceding step. For $i-1-j$ preceding steps, the physical rescaling is therefore controlled by

$$\frac{a_j}{a_i}\,\alpha_*^{2(i-1-j)+1} = C_*\,(B\alpha_*^2)^{i-1-j}, \qquad B\alpha_*^2 \le \tfrac{1}{4}.$$

The propagated remainders are therefore summable. The result is an analytic field $\widehat{\mathcal{E}}_j^a$ on the fine lattice with the same circulations as the reconstruction, whose coefficients are bounded uniformly in the number of steps; we need no such bound for the composed gauge representative itself.

The second idea concerns conditional means. The conditional law of the fluctuation variables is interacting. Using its density, the local covariance estimates of Section 13, and global color-rotation symmetry, we show that the conditional means of the nonlinear terms are of order t_j^2 times the size of the coarse field. Their conditional variances are bounded independently of the number of fluctuation variables.

We keep four kinds of variables apart. The link logarithms $\widehat{\theta}_j$ on the lattice of mesh a_j are dimensionless; the potentials $\widehat{\theta}_j/a_j$ are in physical units; the normalized fluctuation variables w_j are distributed according to the conditional fluctuation kernel k_j of

Theorem 31.5, which is supported on a product of balls; and independent standard Gaussian coordinates occur only in the linearized calculation of Theorem 31.6. All circulations are computed for the same gauge representative and with the componentwise heat semigroup.

The inputs come from Sections 4, 8, 10 to 13, 15, 16, and 23. Section 31.1 fixes notation. Section 31.2 defines the circulations and computes their covariance under the lattice Maxwell Gaussian field. Section 31.3 compares linearized reconstructions and controls the nonlinear remainders. Section 31.4 estimates the coefficients and the conditional means. Section 31.5 proves the covariance identity, Section 31.6 proves the decomposition and sums over scales, and Section 31.7 records that all estimates hold at every fixed positive coupling. All results are used in Section 32.

31.1 Setting and conventions

Fix $L > 0$, an odd integer $M \geq 3$, and an upper bound $\Gamma > 0$ on the dimensionless coupling. Let J, $B = M^J$, the parameter tuple Θ, the reconstruction maps, and the minimal coarse side n_Γ be as in Theorem 23.5; they are chosen before the coupling. Fix $0 < \gamma \leq \Gamma$ and set $g_3^2 = \gamma / L$. Fix $n_* \in 4\mathbb{N}$ and the sequence of lattice sides $N_K = n_* B^K$. For a coarse index $s \geq 0$ with $n_s \geq n_\Gamma$ and for $K \geq s$, set

$$n_s = n_* B^s, \qquad H_s = L / n_s, \qquad k = K - s,$$

$$a_j = H_s B^{-j} \quad (0 \leq j \leq k), \qquad a = a_k = L / N_K,$$

$$d_j = J(k - j), \qquad g_j = g_3 \sqrt{a_j}, \qquad \lambda_B = M^{(J-1)/2}, \qquad t_j = \lambda_B g_j, \qquad p_j = A_{\mathrm{w}} \log(1/t_j).$$

Here a_j is the mesh of the lattice reached after j RG steps of the reconstruction, starting from the coarse lattice of side n_s. The integer d_j is the number of averaging steps between the fine lattice and the lattice of mesh a_j; it determines the effective classical action used at that scale. In the notation of Section 26, d_j is the depth $\mathfrak{d}_j$, not the increment $x_j - x_{j-1}$ of the heat path. The number t_j is the largest coupling among the J intermediate scales of the j-th RG step, and p_j is the fluctuation cutoff radius, with the amplitude A_{w} fixed in Θ. The couplings $g_{j,\ell}$ of the intermediate scales satisfy $g_{j,\ell} \leq t_j$, and the ratios $g_{j,\ell}/t_j$ depend only on M and J.

Let $\nu_{K,s} = \nu_{N_K, n_s, \gamma} = \mu_{N_K,\gamma}(\,\cdot \mid S_{N_K, n_s, \gamma})$ be the conditioned Wilson measure. Under $\nu_{K,s}$ the fine configuration is described by its backward reconstruction sequence (Sections 4 and 15). The coarse field $\widehat{\theta}_0$ is the array of link logarithms, on the lattice of side n_s, of the chosen representative of the coarse configuration; it satisfies $\|\widehat{\theta}_0\|_\infty \leq r$. For $1 \leq j \leq k$,

$$\widehat{\theta}_j = \widehat{\Phi}_j(\widehat{\theta}_{j-1}, g_{j,\cdot} w_j),$$

where $\widehat{\Phi}_j$ is the reconstruction map of Theorem 15.12 for the j-th RG step, at the classical recursion index d_j, the $w_j = (w_{j,\ell})_\ell$ are the normalized fluctuation variables of that step,

and $g_{j,\cdot} w_j$ is the vector with components $g_{j,\ell} w_{j,\ell}$. By Definition 4.9, the heat-smoothed circulation is $I^{K,s} = \mathcal{I}_a(\widehat{\theta}_k)$, with $\mathcal{I}_a$ as in Definition 31.1 below. We write

$$\mathcal{F}_j = \sigma(\widehat{\theta}_0, w_1, \dots, w_j), \qquad \bar{w}_j = \mathbb{E}[w_j \mid \mathcal{F}_{j-1}], \qquad b_j = \|\widehat{\theta}_j\|_\infty.$$

The zero-fluctuation reconstruction maps and their linear and nonlinear parts are

$$\widehat{P}_j(v) = \widehat{\Phi}_j(v, 0), \qquad \widehat{L}_j = D\widehat{P}_j(0), \qquad \widehat{\mathcal{R}}_j(v) = \widehat{P}_j(v) - \widehat{L}_j v,$$

and for $i \geq j$ we set $\widehat{\Pi}_{i \leftarrow j} = \widehat{P}_i \circ \cdots \circ \widehat{P}_{j+1}$, which is the identity if $i = j$. For $1 \leq j \leq k$, a field θ on the lattice of mesh a_{j-1}, and fluctuation variables w of the j-th step, define

$$G_j(\theta, w) = \mathcal{I}_a\big(\widehat{\Pi}_{k \leftarrow j} \widehat{\Phi}_j(\theta, g_{j,\cdot} w)\big), \qquad \Gamma_j(\theta) = D_w G_j(\theta, 0), \qquad \omega_j = \min\{a_j/\varepsilon, \sqrt{\varepsilon/a_j}\},$$

$$\mathsf{R}_j^{\mathrm{cur}} = G_j(\widehat{\theta}_{j-1}, w_j) - G_j(\widehat{\theta}_{j-1}, 0) - \Gamma_j(\widehat{\theta}_{j-1}) w_j.$$

The matrix $\Gamma_j(\widehat{\theta}_{j-1})$ is $\mathcal{F}_{j-1}$-measurable, and the circulation Taylor remainder $\mathsf{R}_j^{\mathrm{cur}}$ is the nonlinear part of the change in the circulation caused by the fluctuations of the j-th step.

Coefficient norms. We use the norms of Definition 4.6. For a matrix $T = (T_{eu})$ from link variables on a lattice of mesh h to link variables on a lattice of mesh a', the row norm is $\sup_e \sum_u |T_{eu}|$ and the volume-normalized column norm is $\sup_u (a'^3/h^3) \sum_e |T_{eu}|$; we write $\|T\|_{\mathrm{row+col}}$ for the larger of the two. For a tensor of higher degree, a column sum fixes one input index, called the distinguished input, sums over all outputs and all other inputs, and carries the same volume factor. Taylor coefficients are divided by the corresponding factorials, and every coefficient is weighted by $e^{a_{\mathrm{sp}} \mathsf{t}}$, where t is the length of a shortest connected network, with internal vertices allowed, joining the locations of its indices. For an analytic map F vanishing at the origin and a power series ϕ with nonnegative coefficients, we write $F \prec \phi$ if, for every $m \geq 1$, the row norm of the homogeneous degree-m part of F is at most the coefficient of z^m in ϕ, and each of its column norms with a distinguished input is at most the coefficient of z^{m-1} in ϕ'. These bounds on absolute values of coefficients are stronger than bounds on the values of F, and they allow compositions of arbitrary length below.

Parameters and constants. By Lemma 15.15 and Theorem 23.5, there exists a constant C_* bounding the first derivative of the zero-fluctuation reconstruction maps, fixed before J is chosen, such that

$$\alpha_* = C_*/B < 1, \qquad q = B\alpha_*^2 = C_*^2/B \leq \tfrac{1}{4}.$$

Further, there exist a constant β_J and radii r_{eff} and r, chosen in this order, with

$$\frac{\beta_J r_{\mathrm{eff}}}{1 - \alpha_*} < \frac{1}{8}, \qquad r < \frac{r_{\mathrm{eff}}}{4},$$

such that all reconstructed fields $\widehat{\theta}_j$ and all their zero-fluctuation continuations lie in the ball $\{v : \|v\|_\infty \le r_{\mathrm{eff}}\}$, on which the bounds of Lemma 15.15 hold; we call it the reconstruction domain. The deterministic coefficient bounds below hold on this domain. The conditional fluctuation kernels, and all statements about their expectations, concern coarse fields θ with $e^\theta \in B_r$, the small-link domain of Definition 4.4, together with the product-domain and support conditions of Theorem 13.8. On the support of $\nu_{K,s}$ these conditions hold at every step: the coarse configurations of all RG steps lie in D_r, and the thresholds in Theorem 15.12 keep the images of the reconstruction maps inside B_r, so that $e^{\widehat{\theta}_j} \in B_r$ for $0 \le j \le k$. We write E_{q} for the bound, fixed in Θ, on the weighted analytic norm of the input effective interaction, which is produced by the integrations at finer scales.

Unless stated otherwise, C and c denote positive constants that may depend on L, γ, M, J, Θ, n_*, the analytic domains of Theorem 23.5, the loops, and σ; this is the dependence described in item (5) of Definition 4.14. They do not depend on K, j, d_j, the point x, the lattice offset (defined below), or the coarse field. We say explicitly when a constant does not depend on s; otherwise it may depend on s through H_s and n_s. All estimates are on the periodic torus. In the limit statements $\gamma > 0$ and s are fixed, the number of steps K tends to infinity first, $\varepsilon \downarrow 0$ second, and no rate uniform as $\gamma \downarrow 0$ is claimed.

31.2 Divergence-free currents and the Maxwell covariance

We define the circulations and the limiting covariance Σ, compute the covariance of the circulation of the lattice Maxwell Gaussian field, and show that it converges to Σ when the lattice spacing and then the loop size tend to zero.

Definition 31.1. Fix $\sigma > 0$ and finitely many smooth closed loops $\ell_i : [0,1] \to \mathbb{R}^3$, $1 \le i \le m$. For $\varepsilon > 0$ put $\eta = g_3^2 \varepsilon$, and for $p \in \mathbb{R}^3$ define

$$\widehat{J}_i(p) = \int_0^1 \dot{\ell}_i(v) e^{-ip\cdot \ell_i(v)}\, dv, \qquad \Sigma_{ih} = \frac{1}{(2\pi)^3} \int_{\mathbb{R}^3} \frac{e^{-2\sigma|p|^2}}{|p|^2}\, \overline{\widehat{J}_i(p)} \cdot \widehat{J}_h(p)\, dp.$$

Let $G = (G_i^c)_{1\le i\le m,\, 1\le c\le 3}$ be a centered Gaussian vector with covariance $\Sigma \otimes I_3$, write $G_i = (G_i^1, G_i^2, G_i^3)$, and set $\mathsf{Z}_i = |G_i|^2/8$. In Theorem 2.8 and Section 32 this vector is denoted C, and $(\mathsf{Z}_i)_i$ is denoted Z_G.

For a lattice mesh $a = L/N \le \varepsilon$ and $x \in \mathbb{T}_L^3$, let $\ell_{i,\varepsilon,a,x}$ be a closed oriented lattice cycle approximating the loop $x + \varepsilon \ell_i$ in $\mathbb{T}_L^3$, such that its physical length and diameter are at most $C_\ell \varepsilon$, it has zero winding when $\varepsilon \le \varepsilon_{\mathrm{loop}}$, and there is a based homotopy between it and $x + \varepsilon \ell_i$ whose swept area, counted with multiplicity, is at most $C_\ell \varepsilon a$. The constants C_ℓ and $\varepsilon_{\mathrm{loop}}$ depend only on the loops; they are uniform in x and in the choice of rounding

of the loop to the lattice, which we call the lattice offset. For a link potential A on the lattice of mesh a, in physical units, set

$$(\mathscr{C}_{a,\varepsilon,x}A)_i^c = \frac{a}{\sqrt{\eta}} \sum_{e \in \ell_{i,\varepsilon,a,x}} \operatorname{sgn}(e)\, (P^a_{\sigma\varepsilon^2}A)^c_{\operatorname{dir}(e)}(x_{\text{positive}}(e)), \qquad \mathcal{I}_a(v) = \mathscr{C}_{a,\varepsilon,x}(v/a),$$

for $1 \le i \le m$ and $1 \le c \le 3$. Here $P^a_t = e^{t\Delta_a}$ is the lattice heat semigroup, acting componentwise; $\operatorname{dir}(e)$ is the coordinate direction of e; $x_{\text{positive}}(e)$ is the starting vertex of the positively oriented link underlying e; and $\operatorname{sgn}(e) = -1$ if e is traversed against its positive orientation, so that a reversed link contributes minus the value on its positive orientation. The coefficient array $e \mapsto a \operatorname{sgn}(e)$ is a divergence-free lattice current, since the cycle is closed. We call $\mathscr{C}_{a,\varepsilon,x}A$ the heat-smoothed circulation of A, and $\mathcal{I}_a(v)$ that of the link logarithms v.

Finally, for $k \in (2\pi/L)\mathbb{Z}^3$ (a frequency) set

$$J_{i,\varepsilon,a,x}(k) = a \sum_{e \in \ell_{i,\varepsilon,a,x}} \operatorname{sgn}(e)\, e_{\operatorname{dir}(e)}\, e^{-ik\cdot x_{\text{positive}}(e)}, \qquad \lambda_a(k) = 4a^{-2} \sum_{r=1}^{3} \sin^2(ak_r/2),$$

$$C^{a,\varepsilon,L}_{ih} = \frac{1}{\varepsilon L^3} \sum_{k \neq 0} \frac{e^{-2\sigma\varepsilon^2\lambda_a(k)}}{\lambda_a(k)}\, \overline{J_{i,\varepsilon,a,x}(k)} \cdot J_{h,\varepsilon,a,x}(k),$$

where k ranges over representatives of $(2\pi/L)\mathbb{Z}^3$ modulo $(2\pi/a)\mathbb{Z}^3$ with $|ak_r| \le \pi$, and

$$C^{\varepsilon,L}_{ih} = \Big(\frac{\varepsilon}{L}\Big)^3 \sum_{k \in (2\pi/L)\mathbb{Z}^3 \setminus \{0\}} \frac{e^{-2\sigma|\varepsilon k|^2}}{|\varepsilon k|^2}\, \overline{\widehat{J}_i(\varepsilon k)} \cdot \widehat{J}_h(\varepsilon k).$$

The matrix Σ is the covariance of heat-smoothed circulations of a massless transverse field on $\mathbb{R}^3$: before smoothing, the Fourier covariance of that field is $|p|^{-2}(I - pp^{\mathsf{T}}/|p|^2)$ in each of three independent colors, and the transverse projection drops out against $\widehat{J}_i$ because $p \cdot \widehat{J}_i(p) = 0$.

Lemma 31.2. *In the notation of Definition 31.1, the following statements hold.*

1. *We have $p \cdot \widehat{J}_i(p) = 0$ and $|\widehat{J}_i(p)| \le C_\ell \min\{|p|, 1\}$. The integral defining Σ converges, and Σ is a real symmetric positive semidefinite matrix; it may be singular.*
2. *For $v_1, \dots, v_m \ge 0$, with $V = \operatorname{diag}(v_i)$,*

$$\mathbb{E} e^{-\sum_i v_i \mathsf{Z}_i} = \det\big(I + \tfrac{1}{4}\Sigma^{1/2} V \Sigma^{1/2}\big)^{-3/2},$$

$$\mathbb{E}\mathsf{Z}_i = \tfrac{3}{8}\Sigma_{ii}, \qquad \operatorname{Cov}(\mathsf{Z}_i, \mathsf{Z}_h) = \tfrac{3}{32}\Sigma^2_{ih}.$$

3. *The functional $\mathscr{C}_{a,\varepsilon,x}$ vanishes on every periodic lattice gradient. If $\varepsilon \le \varepsilon_{\text{loop}}$, it also vanishes on every constant field. For the initial potential $A^{K,s} = a_{N_K}^{-1}\widehat{\theta}_{K-s}$ of Definition 4.9, we have $I^{K,s} = \mathcal{I}_{a_{N_K}}(\widehat{\theta}_{K-s})$.*

4. *Let $\varepsilon \le \varepsilon_{\mathrm{loop}}$, and let A be the physical Maxwell Gaussian field on the lattice of mesh a, in three independent colors: the centered Gaussian field on link potentials modulo gradients and constants whose density is proportional to $\exp(-\|d\theta\|_{\ell^2}^2/(2g_3^2 a))$, where $\theta = aA$ and d is the dimensionless plaquette coboundary. Equivalently, its covariance is $g_3^2(-\Delta_a)^{+}P_{\mathrm{tr},a}$, where $P_{\mathrm{tr},a}$ is the projection onto lattice divergence-free fields and $(-\Delta_a)^{+}$ is the inverse of $-\Delta_a$ on fields with zero mean. Then $\mathbb{E}[(\mathscr{C}_{a,\varepsilon,x}A)_i^c(\mathscr{C}_{a,\varepsilon,x}A)_h^{c'}] = \delta_{cc'}C_{ih}^{a,\varepsilon,L}$. The longitudinal part of the covariance drops out by the exact closedness of the cycles, before any limit is taken.*
5. *For each fixed $\varepsilon \in (0, \varepsilon_{\mathrm{loop}}]$, $C^{a,\varepsilon,L} \to C^{\varepsilon,L}$ as $a \downarrow 0$, uniformly in x and the lattice offset. Further, $C^{\varepsilon,L} \to \Sigma$ as $\varepsilon \downarrow 0$.*

The constants in these statements depend only on the loops, L, σ, C_ℓ, and $\varepsilon_{\mathrm{loop}}$. The covariances $C^{a,\varepsilon,L}$, $C^{\varepsilon,L}$, and Σ do not depend on g_3.

Proof. We verify the statements in order.

Step 1: the continuum current. Let $l_i = \int_0^1 |\dot\ell_i(v)|\,dv$, and let y_i be a point on the i-th loop. Integrating the derivative of $v \mapsto e^{-ip\cdot\ell_i(v)}$ over the closed loop, we find $p \cdot \widehat{J}_i(p) = 0$. Since $\int_0^1 \dot\ell_i = 0$, we also have

$$\widehat{J}_i(p) = \int_0^1 \dot\ell_i(v)\big[e^{-ip\cdot\ell_i(v)} - e^{-ip\cdot y_i}\big]\,dv, \qquad |\widehat{J}_i(p)| \le l_i \min\{2, |p|\operatorname{diam}\ell_i\}.$$

The integrand defining Σ is therefore bounded near zero and bounded by $C|p|^{-2}e^{-2\sigma|p|^2}$ for $|p| \ge 1$; both bounds are integrable in three dimensions. For real numbers u_i, the quadratic form of Σ is

$$(2\pi)^{-3}\int_{\mathbb{R}^3} \frac{e^{-2\sigma|p|^2}}{|p|^2}\Big|\sum_i u_i \widehat{J}_i(p)\Big|^2\,dp \ge 0.$$

The substitution $p \mapsto -p$, together with $\widehat{J}_i(-p) = \overline{\widehat{J}_i(p)}$, shows that the entries are real, and interchanging i and h shows that Σ is symmetric.

Step 2: the Gaussian comparison vector. Let Z^1, Z^2, Z^3 be independent standard Gaussian vectors in $\mathbb{R}^m$ and set $G^c = \Sigma^{1/2}Z^c$; this constructs G also when Σ is singular. Then $\sum_i v_i \mathsf{Z}_i = (1/8)\sum_c (Z^c)^{\mathsf{T}}\Sigma^{1/2}V\Sigma^{1/2}Z^c$. Diagonalizing the positive semidefinite matrix $\Sigma^{1/2}V\Sigma^{1/2}$ by an orthogonal matrix reduces the Laplace transform to a product, over its eigenvalues λ and the three colors, of

$$(2\pi)^{-1/2}\int_{\mathbb{R}} e^{-(1+\lambda/4)z^2/2}\,dz = (1+\lambda/4)^{-1/2},$$

which gives the determinant formula. For a centered Gaussian pair (X, Y) we have $\mathbb{E}(X^2Y^2) = \mathbb{E}X^2\,\mathbb{E}Y^2 + 2(\mathbb{E}XY)^2$; this is Isserlis' formula [112]. Applying it to the coordinates of G, we obtain $\mathbb{E}\mathsf{Z}_i = (3/8)\Sigma_{ii}$ and $\operatorname{Cov}(\mathsf{Z}_i, \mathsf{Z}_h) = (1/64)\sum_c 2\Sigma_{ih}^2 = (3/32)\Sigma_{ih}^2$.

Step 3: gradients and constants. For a vertex function f, let $d_a f$ be the field whose value on the positive link from y to $y + ae_r$ is $(f(y + ae_r) - f(y))/a$. The heat semigroup commutes with d_a, since the lattice Laplacian is a sum of translations, which commute. The oriented sum of $a(P_t^a d_a f)_{\mathrm{dir}(e)}(x_{\mathrm{positive}}(e))$ around the lattice cycle telescopes to zero. The heat semigroup fixes constant fields, and the sum of the oriented displacement vectors $a\,\mathrm{sgn}(e)e_{\mathrm{dir}(e)}$ vanishes for a cycle of zero winding; hence the current also annihilates constants. Both assertions use the convention that a reversed link is evaluated on its positive orientation, at the starting vertex of that positive link. The identity $I^{K,s} = \mathcal{I}_{a_{N_K}}(\widehat{\theta}_{K-s})$ is the substitution $A = a_{N_K}^{-1}\widehat{\theta}_{K-s}$ in Definition 4.9; the gauge representative is not changed.

Step 4: the lattice covariance. We take the representatives k with $|ak_r| \le \pi$ and define

$$d_r(k) = a^{-1}(e^{iak_r} - 1), \qquad \text{so that} \qquad \lambda_a(k) = \sum_r |d_r(k)|^2.$$

The Fourier transform of the boundary of the cycle is zero, which is the identity

$$\sum_r \overline{d_r(k)}\, J_{i,\varepsilon,a,x,r}(k) = 0 \tag{31.1}$$

at every frequency, with repeated links counted with multiplicity. Indeed, the left side equals $\sum_e \mathrm{sgn}(e)(e^{-ik\cdot y_+(e)} - e^{-ik\cdot y_-(e)})$, where $y_\pm(e)$ are the endpoints of the positive link underlying e, and this sum telescopes around the closed cycle. At $k = 0$, zero winding implies $J_i(0) = 0$. On each nonzero frequency, the algebraic identity

$$\sum_{r<q} |d_r A_q - d_q A_r|^2 = \lambda_a |A|^2 - \Big|\sum_r \overline{d_r} A_r\Big|^2$$

identifies the inverse of the Maxwell quadratic form, restricted to transverse fields, as $\lambda_a^{-1} P_{\mathrm{tr},a}$. This normalization agrees with the Wilson normalization of Theorem 8.3: writing $\theta = aA$, the quadratic exponent is

$$\frac{\|d\theta\|_{\ell^2}^2}{2g_3^2 a} = \frac{a^3}{2g_3^2} \sum_y \sum_{r<q} |(d_a A)_{rq}(y)|^2,$$

where d on the left is dimensionless and d_a on the right is in physical units. With $\widehat{A}(k) = a^3 \sum_y e^{-ik\cdot y} A(y)$, the covariance of the Fourier coefficients is $g_3^2 L^3 \mathbf{1}_{k'=-k} \lambda_a(k)^{-1} P_{\mathrm{tr},a}(k)$. Pairing twice with the cycle, applying the two heat factors $e^{-\sigma\varepsilon^2\lambda_a(k)}$, and dividing by η, we obtain the covariance

$$\frac{g_3^2}{\eta L^3} \sum_{k\neq 0} \frac{e^{-2\sigma\varepsilon^2\lambda_a(k)}}{\lambda_a(k)}\, \overline{J_i(k)} \cdot J_h(k),$$

in each color separately. Here (31.1) removed the projection $P_{\mathrm{tr},a}$. Since $g_3^2/\eta = 1/\varepsilon$, this is the formula for $C^{a,\varepsilon,L}$.

Step 5: the limit $a \downarrow 0$. We lift the small cycle and the loop $x + \varepsilon\ell_i$ to a ball of diameter $C\varepsilon$ in $\mathbb{R}^3$. For a C^1 one-form f, replacing its integral over each oriented link by the value at the starting vertex of the positive link changes the integral by at most $a^2\|Df\|_\infty/2$ per link; summing over at most $C_\ell\varepsilon/a$ links gives an error at most $C\varepsilon a\|Df\|_\infty$. For a piecewise smooth based homotopy $H(u,v)$ between the polygon and the loop, differentiating $\int f(H)\partial_v H\,dv$ in u and integrating by parts in v gives

$$\oint_{\text{polygon}} f - \oint_{x+\varepsilon\ell_i} f = \int_0^1\int_0^1 df(H)(\partial_u H, \partial_v H)\,du\,dv.$$

The endpoint terms cancel because the paths are closed and the homotopy is based; for a piecewise smooth homotopy the formula holds piece by piece, and the internal boundaries cancel. The swept area bounds this difference by $C\varepsilon a\|df\|_\infty$. Applying both estimates to $f(y) = e^{-ik\cdot y}dy_r$, and using $\oint_{x+\varepsilon\ell_i} e^{-ik\cdot y}dy = \varepsilon e^{-ik\cdot x}\widehat{J_i}(\varepsilon k)$, we obtain for each fixed ε and k

$$\left|J_{i,\varepsilon,a,x}(k) - \varepsilon e^{-ik\cdot x}\widehat{J_i}(\varepsilon k)\right| \le C\varepsilon a|k|, \tag{31.2}$$

uniformly in x and the lattice offset; a rounding of the common base point is included in the same estimate. Subtracting from each exponential in the definition of J_i its value at one vertex of the cycle, which is allowed since $J_i(0) = 0$, and using the bounds on length and diameter, we find

$$|J_i(k)| \le C\varepsilon\min\{1, \varepsilon|k|\}, \qquad \frac{4}{\pi^2}|k|^2 \le \lambda_a(k) \le |k|^2. \tag{31.3}$$

The second assertion follows in each coordinate from $2|u|/\pi \le |\sin u| \le |u|$ for $|u| \le \pi/2$. For fixed $\varepsilon > 0$, we extend the summand defining $C^{a,\varepsilon,L}$ by zero outside the chosen representatives. By (31.3) its absolute value is bounded by a summable Gaussian function of k on the fixed reciprocal lattice $(2\pi/L)\mathbb{Z}^3$, uniformly in a, x, and the offset. Given a tolerance, we first truncate this Gaussian tail. On the finitely many remaining frequencies, (31.2) and $\lambda_a(k) \to |k|^2$ give uniform convergence. Substituting $J_i(k) = \varepsilon e^{-ik\cdot x}\widehat{J_i}(\varepsilon k)$, the two translation phases cancel and the prefactor becomes $\varepsilon^2/(\varepsilon L^3|k|^2) = (\varepsilon/L)^3|\varepsilon k|^{-2}$. This proves $C^{a,\varepsilon,L} \to C^{\varepsilon,L}$.

Step 6: the limit $\varepsilon \downarrow 0$. Let $\delta = 2\pi\varepsilon/L$ and, for $p \neq 0$, define

$$f_{ih}(p) = \frac{e^{-2\sigma|p|^2}}{|p|^2}\,\overline{\widehat{J_i}(p)}\cdot\widehat{J_h}(p).$$

By Step 1, f_{ih} is bounded near zero, smooth away from zero, and has a Gaussian tail. We have $C_{ih}^{\varepsilon,L} = (2\pi)^{-3}\delta^3\sum_{v\in\mathbb{Z}^3\setminus\{0\}} f_{ih}(\delta v)$. For $r > 0$, the contribution of the points with $|\delta v| < r$ is at most $C(r+\delta)^3$, as one sees by counting the disjoint cubes of side δ centered at these points inside the ball of radius $r + \sqrt{3}\delta$; the corresponding integral is at most

Cr^3. On a fixed annulus $r \le |p| \le R$, uniform continuity bounds the difference between the integral over each cube and the sampled value by the modulus of continuity at $\sqrt{3}\delta$, and the boundary cubes have total volume tending to zero. The tails are uniform for $0 < \delta \le 1$: for $R \ge 2$, the absolute sum over the shell $2^q R \le |p| < 2^{q+1}R$ is at most $C(2^{q+1}R+1)^3 e^{-c_\sigma (2^q R)^2}$, and these bounds are summable in q with sum tending to zero as $R \to \infty$. Letting $\delta \downarrow 0$, then $r \downarrow 0$, and then $R \to \infty$, we obtain $C_{ih}^{\varepsilon,L} \to (2\pi)^{-3} \int f_{ih} = \Sigma_{ih}$. The constants used depend only on the stated data, and g_3 appeared only through $g_3^2/\eta = 1/\varepsilon$. □

31.3 Linearized reconstruction and nonlinear error terms

This section constructs the field $\widehat{\mathcal{E}}_j^a$ described at the beginning of the section and proves the deterministic bounds that convert coefficient bounds into bounds for circulations. The linear comparison follows the constrained Gaussian calculations for Bałaban's averaging operation [10, Section A, (1.1)–(1.8), pp. 18–19, and Section D, (1.47)–(1.49), p. 26, and (1.64)–(1.67), p. 29]; the averaging map, the effective actions, and the gauge representatives used here are those of Sections 8, 10, 11, and 15, and the comparison is proved below for them.

Theorem 31.3. *Assume the setting of Section 31.1 and the loop data of Definition 31.1. Fix a coarse index s with $n_s \ge n_\Gamma$ and $K \ge s$. Then the following statements hold.*

1. *On the larger analytic domain fixed in Theorem 23.5, the zero-fluctuation reconstruction maps satisfy*

$$\widehat{P}_j \prec \phi(z) = \frac{\alpha_* z}{1-\beta_J z}, \qquad \big(v \mapsto \widehat{P}_j(v) - D\widehat{P}_j(0)v\big) \prec \frac{\alpha_* \beta_J z^2}{1-\beta_J z},$$

   with output rows, every volume-normalized column with a distinguished input, and a fixed spatial weight. The constant β_J is chosen on that domain before r_{eff} and r.

2. *There exist deterministic matrices E_j^a, $0 \le j \le k$, with $E_k^a = I$, each a scalar multiple of the identity on the color factor, with rows and volume-normalized columns (with factor a^3/a_j^3) bounded by a constant, and with a fixed positive spatial decay rate measured in units of a_j, such that*

$$a^{-1}\widehat{L}_k \cdots \widehat{L}_{j+1} v - a_j^{-1} E_j^a v = d_a f_j(v)$$

   for a periodic vertex function $f_j(v)$ on the fine lattice depending linearly on v. The difference has no constant part, because the block averaging constraint fixes the componentwise means in physical units. These bounds do not depend on $k - j$.

3. *Let T be a matrix from link variables on a lattice of mesh h to link variables on the fine lattice, with row norm and volume-normalized column norm at most A_0, and with at most a fixed number of input coordinates per cell of side h. Then for $0 \le t \le \sigma\varepsilon_{\mathrm{loop}}^2$,*

$$\sup_y \|\operatorname{row}_y(P_t^a T)\|_{\ell^2} \le C A_0 \min\{1, h^{3/2}(t+a^2)^{-3/4}\}, \qquad \|P_t^a T\|_{\ell^\infty \to \ell^\infty} \le A_0.$$

Consequently, for $a \le \varepsilon \le \varepsilon_{\mathrm{loop}}$,

$$\left\| \mathscr{C}_{a,\varepsilon,x} \frac{g_3\sqrt{h}}{h} T \right\|_{\ell^2 \to \mathbb{R}^{3m}} \le C A_0 \min\{h/\varepsilon, \sqrt{\varepsilon/h}\},$$

$$\left\| \mathscr{C}_{a,\varepsilon,x} \frac{g_3\sqrt{h}}{h} T \right\|_{\ell^\infty \to \mathbb{R}^{3m}} \le C A_0 \sqrt{\varepsilon/h},$$

where ℓ^2 and ℓ^∞ refer to the counting norms on the inputs.

4. *For $i > j$ put $r' = i - 1 - j$ and $D = \beta_J/(1-\alpha_*)$. Then*

$$\big(v \mapsto \widehat{\mathcal{R}}_i(\widehat{\Pi}_{i-1\leftarrow j}(v))\big) \prec C\alpha_*^{2r'+1} \frac{z^2}{(1-Dz)^2},$$

for rows and for columns with the normalization a_i^3/a_j^3. Derivatives with a distinguished input are bounded by derivatives of the same series, with the same spatial decay rate.

5. *Define the field on the fine lattice*

$$\widehat{\mathcal{E}}_j^a(v) = E_j^a v + \sum_{i=j+1}^{k} \frac{a_j}{a_i} E_i^a \, \widehat{\mathcal{R}}_i\big(\widehat{\Pi}_{i-1\leftarrow j}(v)\big).$$

For $\|v\|_\infty \le r_{\mathrm{eff}}$, it is equivariant under global color rotations, vanishes at $v = 0$, and satisfies

$$\mathcal{I}_a\big(\widehat{\Pi}_{k\leftarrow j}(v)\big) = \mathscr{C}_{a,\varepsilon,x}\big(a_j^{-1}\widehat{\mathcal{E}}_j^a(v)\big).$$

Its rows and its columns with normalization a^3/a_j^3 are bounded by a power series independent of k, j, and d_j. In particular, on the reconstruction domain,

$$\|D\widehat{\mathcal{E}}_j^a(v)\|_{\mathrm{row+col}} \le C, \qquad \|D\widehat{\mathcal{E}}_j^a(v) - D\widehat{\mathcal{E}}_j^a(0)\|_{\mathrm{row+col}} \le C\|v\|_\infty,$$

and every fixed higher derivative obeys the corresponding bound. The conversion to physical units is governed by the identities

$$\frac{a_j}{a_i}\alpha_*^{2r'+1} = B^{r'+1}\alpha_*^{2r'+1} = C_* q^{r'}, \qquad \frac{a^3}{a_i^3}\cdot\frac{a_i^3}{a_j^3} = \frac{a^3}{a_j^3}.$$

The constants in the coefficient bounds depend only on M, J, Θ, the analytic domains and their ratios, the spatial decay rates, and the number of coordinates per cell; the constants in the heat and circulation bounds may in addition depend on L, σ, C_ℓ, and $\varepsilon_{\mathrm{loop}}$. None depends on K, s, j, d_j, or the coarse field in the reconstruction domain.

Remark 31.4. The identity in part (5) is an identity between circulations. It does not say that the composed nonlinear reconstruction $\widehat{\Pi}_{k\leftarrow j}$ coincides with a single reconstruction over all intermediate scales, and no inverse of the Maxwell operator on the coarse lattice is used.

Proof. The proof has six steps. Step 1 recalls the analytic input. Step 2 proves the linear comparison of part (2), which is the source of the exact cancellation of gradients. Step 3 proves the heat and circulation bounds of part (3). Steps 4 and 5 show that coefficient bounds survive compositions of arbitrary length and prove part (4). Step 6 assembles the field $\widehat{\mathcal{E}}_j^a$.

Step 1: the analytic input. The coefficient bound on the larger domain and the order in which the constants are chosen are given by Lemma 15.15. The identification of C_* with the constant C_{CP} of that lemma and the choice of J are part of Theorem 23.5; in particular we use $q \le 1/4$, and no constant of an all-order bound at fixed J is used to choose J. Restricting the joint coefficient series of Lemma 15.15 to zero fluctuation variables gives the two majorants of part (1), with the stated output and distinguished-input conventions. Its domain inclusions hold on the reconstruction domain.

Step 2: the linear comparison. For $j < k$ we apply Lemma 11.9 once, with $J(k-j)$ averaging steps, preceding classical recursion index zero, coarse mesh a_j, and relative fine spacing $u = a/a_j$. The logarithm of the representative given by that lemma is $u\overline{A}_u(v)$, and we define

$$E_j^a = D\overline{A}_u(0).$$

By the first-derivative clause of that lemma, we have the row bound and the column factor $u^3 = a^3/a_j^3$, with one positive spatial decay rate in units of a_j, uniformly in the number $J(k-j)$ of averaging steps. We use no bound on the dependence on fluctuation variables at this growing number of steps. By global color equivariance, each 3×3 color block of E_j^a commutes with every rotation. Commuting with the rotations by π about the coordinate axes makes the block diagonal, and commuting with the rotations that permute the axes makes its three diagonal entries equal. Hence E_j^a is a scalar multiple of the identity on the color factor. We set $E_k^a = I$.

We now show that uE_j^a represents the composed linearization for circulations. First let v be real; all minimizations and comparisons of nonnegative quadratic forms in this paragraph are on real tangent spaces. By the quadratic part of the nested minimization

identity of Theorem 10.10, each linearized reconstruction minimizes the inherited nonnegative Maxwell quadratic form over the free coordinates, on which this form is positive definite. If a quadratic form $Q(x,y,z)$ has positive blocks in the constrained variables y and z, then

$$\inf_z \inf_y Q(x,y,z) = \inf_{(y,z)} Q(x,y,z).$$

Indeed, every value of the problem on the right bounds the left side from above, and for each fixed z the inner minimizer realizes the infimum over y. Completing the squares in the positive blocks shows that both infima are attained at the classical tangents. We iterate this equality over the finitely many averaging steps. Since the indices $d_j = J(k-j)$ are compatible, the inherited forms are exactly the successive Schur complements. Thus the composed tangent $\widehat{L}_k \cdots \widehat{L}_{j+1} v$ and the tangent $uE_j^a v$ minimize the same quadratic form on the fine lattice subject to the same linearized averaging constraint v. The gauge transformations of Theorem 15.12 depend only on the coarse field and equal the identity at the tree roots; they preserve the constraint and the gauge orbit of the minimizer. Their derivatives at zero add periodic gradients, which do not affect this conclusion.

Let X and Y be these two minimizers, and let Q_0 be the Maxwell quadratic form. Since the constraint is linear, the midpoint satisfies it. By the parallelogram identity, we have

$$Q_0\Big(\frac{X+Y}{2}\Big) = \frac{1}{2}Q_0(X) + \frac{1}{2}Q_0(Y) - \frac{1}{4}Q_0(X-Y).$$

Minimality and nonnegativity imply $Q_0(X-Y) = 0$; in particular $d(X-Y) = 0$. We determine the kernel. Let $Z = X - Y$ and fix a nonzero lattice frequency, with $b_r = e^{iak_r} - 1$. Zero curl says $b_r \widehat{Z}_q = b_q \widehat{Z}_r$. Choosing an index r with $b_r \neq 0$, we have $\widehat{Z}_q = b_q(\widehat{Z}_r / b_r)$ for every q; that is, every nonzero-frequency part of Z is a periodic gradient. The zero-frequency part is a constant field, and its componentwise means in physical units are its constant components.

This constant vanishes for $X - Y$. By Lemma 8.1, the derivative of the composed block averaging map is the box and segment average plus a periodic gradient on the coarse lattice, and its version in physical units preserves each componentwise mean. Explicitly, if $m' = a_j/a$ is the total blocking factor and $K_{m'}$ the box and segment average, the box and segment formula counts each fine link m' times before its factor m'^{-3}, so that

$$\sum_Y (K_{m'} Z)_r(Y) = m'^{-2} \sum_y Z_r(y), \qquad (m'a)^3 \sum_Y \frac{(K_{m'} Z)_r(Y)}{m'a} = a^3 \sum_y \frac{Z_r(y)}{a}.$$

The coarse gradient has mean zero. Since $X - Y$ satisfies the homogeneous constraint, its mean in physical units is zero. The same argument applies to coarse fields with nonzero constant components, which are fixed by the constraint. We conclude that $a^{-1}(X-Y) = d_a f_j(v)$ for a periodic vertex function, chosen with mean zero, which depends linearly on v by the frequency formula above. This proves part (2), and by

Lemma 31.2 the circulation annihilates the gradient. The maps in this identity are real linear; their complex-linear extensions give the same identity for complex v.

Step 3: heat and circulation bounds. Let $R(T)$ and $C(T)$ be the row norm and the volume-normalized column norm of T. For a vector z of inputs, by the Cauchy–Schwarz inequality with the weights $|T_{eu}|$, we have

$$\sum_e \Big|\sum_u T_{eu} z_u\Big|^2 \le R(T) \sum_{e,u} |T_{eu}||z_u|^2 \le R(T)C(T)(h/a)^3 \sum_u |z_u|^2,$$

since $\sum_e |T_{eu}| \le (h/a)^3 C(T)$. Thus $\|T\|_{\ell^2\to\ell^2} \le A_0(h/a)^{3/2}$. We use Lemma 16.1 with the fixed horizon $T_{\mathrm{heat}} = \sigma\varepsilon_{\mathrm{loop}}^2$ and difference order zero. Its hypotheses hold on the periodic fine lattice of mesh $a = L/N_K$, with $N_K \ge 4$, and all times considered lie in $[0, T_{\mathrm{heat}}]$. Since the heat kernel of that lemma is a density with respect to $a^3\sum_y$, the row of P_t^a at y, as a vector in the counting norm, is $a^3 p_t^a(y,\cdot)$, and its ℓ^2 norm is at most $Ca^{3/2}(t+a^2)^{-3/4}$. Applying this row to T, we obtain

$$\|\operatorname{row}_y(P_t^a T)\|_{\ell^2} \le \|a^3 p_t^a(y,\cdot)\|_{\ell^2}\|T\|_{\ell^2\to\ell^2} \le CA_0 h^{3/2}(t+a^2)^{-3/4}.$$

Since the heat kernel is positive with unit mass, the absolute row sums of $P_t^a T$ are at most A_0; this bounds both the ℓ^2 norm of each row and the $\ell^\infty \to \ell^\infty$ norm, including at $t = 0$. The finitely many directions and input types are absorbed into C. Since the horizon is fixed, the constants depend on its ratio to L^2, and the constant mode of the heat semigroup is included.

For $\varepsilon \le \varepsilon_{\mathrm{loop}}$ the time $t = \sigma\varepsilon^2$ lies in $[0, T_{\mathrm{heat}}]$, and $a \le \varepsilon$ implies $(t+a^2)^{-3/4} \le C_\sigma \varepsilon^{-3/2}$. The circulation sums the rows over at most $C_\ell \varepsilon/a$ links with the weight $a/\sqrt{\eta}$, so the prefactor multiplying a single row is

$$\frac{\varepsilon}{\sqrt{\eta}} \cdot \frac{g_3\sqrt{h}}{h} = \sqrt{\varepsilon/h}.$$

Multiplying it by $\min\{1, C(h/\varepsilon)^{3/2}\}$ proves the ℓ^2 circulation bound, and multiplying it by the absolute row bound proves the ℓ^∞ bound. Summing over the fixed number of loop and color components gives a fixed factor.

Step 4: compositions of coefficient bounds. In the composition of two tensors, fixing an output and summing over all inputs uses the row bound of the outer tensor and a row bound of the inner tensor at every input slot of the outer tensor. If instead we fix one input of the inner tensor, we follow the chain of factors through which this input enters. Along this chain we use the column bound of the inner tensor and the column bound of the outer tensor with the corresponding distinguished input; all other factors use rows. For example, let B be a bilinear tensor from mesh a_{i-1} to mesh a_i and G a linear tensor from

mesh a_j to mesh a_{i-1}, and consider $(B(Gv, Gv))_e = \sum_{y,y',u,u'} B_{e;yy'} G_{yu} G_{y'u'} v_u v_{u'}$. Fixing u in the first slot, we have

$$\sum_{e,u'} \Big| \sum_{y,y'} B_{e;yy'} G_{yu} G_{y'u'} \Big| \le \sum_{y} |G_{yu}| \sum_{e,y'} |B_{e;yy'}| \sum_{u'} |G_{y'u'}| \le \frac{a_j^3}{a_{i-1}^3} C(G) \cdot \frac{a_{i-1}^3}{a_i^3} C_1(B) \cdot R(G),$$

where $C_1(B)$ is the column norm of B with its first input distinguished. After multiplication by the volume factor a_i^3 / a_j^3, the volume factors cancel:

$$\frac{a_i^3}{a_{i-1}^3} \cdot \frac{a_{i-1}^3}{a_j^3} = \frac{a_i^3}{a_j^3}.$$

In general there is exactly one chain of factors carrying the fixed input; summing over its possible positions corresponds to differentiating the scalar power series. The Taylor coefficients $D^n / n!$ distribute the input indices among the input slots of the outer tensor with exactly the multiplicities of scalar substitution: ordering the slots first and then dividing by their factorials counts each partition once. We conclude that composition of the scalar majorants majorizes these tensor contractions, also with a distinguished input, and that no constant is lost at successive levels.

The spatial weights are treated in the same contraction. We take the union of the connecting networks of the participating coefficients, joined at the contracted indices. It is a connected network joining all the external indices, so its length is at least their minimal network length. Every later input mesh is at most a_j, so the weight of each part of the network at its own scale dominates its weight in units of a_j. Multiplying the weights bounds the weight of the union with the initially fixed decay rate. This holds for compositions of arbitrary length, without a reduction of the decay rate at each step.

Step 5: iterated majorants and the remainder bound. Let $S_r = \sum_{v=0}^{r-1} \alpha_*^v$, with $S_0 = 0$. By induction, using the formula for ϕ, we have the identity

$$\phi^{\circ r}(z) = \frac{\alpha_*^r z}{1 - \beta_J S_r z}. \tag{31.4}$$

For the inductive step, we substitute the right side into $\alpha_* y / (1 - \beta_J y)$ and use $S_{r+1} = S_r + \alpha_*^r$. By Step 4, $\widehat{\Pi}_{i-1 \leftarrow j} \prec \phi^{\circ r'}$ with $r' = i - 1 - j$, and the remainder satisfies, coefficientwise,

$$\begin{aligned} \widehat{\mathcal{R}}_i \circ \widehat{\Pi}_{i-1 \leftarrow j} \prec \frac{\alpha_* \beta_J (\phi^{\circ r'}(z))^2}{1 - \beta_J \phi^{\circ r'}(z)} &= \frac{\beta_J \alpha_*^{2r'+1} z^2}{(1 - \beta_J S_{r'} z)(1 - \beta_J S_{r'+1} z)} \\ &\preceq \frac{\beta_J \alpha_*^{2r'+1} z^2}{(1 - Dz)^2}, \qquad D = \frac{\beta_J}{1 - \alpha_*}. \end{aligned} \tag{31.5}$$

Here $\preceq$ denotes coefficientwise inequality of power series. In the equality we used $1-\beta_J\phi^{\circ r'}(z) = (1-\beta_J S_{r'+1}z)/(1-\beta_J S_{r'}z)$, and the coefficientwise inequality holds because $\beta_J S_r \le D$ for every r. This proves the row, column, and distinguished-derivative assertions of part (4), with $C=\beta_J$, enlarged once for the fixed convention on components. The bound $Dr_{\mathrm{eff}} < 1/8$ makes all these substitutions convergent on the reconstruction domain. The two inputs that every monomial of the remainder contains each contribute a factor $\alpha_*^{r'}$; this is the origin of the exponent $2r'+1$.

Step 6: the field $\widehat{\mathcal{E}}_j^a$. For a finite composition we have the identity

$$\widehat{\Pi}_{k\leftarrow j}(v) = \widehat{L}_k\cdots\widehat{L}_{j+1}v + \sum_{i=j+1}^{k} \widehat{L}_k\cdots\widehat{L}_{i+1}\,\widehat{\mathcal{R}}_i\big(\widehat{\Pi}_{i-1\leftarrow j}(v)\big), \tag{31.6}$$

which follows by induction on $k-j$: to pass from $k-1$ to k, apply $\widehat{L}_k$ to the identity at $k-1$ and add $\widehat{\mathcal{R}}_k(\widehat{\Pi}_{k-1\leftarrow j}(v))$. We apply the linear functional $\mathcal{I}_a$ to (31.6) and use the linear comparison of Step 2 on each summand, with the remainder $\widehat{\mathcal{R}}_i(\widehat{\Pi}_{i-1\leftarrow j}(v))$ as input at scale i. Since the circulation annihilates the gradients, we obtain

$$\mathcal{I}_a\big(\widehat{\Pi}_{k\leftarrow j}(v)\big) = \mathscr{C}_{a,\varepsilon,x}\Big(a_j^{-1}E_j^a v + \sum_{i=j+1}^{k} a_i^{-1}E_i^a\,\widehat{\mathcal{R}}_i\big(\widehat{\Pi}_{i-1\leftarrow j}(v)\big)\Big),$$

which is the identity of part (5). Each remainder is equivariant and vanishes at zero, and each E_i^a is a scalar multiple of the identity on the color factor; hence $\widehat{\mathcal{E}}_j^a$ has both properties.

Let C_E be a common bound for the rows and volume-normalized columns of all E_i^a. Composing E_i^a with a remainder multiplies its column normalization a_i^3/a_j^3 by a^3/a_i^3, which gives a^3/a_j^3. The factor a_j/a_i in the definition of $\widehat{\mathcal{E}}_j^a$ combines with (31.5) to give

$$\frac{a_j}{a_i}\alpha_*^{2r'+1} = B^{r'+1}\alpha_*^{2r'+1} = C_* q^{r'}.$$

Summing over i, a common majorant for $\widehat{\mathcal{E}}_j^a$ is

$$\Psi(z) = C_E z + \frac{C_E\beta_J C_*}{1-q}\,\frac{z^2}{(1-Dz)^2}. \tag{31.7}$$

By the fixed-input calculation of Step 4, its derivatives bound the columns with a distinguished input. It converges on a disk of radius larger than r_{eff}. Its first derivative bounds $D\widehat{\mathcal{E}}_j^a$; its second derivative, integrated along the segment from 0 to v, gives $\|D\widehat{\mathcal{E}}_j^a(v) - D\widehat{\mathcal{E}}_j^a(0)\|_{\mathrm{row+col}} \le C\|v\|_\infty$; and each fixed further derivative is bounded by the corresponding derivative of Ψ, since $Dr_{\mathrm{eff}} < 1/8$. All constants are functions of the coefficient data listed in the theorem; only Step 3 introduced the loops, the heat horizon, and the torus. This completes the proof. □

31.4 Conditional current coefficients and means

We now bring in the conditioned Wilson measure. The next theorem collects the properties of the conditional fluctuation kernels that we need, bounds the coefficient matrices Γ_j and their dependence on the coarse field, and bounds the conditional mean and the conditional variance of the circulation Taylor remainders $\mathsf{R}_j^{\mathrm{cur}}$. The conditional kernels satisfy a uniform convexity bound on a product of balls. The resulting dimension-free Poincaré, logarithmic Sobolev, and covariance estimates are in the tradition of Brascamp and Lieb [33], Bakry and Émery [8], and Helffer and Sjöstrand [110]; their versions on products of balls are proved in Sections 5 and 13.

Theorem 31.5. *Assume the setting of Section 31.1 and the loop data of Definition 31.1, with one family of reconstruction maps on the whole sequence of lattices. There exists $s_0 < \infty$ such that for every integer $s \geq s_0$, every $K \geq s$, every $1 \leq j \leq K - s$, and every ε with $a = a_{K-s} \leq \varepsilon \leq \varepsilon_0(s)$, the following statements hold. One may take $\varepsilon_0(s) \leq \min\{cH_s, \varepsilon_{\mathrm{loop}}, c/g_3^2\}$ for a fixed small $c > 0$.*

1. *Under $\nu_{K,s}$, the conditional law of w_j given $\mathcal{F}_{j-1}$ is $k_j(\widehat{\theta}_{j-1}, dw)$, where*

$$k_j(\theta, dw) = \frac{\mathbf{1}_{\Omega_j}(w) e^{-V_j(\theta,w)}\, dw}{\int_{\Omega_j} e^{-V_j(\theta,w)}\, dw}, \qquad \Omega_j = \prod_{\ell=1}^{m_j} \overline{B}_{\mathbb{R}^3}(0, p_{j,\ell}), \qquad p_j \leq p_{j,\ell} \leq p_j + C_J.$$

   The potential V_j contains the part of the classical action beyond its quadratic approximation, the input effective interaction, the Haar disintegration density, and the determinants of the triangular change of variables. The restrictions at coarser scales do not change this kernel once θ is fixed. On all of Ω_j,

$$\|D_w^2 V_j - I\|_{\mathrm{row+col}} \leq \vartheta_j = C\big[t_j p_j + t_j^2(1 + \mathsf{E}_{\mathrm{q}})\big], \qquad D_w^2 V_j \geq \tfrac{1}{2} I,$$

$$\mathrm{Var}_{k_j} f \leq 2\mathbb{E}_{k_j}|\nabla f|^2, \qquad \mathrm{Ent}_{k_j}(f^2) \leq 4\mathbb{E}_{k_j}|\nabla f|^2.$$

   The number of three-dimensional blocks satisfies $m_j \leq C_J(L/a_j)^3 \leq C_{J,L,\gamma} t_j^{-6}$, and the conditional means satisfy $\sup_\ell |\mathbb{E}_\theta w_{j,\ell}| \leq C t_j \|\theta\|_\infty$; in particular they vanish at $\theta = 0$. Here $\mathbb{E}_\theta$ denotes expectation under $k_j(\theta, \cdot)$, for a coarse field with $e^\theta \in B_r$ as in Section 31.1. The threshold s_0 can be chosen so that, in addition, $p_j \geq 1$, $6m_j e^{-p_j^2/192} \leq 1/2$, and $|\mathbb{E}_\theta w_{j,\ell}^c| \leq p_j/(16\sqrt{3})$ at all these levels, for every color component c and every coarse field with $e^\theta \in B_r$.

2. *For every θ in the reconstruction domain, with $b = \|\theta\|_\infty$,*

$$\|\Gamma_j(\theta)\|_{\ell^2 \to \mathbb{R}^{3m}} \leq C\omega_j, \qquad \|\Gamma_j(\theta)\|_{\ell^\infty \to \mathbb{R}^{3m}} \leq C\sqrt{\varepsilon/a_j},$$

$$\|\Gamma_j(\theta) - \Gamma_j(0)\|_{\ell^2 \to \mathbb{R}^{3m}} \leq Cb\,\omega_j, \qquad \|\Gamma_j(\theta)\Gamma_j(\theta)^{\mathsf{T}} - \Gamma_j(0)\Gamma_j(0)^{\mathsf{T}}\| \leq Cb\,\omega_j^2,$$

   where ℓ^2 and ℓ^∞ refer to the counting norms on the fluctuation variables.

3. *Let $t = t_j$, and recall that the couplings $g_{j,\ell} \le t_j$ of the intermediate scales have fixed ratios to t_j. Let $F_e(\theta, q)$ be an analytic function of the coarse field θ and the coupling-scaled fluctuation inputs q on the common larger coarse/free domain, with values in $\mathbb{R}^3$, equivariant under global color rotations, such that $F(0,0) = 0$, such that its absolute coefficient row sum at the fixed output e is at most a given constant $C_F < \infty$, and such that, after the substitution $q_\ell = g_{j,\ell} w_\ell$, every term of degree l in w carries a factor t^l, also after one derivative in θ. The constants in this part may depend on C_F and on the radius of the larger domain, but not on the output resolution. For $D_e(\theta, w) = F_e(\theta, g_{j,\cdot} w) - F_e(\theta, 0)$ and every coarse field θ with $e^\theta \in B_r$, we have*

$$|\mathbb{E}_\theta D_e| \le C t^2 \|\theta\|_\infty, \qquad \mathbb{E}_0 D_e = 0.$$

For $\theta_u = u\theta$, $0 \le u \le 1$, and the potential $V_{\theta_u} = V_j(\theta_u, \cdot)$,

$$\frac{d}{du} \mathbb{E}_{\theta_u} D_e(\theta_u, w) = \mathbb{E}_{\theta_u} \partial_u D_e - \mathrm{Cov}_{\theta_u}(D_e, \partial_u V_{\theta_u}),$$

and the local estimates

$$\sup_l \|\partial_{w_l} \partial_u V_{\theta_u}\|_{L^2(k_j(\theta_u, \cdot))} \le C t \|\theta\|_\infty, \qquad \sum_l \|\partial_{w_l} D_e\|_{L^2(k_j(\theta_u, \cdot))} \le C t$$

hold. The derivative of the normalization, the input effective interaction, the Haar disintegration density, and all determinants are included in these statements. At $\theta = 0$ the covariance of the fluctuation variables has the form $\mathbb{E}_0[w_l^a w_h^b] = S_{lh} \delta_{ab}$, with all spatial correlations S_{lh} retained, and its contraction with any equivariant bilinear coefficient with values in $\mathbb{R}^3$ is zero. This is a consequence of global color equivariance, not of parity.

4. *With $b_{j-1} = \|\widehat{\theta}_{j-1}\|_\infty$,*

$$\big|\Gamma_j(\widehat{\theta}_{j-1}) \bar{w}_j + \mathbb{E}[\mathsf{R}_j^{\mathrm{cur}} \mid \mathcal{F}_{j-1}]\big| \le C t_j b_{j-1} \sqrt{\varepsilon / a_j},$$

$$\mathbb{E}\big[|\mathsf{R}_j^{\mathrm{cur}} - \mathbb{E}(\mathsf{R}_j^{\mathrm{cur}} \mid \mathcal{F}_{j-1})|^2 \,\big|\, \mathcal{F}_{j-1}\big] \le C t_j^2 p_j^2 \omega_j^2.$$

The same mean bound holds separately for $|\Gamma_j(\widehat{\theta}_{j-1}) \bar{w}_j|$ and for $|\mathbb{E}[\mathsf{R}_j^{\mathrm{cur}} \mid \mathcal{F}_{j-1}]|$, and both vanish when $\widehat{\theta}_{j-1} = 0$.

All constants in parts (1)–(4) are independent of $s \ge s_0$, K, j, d_j, the output resolution, the point x, and the lattice offset. They may depend on L, γ, M, J, Θ, the loops, σ, the analytic domains, and, in part (3), on C_F and the larger domain.

Proof. We first identify the conditional kernels and choose s_0. We then bound the coefficients at a general coarse field (Step 2), prove the moment and coupling bounds needed for general outputs (Steps 3–5), prove part (3) (Step 6), and apply it to the circulation (Step 7).

Step 1: the kernels and the threshold. By Theorem 15.12, the reconstruction maps preserve the conditional law and its product of balls at every index d_j. We apply Theorem 13.8 to this law; its bound on the input effective interaction is E_{q}, and its largest coupling is t_j. The finitely many cutoff radii within one RG step differ by at most a fixed C_J; write $p_j^+ = p_j + C_J$. For $p_j \geq 1$ this is at most $(1 + C_J)p_j$, so replacing p by p_j^+ in the rational estimate of that theorem changes only its constant, and choosing the coarse side large bounds its denominator away from zero. This gives the bound ϑ_j, and the convexity, Poincaré, and entropy statements on the closed product. Every factor coming from coarser restrictions is a function of the coarse field and cancels in the normalized kernel, as stated in the same theorem. Neither this cancellation nor the choice of gauge representatives removes from V_j a term that depends on w.

The count of free coordinates in Theorem 12.13, summed over the J intermediate scales, bounds the number of three-dimensional blocks by $C_J(L/a_j)^3$. Since $t_j = \lambda_B g_3 \sqrt{a_j}$, we have $(L/a_j)^3 = L^3(\lambda_B g_3)^6 t_j^{-6}$. The mean bound of Theorem 13.10, applied to this product with its individual radii, implies that $\sup_\ell |\mathbb{E}_\theta w_{j,\ell}| \leq C t_j b$; in particular the means vanish at $\theta = 0$.

At coarse index s the largest coupling is

$$t_1(s) = g_3 \sqrt{H_s / M}, \qquad t_j(s) = t_1(s) B^{-(j-1)/2}, \tag{31.8}$$

and $t_1(s) \to 0$ as $s \to \infty$. All the domain, analytic, curvature, and moment conditions required here are finitely many fixed inequalities in t and in its cutoff radius $p(t) = A_{\mathrm{w}} \log(1/t)$. We also require $n_s \geq n_\Gamma$ for every $s \geq s_0$. We increase s_0 until all these inequalities hold for every $0 < t \leq t_1(s_0)$. This is possible also for the condition $6m_j e^{-p_j^2/192} \leq 1/2$, which involves the number of blocks: with $u = \log(1/t)$ its left side is at most

$$C_{J,L,\gamma} \exp\bigl(6u - A_{\mathrm{w}}^2 u^2/192\bigr) \longrightarrow 0 \qquad (u \to \infty).$$

The same reasoning bounds the quantity $(1 + 3m_j)(6m_j)^{1/2} e^{-p_j^2/384}$, which appears in the cutoff estimates of Lemma 32.6. As a function of $h = a_j$, we have

$$(1 + 3m_j)(6m_j)^{1/2} e^{-p_j^2/384} \leq C\bigl(1 + (L/h)^3\bigr)(L/h)^{3/2} e^{-c \log^2(1/(c' g_3 \sqrt{h}))}, \tag{31.9}$$

and for every fixed $v > 0$ the right side is $O(h^v)$ as $h \downarrow 0$, since after taking logarithms the negative quadratic term dominates every fixed linear term. The bound on the mean in part (1) follows from $C t_j r \leq p_j/(16\sqrt{3})$ after another increase of s_0, since $\|\theta\|_\infty < r$ when $e^\theta \in B_r$. These inequalities persist at every later s and every level j. Finally, we choose $\varepsilon_0(s)$ as in the statement, with c small enough that $\eta < 1$ and the small lattice cycles have zero winding. None of these choices changes the reconstruction maps, their thresholds, or the small-field event at any side.

Step 2: coefficients at a general coarse field. We suppress a, ε, and x from $\mathscr{C} = \mathscr{C}_{a,\varepsilon,x}$, and define the map to the fine lattice

$$Z_j(\theta, w) = \widehat{\mathcal{E}}_j^a\big(\widehat{\Phi}_j(\theta, g_{j,\cdot} w)\big). \tag{31.10}$$

By the identity of Theorem 31.3(5), we have $G_j = \mathscr{C}(a_j^{-1} Z_j)$. We compose the joint coefficient series of Theorem 15.12 with the majorant (31.7). The column bound for compositions, proved in Step 4 of the proof of Theorem 31.3, applies with one fluctuation input distinguished, and we obtain

$$D_w Z_j(\theta, 0) = g_j T_j(\theta), \qquad \|T_j(\theta)\|_{\mathrm{row+col}} \le C, \qquad \|T_j(\theta) - T_j(0)\|_{\mathrm{row+col}} \le Cb. \tag{31.11}$$

Here the fluctuation variables are referred to the mesh a_j. Their meshes differ from a_j by the fixed factors $1, M, \dots, M^{J-1}$, and their couplings differ from g_j by the corresponding fixed square-root factors, so converting their columns and densities to the mesh a_j introduces only constants depending on J. A derivative in θ introduces a factor depending only on the fixed gap between the larger and the smaller domain, and integrating it from 0 to θ proves the last bound; no depth-dependent derivative bound or new domain is used. Since $\Gamma_j(\theta) = \mathscr{C}\big((g_3\sqrt{a_j}/a_j) T_j(\theta)\big)$, Theorem 31.3(3), applied to $T_j(\theta)$ and to $T_j(\theta) - T_j(0)$ with $h = a_j$, proves the three bounds on Γ_j in part (2). For the Gram matrices we use, with $A = \Gamma_j(\theta)$ and $A_0 = \Gamma_j(0)$,

$$\|AA^{\mathsf{T}} - A_0 A_0^{\mathsf{T}}\| \le \|A - A_0\|\,(\|A\| + \|A_0\|),$$

which gives the bound $Cb\,\omega_j^2$.

Step 3: local moments. We fix one of these products of balls, set $\theta_u = u\theta$, and write $\mathbb{E}_u$ for expectation under $k_j(\theta_u, \cdot)$. By the mean bound and the inequalities of Step 1, we have $\sup_l |\mathbb{E}_u w_l| \le 1$. For a scalar coordinate let $\xi = w_l^c - \mathbb{E}_u w_l^c$. Applying the Poincaré inequality first to ξ and then to ξ^2, we obtain

$$\mathbb{E}_u \xi^2 \le 2, \qquad \mathbb{E}_u \xi^4 - (\mathbb{E}_u \xi^2)^2 \le 2\mathbb{E}_u |\nabla \xi^2|^2 = 8\mathbb{E}_u \xi^2 \le 16.$$

Hence all fourth moments of scalar coordinates are bounded by a fixed constant, and the inequality $(x_1^2 + x_2^2 + x_3^2)^2 \le 3\sum_c x_c^4$ gives the same for each three-dimensional block. These bounds are uniform in u, the dimension of the product, and the output mesh.

Step 4: coupling powers in the potential. We read off the powers of the coupling in the potential from Theorem 12.13. The first derivative of each classical action with respect to the free coordinates vanishes at its conditional constrained minimizer. Its quadratic term becomes exactly $|w_i|^2/2$, because the normalization uses $K_i^{-1/2}$, the inverse square root of the constrained Hessian. Although the minimizer and the square root depend on the fluctuation variables of the coarser intermediate scales, this quadratic expression

does not. After subtracting $|w|^2/2$, the classical part has total degree at least three in w. The coupling-scaled fluctuation inputs are $q_i = g_i w_i = t\lambda_i w_i$, with fixed λ_i, and the free logarithmic coordinates are $z_i = z_i^* + K_i^{-1/2} q_i$, where z_i^* and K_i depend on the coarser fields. We expand the analytic reconstruction in the inputs q_i, keeping the conditional constrained minimizers and the Hessian factors inside it. Each term of total degree r then contributes t^r after the substitution, and the classical divisor g_i^2 removes two powers of t. The differences of the Haar disintegration density and of the determinants have positive degree and no inverse power of the coupling. Writing H_r for the part of degree r in w of the interaction generated at the current integration step, there are tensors A_r and B_r (unrelated to the small-link domain B_r) such that

$$H_r(\theta, w; t) = t^{r-2} A_r(\theta)[w^r] + t^r B_r(\theta)[w^r], \qquad A_1 = A_2 = 0. \tag{31.12}$$

The differences of the Haar density and of the determinants belong to the terms B_r, and their dependence on the fluctuation variables of the coarser intermediate scales is kept in this decomposition.

Step 5: the mixed derivative of the potential. Fix a level j and condition on $\mathcal{F}_{j-1}$. We apply the local clause of Theorem 13.10 with

$$t = t_j, \qquad \theta = \widehat{\theta}_{j-1}, \qquad E_* = \mathsf{E}_{\mathrm{q}}, \qquad \theta_u = u\theta \quad (0 \le u \le 1),$$

and check its hypotheses. The coarse field satisfies $e^\theta \in B_r$ on the support of $\nu_{K,s}$, as noted in Section 31.1; its radial segment remains in B_r and in the larger analytic domain. The ratios $g_{j,\ell}/t_j$ are the fixed ratios of that theorem. The product is exactly Ω_j, with its radii $p_{j,\ell}$, which depend on the level and the coupling but not on u. The conditions on the product, including the smallness of $t_j(p_j + C_J)^3$, were imposed in the choice of s_0, and the input effective interaction has norm at most E_{q} at every index d_j. By Theorem 15.12, the change of gauge representative preserves the fluctuation variables, the product of balls, the part of the classical action beyond its quadratic approximation, the Haar disintegration density, the determinants, the normalization constant, and the normalized conditional kernel; hence the theorem applies to this kernel. A difference between two choices of the potential that depends only on the coarse field has zero mixed derivative. We conclude that

$$\sup_l \|\partial_{w_l} \partial_u V_j(\theta_u, \cdot)\|_{L^2(k_j(\theta_u, \cdot))} \le C t_j \|\theta\|_\infty, \tag{31.13}$$

with a constant independent of the side, j, K, d_j, and u. This is a bound at each fluctuation index, with a summable spatial profile; no global norm of the extensive derivative $\partial_u V$ is used. The Gaussian part, the dependence of the determinants on the coarser fluctuation variables, and the derivatives of the input effective interaction through the chain rule are included.

For the mean bounds below the following weaker estimate suffices. Summing the pointwise clause for the mixed derivative in Theorem 13.10 against θ, we obtain

$$\sup_l \|\partial_{w_l}\partial_u V_{\theta_u}\|_{L^2} \le \sup_l \|\partial_{w_l}\partial_u V_{\theta_u}\|_\infty \le Ct(p^+)^2 b, \qquad p^+ = p + C_J; \tag{31.14}$$

the exponential decay in the coarse index is summable since the number of coordinates per cell is bounded. We increase s_0 once more so that $t(p^+)^2 \le 1$ at every level. Both estimates concern the same potential.

Step 6: general equivariant outputs. Fix C_F and the larger domain, and let F range over the class described in part (3). Since F is bounded on the larger domain, its absolute coefficient series on the smaller domain also bounds one derivative in θ. All constants in this step may depend on C_F, the radius, and the fixed ratios of radii, but not on the number of output sites or on the resolution. The part of degree r in w of $D_e = F_e(\theta, t\lambda w) - F_e(\theta, 0)$ has row coefficients bounded by $C_1 C_2^r t^r$, also after a derivative in θ. We split $D_e = D_e^{(1)} + D_e^{(\ge 2)}$ into its part of degree one and the sum of all higher degrees. By the mean bound and the absolute output row, we have

$$|\mathbb{E}_\theta D_e^{(1)}| \le Ct \sup_l |\mathbb{E}_\theta w_l| \le Ct^2 b.$$

For the terms of degree $r \ge 2$ in $\partial_u D_e^{(\ge 2)}$, we bound two of the fluctuation factors in L^4 and the others by p^+. For a derivative in one fluctuation variable instead, one factor is bounded in L^2 and the remaining $r-2$ by p^+. Summing the absolute coefficient series, we obtain

$$|\mathbb{E}_u \partial_u D_e^{(\ge 2)}| \le Cbt^2, \qquad \sum_l \|\partial_{w_l} D_e^{(\ge 2)}\|_{L^2} \le Ct^2; \tag{31.15}$$

for example, the second sum is at most $C\sum_{r\ge 2} r C_2^r t^r (p^+)^{r-2} \le Ct^2$. The derivative of the part of degree one has output row at most Ct; hence $\sum_l \|\partial_{w_l} D_e\|_{L^2} \le Ct$ for the whole increment. All sums are at the single fixed output e, so the number of outputs does not appear.

The local covariance inequality of Theorem 13.8 has kernel $Ce^{-b'\,\mathrm{dist}(l,h)}$. Its rows sum to a fixed constant, since the number of fluctuation coordinates per cell is bounded and $\sum_{q\ge 0}(q+1)^3 e^{-b'q} < \infty$. Combining it with (31.14) and (31.15), we find

$$|\operatorname{Cov}_u(D_e^{(\ge 2)}, \partial_u V_{\theta_u})| \le C\sum_{l,h} e^{-b'\,\mathrm{dist}(l,h)} \|\partial_{w_l} D_e^{(\ge 2)}\|_{L^2} \|\partial_{w_h}\partial_u V_{\theta_u}\|_{L^2} \le Ct^3(p^+)^2 b \le Ct^2 b.$$

For each finite product, differentiation under the integral is justified: the domain is compact and fixed, and the functions and their derivatives in the coarse field are continuous on an open neighborhood. Differentiating the numerator and the denominator separately gives exactly

$$\frac{d}{du}\mathbb{E}_u D_e = \mathbb{E}_u \partial_u D_e - \operatorname{Cov}_u(D_e, \partial_u V_{\theta_u}).$$

Thus the derivative of the normalization is present, with the minus sign in the statement, and all Haar, determinant, and effective-interaction terms are those of the same V_j.

The same identity holds with $D_e^{(\geq 2)}$ in place of D_e. At $\theta = 0$ the conditional law is invariant under simultaneous color rotation of all blocks. Both $D_e(0, w)$ and $D_e^{(\geq 2)}(0, w)$ transform as vectors in the adjoint representation, since taking a homogeneous part of fixed degree commutes with color rotations. Each of their expectations is fixed by every rotation, and a vector in $\mathbb{R}^3$ fixed by the rotations by π about two perpendicular axes is zero. Hence both expectations vanish at $\theta = 0$. Integrating the identity for $D_e^{(\geq 2)}$ from $u = 0$ to $u = 1$ and using the two bounds above, we obtain $|\mathbb{E}_\theta D_e^{(\geq 2)}| \leq Ct^2 b$. Adding the bound for the part of degree one, we find $|\mathbb{E}_\theta D_e| \leq Ct^2 b$ for the whole increment. This argument does not use (31.13).

The same reasoning proves the cancellation at $\theta = 0$ without discarding spatial correlations. Let $S_{la,hb} = \mathbb{E}_0[w_l^a w_h^b]$. Invariance makes each 3×3 color matrix $(S_{la,hb})_{a,b}$ commute with every rotation, so $S_{la,hb} = S_{lh}\delta_{ab}$ by the argument used for E_j^a in Step 2 of the proof of Theorem 31.3. If B_e is an equivariant bilinear coefficient with values in $\mathbb{R}^3$, then $\sum_{l,h,a} S_{lh} B_e(e_{la}, e_{ha})$ is fixed by every color rotation and hence zero. Every homogeneous equivariant term with values in $\mathbb{R}^3$ has zero expectation for the same reason. This proves the cancellation for the whole series, which converges absolutely on the product.

Step 7: the remainder of the circulation. We write $\mathbb{E}_{j-1} = \mathbb{E}[\,\cdot \mid \mathcal{F}_{j-1}]$. The map Z_j in (31.10) belongs to one fixed class of outputs as in part (3). Indeed, we choose its larger coarse/free domain inside the domain of Theorem 15.12, with image in the reconstruction domain on which $\widehat{\mathcal{E}}_j^a$ is defined, and we compose the joint coefficient series with (31.7). The composition bound fixes one constant C_F and one larger radius for all j, k, and fine output sites; a distinguished coarse input costs one fixed restriction of the domain. Equivariance and the value zero at $(0, 0)$ are preserved. The substitution $q_{j,\ell} = g_{j,\ell} w_\ell$ gives one factor t_j for each fluctuation factor, also after a derivative in the coarse field. Thus neither C_F nor the radius depends on the remaining number of steps or on the output resolution. By part (3), the increment $Z_j(\theta, w) - Z_j(\theta, 0)$ has conditional mean at most $Ct_j^2 b$ at each output site. Since $G_j(\theta, w) - G_j(\theta, 0) = \mathscr{C}(a_j^{-1}(Z_j(\theta, w) - Z_j(\theta, 0)))$, and since heat smoothing does not increase supremum norms while the cycle has length at most $C_\ell \varepsilon$, we obtain

$$|\Gamma_j \bar{w}_j + \mathbb{E}_{j-1} \mathsf{R}_j^{\mathrm{cur}}| \leq C \frac{\varepsilon}{\sqrt{\eta}} \cdot \frac{t_j^2}{a_j} b = C\lambda_B t_j b \sqrt{\varepsilon / a_j},$$

and we absorb λ_B into C. By the mean bound of part (1) and the ℓ^∞ bound of part (2), we have $|\Gamma_j \bar{w}_j| \leq Ct_j b \sqrt{\varepsilon / a_j}$ separately, and subtracting it from the preceding bound gives

the bound for $|\mathbb{E}_{j-1}\mathsf{R}_j^{\mathrm{cur}}|$. Both vanish at zero coarse field, by the color argument of Step 6 and the vanishing of the conditional mean of w_j.

Finally, every term of $D_w Z_j(\theta, w) - D_w Z_j(\theta, 0)$ has one differentiated fluctuation factor and at least one further fluctuation factor. In the joint coefficient series their sizes are t_j and at most $t_j p_j^+$, respectively. Summing all remaining factors on the fixed larger domain, and using the column bound with a fluctuation input distinguished, we find

$$\|D_w Z_j(\theta, w) - D_w Z_j(\theta, 0)\|_{\mathrm{row+col}} \le C t_j^2 p_j.$$

We divide this matrix by g_j and apply Theorem 31.3(3); since $t_j/g_j = \lambda_B$, we obtain

$$\|D_w \mathsf{R}_j^{\mathrm{cur}}\|_{\ell^2 \to \mathbb{R}^{3m}} \le C t_j p_j \omega_j.$$

The conditional Poincaré inequality bounds the conditional variance of each of the $3m$ components of $\mathsf{R}_j^{\mathrm{cur}}$ by twice its expected squared gradient. Summing over the components and using $\|D_w \mathsf{R}_j^{\mathrm{cur}}\|_{\mathrm{HS}}^2 \le 3m \|D_w \mathsf{R}_j^{\mathrm{cur}}\|_{\mathrm{op}}^2$ proves the variance bound of part (4), with no dependence on the number of fluctuation variables. Every constant was fixed on the common larger domains or by the choice of s_0; none depends on a later s, on K, j, x, the lattice offset, or d_j. Together with (31.13), this proves all claims. □

31.5 Covariance identity for the linearized reconstruction

The coefficients $\Gamma_j(0)$ at the zero field are derivatives of the reconstruction at the origin in all its coordinates. We show that, in the Gaussian theory obtained by linearizing the reconstruction, the fluctuation variables become independent standard Gaussian vectors. Then the sum of the Gram matrices $\Gamma_j(0)\Gamma_j(0)^{\mathsf{T}}$ is the covariance of the fine circulation minus the covariance of its conditional mean given the coarse field. The calculation is Gaussian conditioning applied to the linearized reconstruction; the corresponding constrained Gaussian calculation for Bałaban's averaging operation is in [10, Section D, (1.47)–(1.49), p. 26, and (1.64)–(1.67), p. 29].

Theorem 31.6. *Assume the setting of Section 31.1, and let $s \ge s_0$, $K \ge s$, $k = K - s$, $H_s = L/n_s$, and $a = L/N_K$. Let X_a be the real finite-dimensional space of link fields with three colors on the fine lattice modulo periodic gradients and constant fields, and let $\mathbb{G}_a$ be the Gaussian measure on X_a with density proportional to $\exp(-\|d\theta\|_{\ell^2}^2/(2g_a^2))$, where $g_a^2 = g_3^2 a$, d is the dimensionless plaquette coboundary, and the norm counts each positive plaquette once. Let $Q_{a,H_s} : X_a \to X_{H_s}$ be the derivative at the identity of the composed block averaging map from the fine lattice to the lattice of side n_s, on the corresponding quotients, and let $\mathcal{C}_{s,a} = \sigma(Q_{a,H_s}\theta)$.*

The differential of the reconstruction at zero coarse field and zero fluctuation variables,

$$L(z, w) = L_0 z + \sum_{j=1}^{k} L_j^{\mathrm{w}} w_j,$$

is a bijection from $X_{H_s} \times \prod_j \mathbb{R}^{\dim w_j}$ *onto* X_a*, and it satisfies*

$$\frac{1}{g_a^2}\|dL(z,w)\|_{\ell^2}^2 = \langle z, \mathbf{H}_{s,a} z\rangle + \sum_{j=1}^{k} |w_j|^2, \qquad Q_{a,H_s} L(z,w) = z.$$

Here $\mathbf{H}_{s,a}$ *is the Schur complement of the quadratic form on the coarse lattice given by the nested minimization of Theorem 10.10, including its coupling; it is positive definite on* X_{H_s}*, and its inverse is used only at this fixed* s*. For every linear map* $F : X_a \to \mathbb{R}^d$*,*

$$\sum_{j=1}^{k} (FL_j^{\mathrm{w}})(FL_j^{\mathrm{w}})^{\mathsf{T}} = \mathrm{Cov}_{\mathbf{G}_a}(F\theta) - \mathrm{Cov}_{\mathbf{G}_a}\big(\mathbb{E}[F\theta \mid \mathcal{C}_{s,a}]\big).$$

For the circulation $F = \mathcal{I}_a$ *this reads*

$$\sum_{j=1}^{k} \Gamma_j(0)\Gamma_j(0)^{\mathsf{T}} = C^{a,\varepsilon,L} \otimes I_3 - C^{\mathrm{ret}}_{s,a,\varepsilon}, \qquad C^{\mathrm{ret}}_{s,a,\varepsilon} = \mathrm{Cov}_{\mathbf{G}_a}\big(\mathbb{E}[\mathcal{I}_a\theta \mid \mathcal{C}_{s,a}]\big) \geq 0.$$

Uniformly in K*,* x*, and the lattice offset,*

$$\|C^{\mathrm{ret}}_{s,a,\varepsilon}\| \leq C n_s^2 \varepsilon / H_s \qquad (a \leq \varepsilon \leq \varepsilon_0(s)).$$

Together with Lemma 31.2, this gives, for every fixed $s \geq s_0$*,*

$$\lim_{\varepsilon \downarrow 0} \limsup_{K\to\infty} \sup_{x,\, \mathit{offset}} \Big\| \sum_{j=1}^{K-s} \Gamma_j(0)\Gamma_j(0)^{\mathsf{T}} - \Sigma \otimes I_3 \Big\| = 0.$$

The constants may depend on L*,* γ*,* M*,* J*,* Θ*, the loops,* σ*, and* n_s*, but not on* K *or* d_j*.*

Remark 31.7. The Gaussian coordinates of this theorem are independent only in the linearized calculation; the conditional fluctuation kernels k_j are not Gaussian. The theorem concerns the differential of the reconstruction at the origin in all coordinates. It is not a statement about the nonlinear reconstruction conditioned on $\widehat{\theta}_0 = 0$, whose later fields would remain random. Gradients and constant fields are removed only for this Gaussian identity; they are not removed from the Wilson measure.

Proof. We first set up coordinates on the quotients and prove the energy identity, then prove that L is bijective, and only then change variables in the Gaussian integral. Finally we bound the coarse contribution. All quotient spaces and Gaussian coordinates in this proof are real.

Step 1: coordinates. We choose linear coordinates on each quotient by taking the representatives with mean zero and zero lattice divergence. By the calculation of the kernel of the curl in Step 2 of the proof of Theorem 31.3, these representatives identify exactly the quotient by gradients and constants. The Maxwell form is positive definite on this space: a field of zero energy has zero curl, and its gradient and constant parts have been removed. All Gaussian integrals below are proper finite-dimensional integrals.

We differentiate the reconstruction at its origin and write the resulting linear map, with values in X_a, as $L(z,w) = L_0 z + \sum_j L_j^{\mathrm{w}} w_j$. Here z uses the coordinates on X_{H_s} just described, and w_j ranges over the space of free fluctuation coordinates of Theorem 12.13; the factors $K_i^{-1/2}$ defining them exist by Theorem 10.10. We do not yet claim that L is injective. The gauge transformations of Theorem 15.12, which depend only on the coarse field and equal the identity at the tree roots, add gradients at the identity and therefore do not change this map with values in X_a. The linearized averaging of Lemma 8.1 maps gradients to gradients and constant fields to constant fields, so the differential of the block averaging map descends to the map Q_{a,H_s} between the quotients.

Step 2: the energy identity. We differentiate the exact classical decomposition of Theorem 12.13 at zero coarse field and zero fluctuation variables and take its homogeneous quadratic part. At every intermediate scale the normalized quadratic free action is $|w_i|^2/2$. All remaining classical terms have degree at least three in the fluctuation variables, as shown in (31.12), for every coarse field. They contribute nothing in total degree two, also after composition with the coarser fields. The value and the first derivative of the classical action at the identity vanish. It follows that the quadratic part of the fine action, evaluated on the nonlinear reconstruction, is its quadratic form evaluated on L, with no contribution from second derivatives of the reconstruction. Iterating over all RG steps, we obtain

$$\frac{\|dL(z,w)\|_{\ell^2}^2}{2g_a^2} = \frac{1}{2}\langle z, \mathbf{H}_{s,a} z\rangle + \frac{1}{2}\sum_j |w_j|^2. \tag{31.16}$$

By Theorem 10.10, the form $\langle z, \mathbf{H}_{s,a} z\rangle$ is the nonnegative Schur-complement form, including its coupling. Differentiating the identity expressing that the reconstruction has the prescribed coarse field, we find

$$Q_{a,H_s} L(z,w) = z. \tag{31.17}$$

The Haar, Haar disintegration, determinant, and effective-interaction terms enter the nonlinear conditional law of Theorem 31.5; they are not part of this identity for the classical quadratic form.

Step 3: bijectivity and positivity. If $L(z,w) = 0$ in X_a, its Maxwell energy is zero. Both terms on the right of (31.16) are nonnegative, so every $w_j = 0$, and (31.17) then implies $z = 0$ in X_{H_s}. Thus L is injective. For a lattice of side n, the space of link

fields with three colors has dimension $9n^3$, the gradients have dimension $3(n^3-1)$, and the constant fields have dimension nine, so the quotient has dimension $6n^3-6$. By Theorem 12.13, the number of free fluctuation coordinates from side Mn to side n is $6(M^3-1)n^3$. Summing these numbers over all averaging steps gives $6(N_K^3-n_s^3)$, and adding the dimension $6n_s^3-6$ of X_{H_s} gives exactly $\dim X_a$. Injectivity in equal finite dimensions implies surjectivity. Further, for nonzero z, injectivity makes $L(z,0)$ nonzero in X_a; positivity of its Maxwell energy and (31.16) show that $\mathbf{H}_{s,a}$ is positive definite on X_{H_s}. We do not claim a lower bound on $\mathbf{H}_{s,a}$ independent of the side.

Step 4: the Gaussian change of variables. We make the linear change of variables $\theta = L(z,w)$ in the normalized Gaussian integral on X_a. Its Jacobian is constant and cancels between numerator and denominator. By (31.16), in these coordinates

$$z \sim N(0, \mathbf{H}_{s,a}^{-1}), \qquad w_j \sim N(0, I),$$

and all these vectors are independent; the inverse exists on X_{H_s} at this fixed side. For a linear map F, (31.17) gives

$$\mathbb{E}[F\theta \mid \mathcal{C}_{s,a}] = FL_0 z, \qquad F\theta = FL_0 z + \sum_j FL_j^{\mathrm{w}} w_j.$$

By independence, expanding the covariance of $F\theta$ proves the general covariance identity, and the subtracted covariance is positive semidefinite.

For $F = \mathcal{I}_a$, the closed cycles and their zero winding make F a well-defined functional on X_a, by Lemma 31.2(3). By the chain rule at the origin of the reconstruction, we have

$$FL_j^{\mathrm{w}} = D_w \mathcal{I}_a\big(\widehat{\Pi}_{k\leftarrow j}\widehat{\Phi}_j(0, g_{j,\cdot}w)\big)\big|_{w=0} = \Gamma_j(0).$$

The finite-lattice Fourier calculation of Lemma 31.2(4) identifies $\mathrm{Cov}_{\mathbb{G}_a}(\mathcal{I}_a\theta)$ as $C^{a,\varepsilon,L} \otimes I_3$, since the density of $\mathbb{G}_a$ is that of the Maxwell field of that lemma written in the variable $\theta = aA$. This proves the identity for $\sum_j \Gamma_j(0)\Gamma_j(0)^{\mathsf{T}}$.

Step 5: the coarse contribution. We write $H = H_s$ and $n = n_s$. At $j = 0$, the linear comparison of Theorem 31.3(2) implies that, on circulations, $FL_0 = \mathscr{C}_{a,\varepsilon,x}(H^{-1}E_0^a)$. Using the ℓ^2 circulation bound of Theorem 31.3(3) with input mesh H, dividing out the normalization $g_3\sqrt{H}$, and taking the branch $\sqrt{\varepsilon/H}$, we obtain

$$\|FL_0\|_{\ell^2 \to \mathbb{R}^{3m}} \le \frac{C\sqrt{\varepsilon}}{g_3 H}. \tag{31.18}$$

In unitary Fourier coordinates on the coarse lattice, Theorem 8.3 bounds the covariance of the coarse link variables by $Cg_H^2/\lambda(\vartheta)$ on each nonzero transverse frequency ϑ, uniformly in the number of eliminated scales; the gradient term in the linearized block averaging

map disappears on the quotient by Lemma 8.1. For a nonzero frequency on a lattice of side $n \geq 4$,

$$\lambda(\vartheta) \geq 4\sin^2(\pi/n) \geq 16/n^2,$$

where the second inequality uses $\sin u \geq 2u/\pi$ for $0 \leq u \leq \pi/2$. Since $g_H^2 = g_3^2 H$, this proves

$$\|\mathbf{H}_{s,a}^{-1}\|_{\ell^2 \to \ell^2} \leq C g_3^2 H n_s^2. \tag{31.19}$$

Only the factor n_s^2 of the fixed side has been used. Multiplying the square of (31.18) by (31.19), we obtain

$$\|C_{s,a,\varepsilon}^{\mathrm{ret}}\| = \|(FL_0)\mathbf{H}_{s,a}^{-1}(FL_0)^{\mathsf{T}}\| \leq C n_s^2 \varepsilon / H_s,$$

uniformly in the number of eliminated scales, x, and the lattice offset. The factor n_s^2 is allowed to grow with the fixed coarse side.

Step 6: the limits. The covariance identity implies

$$\Big\|\sum_j \Gamma_j(0)\Gamma_j(0)^{\mathsf{T}} - \Sigma \otimes I_3\Big\| \leq \|C^{a,\varepsilon,L} - C^{\varepsilon,L}\| + \|C^{\varepsilon,L} - \Sigma\| + C n_s^2 \varepsilon / H_s.$$

For each fixed $\varepsilon > 0$ the first term tends to zero as $K \to \infty$, uniformly in x and the lattice offset, by Lemma 31.2(5). After this limit, the second term tends to zero as $\varepsilon \downarrow 0$ by the same lemma, and the last term tends to zero at fixed s. This is the iterated limit in the statement. At $k = 0$ the same change of variables has no fluctuation variables and the whole covariance is the coarse covariance, so the identities also hold in that case. □

31.6 The coarse-field contribution and summation over scales

We now prove the decomposition stated at the beginning of the section and sum the estimates of Theorem 31.5 over all scales. The sums are controlled by a deterministic bound on the size b_j of the reconstructed fields, which we prove first; its constant does not depend on the coarse mesh H_s, which matters because s is later sent to infinity.

Lemma 31.8. *Assume the setting of Theorem 31.5, with s_0 enlarged if necessary depending only on the data fixed in Section 31.1. For every $s \geq s_0$ the following deterministic bounds hold on the support of $\nu_{K,s}$, uniformly in $K \geq s$:*

$$b_0 \leq r, \qquad b_j \leq C\big[r\alpha_*^j + g_3\sqrt{a_j}\,p_j\big],$$

$$\sum_{j=1}^{K-s} b_{j-1} \leq D_s, \qquad D_s = C\Big[\frac{r}{1-\alpha_*} + g_3\sqrt{H_s}\,(p_1(s)+1)\Big], \qquad \sup_{s \geq s_0} D_s < \infty,$$

where $p_1(s) = p_1$ is the cutoff radius of the first RG step. Put

$$T_s = \mathcal{I}_a\big(\widehat{\Pi}_{k\leftarrow 0}\widehat{\theta}_0\big), \qquad \mathsf{N}_{K,s} = \sum_{j=1}^{k}\big[\Gamma_j(\widehat{\theta}_{j-1})\bar{w}_j + \mathsf{R}_j^{\mathrm{cur}}\big].$$

Then we have the exact decomposition

$$I^{K,s} = T_s + \sum_{j=1}^{k}\Gamma_j(\widehat{\theta}_{j-1})(w_j - \bar{w}_j) + \mathsf{N}_{K,s}.$$

For $a \le \varepsilon \le \varepsilon_0(s)$,

$$\sup_{\|\widehat{\theta}_0\|_\infty \le r}|T_s| \le \frac{Cr}{g_3 H_s}\sqrt{\varepsilon},$$

$$\sup_{x,\,\mathit{offset}}\mathbb{E}_{\nu_{K,s}}|\mathsf{N}_{K,s}| + \sup_{\|\widehat{\theta}_0\|_\infty \le r}|T_s| \le \frac{Cr}{g_3 H_s}\sqrt{\varepsilon} + Cg_3 D_s\sqrt{\varepsilon} + C\sqrt{\eta}\,[1+\log(1/\eta)]^2.$$

The constants C and the threshold s_0 have the dependence stated in Theorem 31.5, and C does not depend on s; the quantity D_s has the displayed additional dependence on s. The coarse-field term is allowed to grow like H_s^{-1}. For each fixed $s \ge s_0$, the right side of the last display tends to zero as $\varepsilon \downarrow 0$, uniformly in K; no limit in which s and ε vary together is asserted.

Proof. We first prove the bounds on b_j (Steps 1–3) and their sum (Step 4), then the decomposition (Step 5), and finally the bounds on T_s and $\mathsf{N}_{K,s}$ (Steps 6 and 7).

Step 1: a recurrence. The inputs $q_j = g_{j,\cdot}w_j$ of the j-th reconstruction map satisfy $\|q_j\|_\infty \le t_j(p_j + C_J)$, since $g_{j,\ell} \le t_j$ and $|w_{j,\ell}| \le p_{j,\ell} \le p_j + C_J$. On the fixed larger coarse/free domain let $C_{\mathrm{fr},J}$ bound the derivative of $\widehat{\Phi}_j$ in the coupling-scaled fluctuation inputs; this bound does not depend on the side or on d_j. By the row majorant of Theorem 31.3(1), we have $\|\widehat{P}_j(v)\|_\infty \le \phi(\|v\|_\infty)$. Integrating this derivative along the segment from 0 to q_j, we obtain, with $\kappa = C_{\mathrm{fr},J}(1 + C_J)$ and $p_j \ge 1$,

$$b_j \le \frac{\alpha_* b_{j-1}}{1 - \beta_J b_{j-1}} + \kappa t_j p_j \le a_{\mathrm{map}} b_{j-1} + \kappa t_j p_j, \tag{31.20}$$

as long as $\widehat{\theta}_{j-1}$ lies in the reconstruction domain. Here $a_{\mathrm{map}} = \alpha_*/(1 - \beta_J r_{\mathrm{eff}})^2$ is the bound of Lemma 15.15 on the derivative of the zero-fluctuation maps on the reconstruction domain, which satisfies $a_{\mathrm{map}}\sqrt{B} \le 32/49 < 1$ by Theorem 23.5.

Step 2: a first bound and the sum. Let $\rho_B = B^{-1/2}$ and $d_p = A_{\mathrm{w}} \log B/2$. Since $t_i = t_j B^{(j-i)/2}$ and $p_i \le p_j$ for $i \le j$, iterating the second inequality in (31.20), we obtain

$$b_j \le r a_{\mathrm{map}}^j + \kappa' t_j p_j, \qquad \kappa' = \frac{\kappa}{1 - a_{\mathrm{map}}\sqrt{B}}.$$

For small t the function $t \mapsto tp(t)$ is increasing, so a fixed upper bound on t_1 with $\kappa' t_1 p_1 \le r_{\mathrm{eff}}/4$ keeps this bound below $r + r_{\mathrm{eff}}/4 < r_{\mathrm{eff}}/2$, which justifies the use of (31.20) at every step by induction. Increasing s_0 enforces this bound for every later s, without changing any radius of the construction. The geometric series and its derivative give

$$\sum_{l=0}^{k-1} b_l \le \frac{r_{\mathrm{eff}}}{4(1-a_{\mathrm{map}})} + \kappa' t_1 \Big[\frac{p_1}{1-\rho_B} + \frac{d_p \rho_B}{(1-\rho_B)^2} \Big] \le S_*.$$

Here we fix S_* by replacing $t_1(p_1+1)$ by its supremum over the allowed range $0 < t_1 \le t_1(s_0)$; this supremum is finite since $t\log(1/t) \to 0$. Thus S_* depends neither on H_s nor on s.

Step 3: the rate α_*^j. For $0 \le \beta_J b \le \beta_J r_{\mathrm{eff}} < 1/8$ we have

$$\frac{\alpha_*}{1-\beta_J b} \le \alpha_* \exp(8\beta_J b/7).$$

This implies that every product over h consecutive steps of the multiplicative coefficients $\alpha_*/(1-\beta_J b_l)$ in the first recurrence of (31.20) is at most $C_{\mathrm{mult}}\alpha_*^h$, where $C_{\mathrm{mult}} = \exp(8\beta_J S_*/7)$. Unrolling that recurrence, we find

$$b_j \le C_{\mathrm{mult}} \Big[r\alpha_*^j + \kappa \sum_{i=1}^{j} \alpha_*^{j-i} t_i p_i \Big] \le C_{\mathrm{mult}} \Big[r\alpha_*^j + \frac{\kappa t_j p_j}{1-\alpha_*\sqrt{B}} \Big],$$

where the denominator is positive because $\alpha_*\sqrt{B} = \sqrt{q} \le 1/2$. Substituting $t_j = \lambda_B g_3 \sqrt{a_j}$, we obtain

$$b_j \le C_{\mathrm{cap}} \big(r\alpha_*^j + g_3 \sqrt{a_j}\, p_j \big), \tag{31.21}$$

with C_{cap} independent of H_s and s. This is the first bound of the lemma. The rate α_*^j does not follow from the first bound of Step 2, where the contraction factor is a_{map}; the product argument is needed.

Step 4: the sum of the bounds. By the definition of p_j and $a_j = H_s B^{-j}$,

$$p_j = p_1(s) + (j-1)d_p. \tag{31.22}$$

Summing (31.21), including the separate term $b_0 \le r$, and using $\sqrt{a_l} = \sqrt{H_s}\rho_B^l$, we obtain

$$\begin{aligned} \sum_{j=1}^{k} b_{j-1} &\le \frac{Cr}{1-\alpha_*} + C g_3 \sqrt{H_s} \sum_{l \ge 1} \rho_B^l \big[p_1(s) + (l-1)d_p \big] \\ &\le C \Big[\frac{r}{1-\alpha_*} + g_3 \sqrt{H_s}\, (p_1(s)+1) \Big]. \end{aligned}$$

In the last inequality we used $\sum_{l\ge1}\rho_B^l=\rho_B/(1-\rho_B)$ and $\sum_{l\ge1}(l-1)\rho_B^l=\rho_B^2/(1-\rho_B)^2$. By (31.8), $p_1(s)=A_{\mathrm{w}}\log(\sqrt{M}/(g_3\sqrt{H_s}))$ is affine in s, while $\sqrt{H_s}=\sqrt{L/n_*}\,B^{-s/2}$ decays geometrically, so their product is bounded for $s\ge s_0$. More directly, $g_3\sqrt{H_s}(p_1(s)+1)=\sqrt{M}\,t_1(s)(p_1(s)+1)$ is bounded by the supremum used in Step 2. Since the constant in (31.21) does not depend on s, this proves $\sup_s D_s<\infty$.

Step 5: the decomposition. For $0\le j\le k$, let $F_j=\mathcal{I}_a(\widehat{\Pi}_{k\leftarrow j}\widehat{\theta}_j)$. Then $F_0=T_s$ and $F_k=I^{K,s}$. Since $\widehat{\Pi}_{k\leftarrow j-1}=\widehat{\Pi}_{k\leftarrow j}\circ\widehat{\Phi}_j(\cdot,0)$, and all fields involved lie in the reconstruction domain, we have

$$F_j-F_{j-1}=G_j(\widehat{\theta}_{j-1},w_j)-G_j(\widehat{\theta}_{j-1},0)=\Gamma_j(\widehat{\theta}_{j-1})w_j+\mathsf{R}_j^{\mathrm{cur}}.$$

Summing this finite identity over j, and subtracting and adding $\Gamma_j(\widehat{\theta}_{j-1})\bar{w}_j$ in each summand, gives the decomposition. The coefficients $\Gamma_j(\widehat{\theta}_{j-1})$ are $\mathcal{F}_{j-1}$-measurable and the increments $w_j-\bar{w}_j$ are conditionally centered, so the middle sum is a martingale for the filtration $(\mathcal{F}_j)$.

Step 6: the coarse-field contribution. By the row bound on $D\widehat{\mathcal{E}}_0^a$ in Theorem 31.3(5) and $\widehat{\mathcal{E}}_0^a(0)=0$, we have

$$\|H_s^{-1}\widehat{\mathcal{E}}_0^a(\widehat{\theta}_0)\|_\infty\le Cr/H_s.$$

By the identity of Theorem 31.3(5), the fact that heat smoothing does not increase supremum norms, and the length bound on the cycles, we obtain

$$|T_s|\le\frac{C\varepsilon r}{\sqrt{\eta}\,H_s}=\frac{Cr}{g_3H_s}\sqrt{\varepsilon}. \tag{31.23}$$

This bound is uniform over all coarse fields with $\|\widehat{\theta}_0\|_\infty\le r$ and over K, including $k=0$.

Step 7: conditional means and centered remainders. We write $\mathsf{R}_j^{\mathrm{cur}}=\mathbb{E}_{j-1}\mathsf{R}_j^{\mathrm{cur}}+\zeta_j$, where $\mathbb{E}_{j-1}$ denotes conditional expectation given $\mathcal{F}_{j-1}$. By Theorem 31.5(4), using $t_j\sqrt{\varepsilon/a_j}=\lambda_B g_3\sqrt{\varepsilon}$, we have

$$\sum_{j=1}^{k}\bigl|\Gamma_j(\widehat{\theta}_{j-1})\bar{w}_j+\mathbb{E}_{j-1}\mathsf{R}_j^{\mathrm{cur}}\bigr|\le Cg_3\sqrt{\varepsilon}\sum_{j=1}^{k}b_{j-1}\le Cg_3D_s\sqrt{\varepsilon}.$$

For the centered terms we use the triangle inequality and the conditional Cauchy–Schwarz inequality, without any independence:

$$\mathbb{E}\Bigl|\sum_{j=1}^{k}\zeta_j\Bigr|\le C\sum_{j=1}^{k}t_jp_j\omega_j. \tag{31.24}$$

We bound the right side uniformly in s. Shrinking the constant c in $\varepsilon_0(s)$ if necessary, we may assume $u = \log(1/\eta) \geq 1$. For a scale with $a_j > \varepsilon$,

$$t_j p_j \omega_j = \lambda_B \sqrt{\eta}\, p_j, \qquad p_j \leq C(1+u);$$

the second inequality follows from $\log(1/t_j) = (1/2)\log(1/(g_3^2 a_j)) - \log \lambda_B$ and $a_j > \varepsilon$. The number of such scales is at most $1 + \log(L/\varepsilon)/\log B \leq C(1+u)$, with a constant depending only on L, g_3, and B, since $H_s \leq L/4$. Their contribution is at most $C\sqrt{\eta}(1+u)^2$. If there exists a first index j_ε with $a_{j_\varepsilon} \leq \varepsilon$, let $h_* = a_{j_\varepsilon}$; then $\varepsilon/B < h_* \leq \varepsilon$, since $\varepsilon < cH_s$. Using (31.22), the contribution of the finer scales is at most

$$\begin{aligned}\sum_{r\geq 0} \frac{\lambda_B g_3}{\varepsilon} (h_* B^{-r})^{3/2} \big(p_{j_\varepsilon} + r d_p\big) &\leq C g_3 \sqrt{\varepsilon}\, (p_{j_\varepsilon} + 1) \\ &\leq C\sqrt{\eta}\, (1+u).\end{aligned}$$

In the last inequality we used $h_* > \varepsilon/B$ in the formula for $\log(1/t_{j_\varepsilon})$. Extending the finite sum to all $r \geq 0$ is allowed since all summands are nonnegative, and if there is no such index this contribution is zero. Hence

$$\sum_j t_j p_j \omega_j \leq C\sqrt{\eta}\, [1 + \log(1/\eta)]^2.$$

Combining this with (31.24), the bound on the conditional means, and (31.23) proves the last estimate of the lemma, uniformly in x, the lattice offset, and K in the stated range. For fixed s the first constant is finite and $\sqrt{\eta}(1+\log(1/\eta))^2 \to 0$ as $\varepsilon \downarrow 0$ at fixed $g_3 > 0$. □

Remark 31.9. The bound (31.21) also follows from the forced-recursion estimate of Lemma 15.15, which applies to inputs of size at most $tp(t)$, $t = \lambda_B g \sqrt{a_j}$, for all t up to a fixed threshold τ, with constants uniform in the coarse mesh and in the coupling g in this range. To apply it, we increase s_0 so that $p_1 \geq 1 + C_J + 2A_{\mathrm{w}} \log 2$ and $2t_1 \leq \tau$, and set $\widetilde{t}_j = 2t_j$ and $\widetilde{p}_j = A_{\mathrm{w}} \log(1/\widetilde{t}_j) = p_j - A_{\mathrm{w}} \log 2$. Then $\widetilde{p}_j \geq 1$ and

$$t_j(p_j + C_J) \leq \widetilde{t}_j \widetilde{p}_j \qquad \text{for every } j \geq 1, \tag{31.25}$$

since the difference divided by t_j is $p_j - C_J - 2A_{\mathrm{w}} \log 2 \geq 1$. This is only a deterministic upper bound for the same inputs; the coupling, the measure, the maps, the fluctuation variables, and the cutoff radii are unchanged. Since the constant of that lemma is uniform in H and for the auxiliary coupling in the stated range, the lemma applies with $g = 2g_3$; as $\widetilde{p}_j \leq p_j$, it gives (31.21). Steps 1–3 above verify the independence of H_s directly. No stochastic estimate with a constant depending on a fixed coarse mesh is used.

31.7 Validity at each fixed positive coupling

Lemma 31.10. *Let the parameters be as in Theorem 23.5. Fix $0 < \gamma \le \Gamma$ and one sequence $N_K = n_* B^K$ with its reconstruction maps, and let n_s, H_s, a_j, and t_j be as in Section 31.1. There exists $s_0 < \infty$ such that every $s \ge s_0$ satisfies all conclusions of Lemmas 31.2 and 31.8 and Theorems 31.3, 31.5, and 31.6, with the same quantifiers and the same dependence of the constants. The constants in the bounds on coefficients, potential derivatives, conditional means, reconstructed fields, and conditional remainders do not depend on $s \ge s_0$, while the factor $1/(g_3 H_s)$ in the bound on the coarse-field contribution and the factor n_s^2/H_s in the bound on the coarse covariance remain explicit.*

Proof. We check that each argument of this section uses only the smallness of t_j and never an upper bound on γ such as $\gamma \le 1$.

Deterministic estimates. The zero-fluctuation maps, their coefficient series, the identities expressing that they have the prescribed coarse field, and their column bounds are those of Theorem 23.5 and Lemma 15.15. The proof of Theorem 31.3 uses Lemmas 16.1 and 11.9 and the majorant $\alpha_* z/(1-\beta_J z)$, with $B\alpha_*^2 < 1$; no step uses $\gamma \le 1$. In each circulation coefficient the factor g_3 cancels against $\sqrt{g_3^2\varepsilon}$, and the only remaining scale is $\omega_j = \min\{a_j/\varepsilon, \sqrt{\varepsilon/a_j}\}$. Thus the deterministic coefficient bounds and the expansion in nonlinear remainders hold on the same domains.

Probabilistic estimates. The conditional potential is that of Theorem 13.8, and Theorem 15.12 preserves its coordinates, its balls, and its density. Theorem 13.10, applied to this product and to the radial segment of the coarse field, gives the conditional means of order $t_j b$ and the local bound $\sup_l \|\partial_{w_l}\partial_u V\|_{L^2} \le C t_j b$, with all effective-interaction, determinant, and Haar disintegration terms included. The class of outputs used for the circulation is fixed by the coefficient series on one larger domain (Step 7 of the proof of Theorem 31.5), so its constant C_F depends neither on the remaining number of steps, nor on the output resolution, nor on s. The differentiation formula and the local covariance bound therefore give the mean and remainder conclusions of Theorem 31.5. Global color equivariance at zero coarse field gives the vanishing mean and the cancellation of equivariant bilinear terms. The Poincaré and logarithmic Sobolev inequalities hold for the same conditional kernel, with dimension-free constants.

The threshold. We have exactly

$$t_1(s)^2 = \frac{\gamma}{M n_s}, \qquad t_j = t_1(s) B^{-(j-1)/2},$$

so $t_1(s) \downarrow 0$ as $s \to \infty$ for fixed $\gamma > 0$. Every analytic, domain, Hessian, potential-derivative, and moment condition is a fixed inequality of the form $t[p(t) + c_J]^v \le c'$

or $t^2(1+\mathsf{E}_{\mathrm{q}}) \le c'$, with a fixed finite v, and all of them hold on an interval $0 < t \le \tau_*$. We also require $n_s \ge n_\Gamma$. There are at most $m_j \le C_J(L/a_j)^3 = C_J L^3(\lambda_B g_3)^6 t_j^{-6}$ three-dimensional blocks, and with $u = \log(1/t)$ the quantity $6m_j e^{-p_j^2/192}$ is at most $C_{J,L,\gamma}\exp(6u - A_{\mathrm{w}}^2 u^2/192)$, which tends to zero as $u \to \infty$. Thus a single s_0 enforces $p_j \ge 1$, $6m_j e^{-p_j^2/192} \le 1/2$, and $Ct_j r \le p_j/(16\sqrt{3})$ for all j and all later s, as in Step 1 of the proof of Theorem 31.5. The cutoff error $(1+3m_j)(6m_j)^{1/2}e^{-p_j^2/384}$, which retains the number of blocks, satisfies (31.9); as a function of $h = a_j$ it is $O(h^v)$ for every fixed $v > 0$, and in particular it is summable over the scales.

The bounds on the reconstructed fields. The recurrence (31.20) and Steps 1–4 of the proof of Lemma 31.8 use only the smallness of $t_1(s)$; equivalently, by Remark 31.9, the forced-recursion estimate of Lemma 15.15 applies with the auxiliary input bound (31.25), without changing the measure. They give

$$b_j \le C\big[r\alpha_*^j + g_3\sqrt{a_j}\,p_j\big], \qquad \sum_{j=1}^{K-s} b_{j-1} \le D_s = C\Big\{\frac{r}{1-\alpha_*} + g_3\sqrt{H_s}\,(p_1(s)+1)\Big\},$$

with a constant independent of H_s and of s. Since $p_1(s)$ is affine in s and $\sqrt{H_s}$ decays geometrically, $\sup_{s\ge s_0} D_s < \infty$.

The covariance identity. The identity of Theorem 31.6 is the exact quadratic part of Theorems 10.10 and 12.13 at the origin of the reconstruction, and the bound on $\mathbf{H}_{s,a}^{-1}$ comes from Theorem 8.3. The independent Gaussian coordinates and the coarse Schur complement therefore give

$$\sum_j \Gamma_j(0)\Gamma_j(0)^{\mathsf{T}} = C^{a,\varepsilon,L}\otimes I_3 - C^{\mathrm{ret}}_{s,a,\varepsilon}, \qquad \|C^{\mathrm{ret}}_{s,a,\varepsilon}\| \le Cn_s^2\varepsilon/H_s,$$

and the coupling cancels in the normalized covariance.

All results of this section have now been checked at every $s \ge s_0$. □

SECTION 32

Gaussian short-distance limits and asymptotic independence

This section completes the proof of the short-distance theorem, Theorem 2.8. Fix smooth closed loops $\ell_1, \dots, \ell_m$ in $\mathbb{R}^3$ and $\sigma > 0$, set $g_3^2 = \gamma/L$, and for $x \in \mathbb{T}_L^3$ and $\varepsilon > 0$ let

$$Z_\varepsilon(x) = \Big(\frac{1 - W_{x+\varepsilon\ell_i, \sigma\varepsilon^2}}{g_3^2 \varepsilon} \Big)_{i=1}^m,$$

where $W_{x+\varepsilon\ell_i,\sigma\varepsilon^2}$ is the normalized fundamental Wilson loop of the trajectory at time $\sigma\varepsilon^2$. We prove that under the continuum measure λ of Theorem 2.3, the law of $Z_\varepsilon(x)$ converges to the law of $Z_G = (|C_i|^2/8)_{i=1}^m$, uniformly in x (Theorem 32.13). Here the three color components of C are independent centered Gaussian vectors with the covariance Σ of Definition 31.1, the covariance of heat-smoothed circulations of a Gaussian Maxwell field; in the notation of that definition, $C_i = G_i$ and $(Z_G)_i = \mathsf{Z}_i$. We deduce a lower bound on the variance of small Wilson loops (Corollary 32.14), and we prove that $Z_\varepsilon(x)$ is asymptotically independent of every fixed bounded Borel function of the trajectory (Theorems 32.16 and 32.17). All results are at a fixed positive coupling; no weak-coupling limit is taken.

The form of the limit has a short heuristic explanation. By the computation at the beginning of Section 31, the circulation of the heat-smoothed Gaussian Maxwell field around $x + \varepsilon\ell_i$ is a centered Gaussian vector with covariance of order $g_3^2 \varepsilon \Sigma$ in each color. A Wilson loop sees only the squared norm of this circulation, since for $X \in \mathfrak{su}(2)$

$$1 - \tfrac{1}{2} \operatorname{tr} e^X = |X|^2/8 + O(|X|^4).$$

Dividing by $g_3^2\varepsilon$ therefore produces $|C_i|^2/8$. The proof shows that the nonlinear terms, the coarse field, and the conditioning on the small-field event do not change this picture.

The proof proceeds as follows. By Lemma 31.8, the heat-smoothed circulation $I^{K,s}$ is the sum of a coarse-field term, a martingale whose increments are linear in the centered fluctuation variables, and a small remainder. For each RG step we compare the conditional law of the linear increment with a Gaussian law by an integration by parts with a cutoff, in the spirit of Stein's method [147] (Lemma 32.4), and we telescope the conditional characteristic functions (Lemma 32.5). The cutoff error grows with the number of fluctuation variables, which is polynomial in $1/t_j$, but the probability that the

cutoff is active decays like $\exp(-c\log^2(1/t_j))$ (Lemma 32.6). We then replace the coefficient matrices by their values at the zero field, whose Gram sum converges to $\Sigma \otimes I_3$ by Theorem 31.6. This proves a Gaussian limit for the circulations under the conditioned measure (Theorem 32.8), and the same proof applies conditionally on the first q RG steps, uniformly in their values (Lemma 32.10). Next we compare flowed Wilson loops with circulations (Lemma 32.11), remove the conditioning using the bound of Theorem 23.10, and pass to the continuum measure using Section 29. For asymptotic independence we approximate macroscopic flowed Wilson loops by functions of the first q RG steps (Lemma 32.15).

Four length scales appear: the coarse mesh H_s, the mesh $a_q = H_{s+q}$ after q RG steps, the loop size ε, and the fine mesh a, with $a \le \varepsilon \ll a_q \le H_s$. The estimates split at the scales with $a_j \approx \varepsilon$; the meshes H_s and a_q stay fixed while $\varepsilon \to 0$. The limits are taken in the following order. For the Gaussian limit,

$$K \to \infty, \qquad \varepsilon \downarrow 0 \ \ (s, R \text{ fixed}), \qquad R \to \infty, \qquad s \to \infty,$$

where R is the radius of a ball for the linear and quadratic flow data; for asymptotic independence,

$$K \to \infty, \qquad \varepsilon \downarrow 0 \ \ (s, q, R, \delta \text{ fixed}), \qquad q \to \infty, \qquad \delta \downarrow 0, \qquad R \to \infty, \qquad s \to \infty,$$

where δ is a tolerance. No estimate allows these parameters to vary simultaneously.

Besides Section 31, we use the bound for conditioning of Lemma 5.5, the identity for finite-scale reconstructions of Theorem 15.13, and the bound on the small-field failure probability of Theorem 23.10. We also use the local theory of the Wilson flow and its stability, Theorem 24.5 and Corollary 25.11, the estimates on the linear and quadratic flow data of Lemmas 28.4 and 28.10, and the construction of the continuum measure in Section 29. The section ends with the proof of Theorem 2.8.

32.1 Setting and inputs

Definition 32.1. Fix $L > 0$, $\Gamma > 0$, $0 < \gamma \le \Gamma$, and the parameters of Theorem 23.5, chosen before γ: an odd integer $M \ge 3$, the integer J, $B = M^J$, the reconstruction maps, and their analytic domains. Fix $n_* \in 4\mathbb{N}$, smooth closed loops $\ell_1, \dots, \ell_m$ in $\mathbb{R}^3$, and $\sigma > 0$. We use the notation of Section 31.1: $N_K = n_* B^K$, $n_s = n_* B^s$, $H_s = L/n_s$, $k = K - s$, $a_j = H_s B^{-j}$, $a = a_k$, $g_3^2 = \gamma/L$, $\eta = g_3^2\varepsilon$, $t_j = M^{(J-1)/2} g_3 \sqrt{a_j}$, and $p_j = A_{\mathrm{w}} \log(1/t_j)$. The probability measure is the conditioned Wilson measure

$$\nu_{K,s} = \nu_{N_K, n_s, \gamma} = \mu_{N_K,\gamma}(\,\cdot \mid S_{N_K, n_s, \gamma}).$$

Its backward reconstruction sequence is

$$\widehat{\theta}_j = \widehat{\Phi}_j(\widehat{\theta}_{j-1}, g_{j,\cdot} w_j), \qquad \mathcal{F}_j = \sigma(\widehat{\theta}_0, w_1, \dots, w_j),$$

where $g_{j,\ell}$ are the couplings of the intermediate scales of the j-th RG step, and, conditionally on $\mathcal{F}_{j-1}$, the vector w_j has the conditional fluctuation kernel $k_j(\widehat{\theta}_{j-1},\cdot)$ of Theorem 31.5, whose potential includes the input effective interaction produced by the integrations at finer scales, the Haar disintegration density, and the determinants of the change of variables. We write $\bar{w}_j = \mathbb{E}(w_j \mid \mathcal{F}_{j-1})$. All maps, zero-fluctuation continuations, and circulations use the same reconstruction maps and the same choice of representative of the coarse field. Put

$$\widehat{\Pi}_{k\leftarrow j} = \widehat{\Phi}_k(\cdot,0)\circ\cdots\circ\widehat{\Phi}_{j+1}(\cdot,0), \qquad \widehat{\Pi}_{k\leftarrow k} = \mathrm{id}\,.$$

The circulation map $\mathcal{I}$ is the map denoted $\mathcal{I}_a$ in Definition 31.1, with lattice cycles of physical length at most $C_\ell\varepsilon$, zero winding, and swept area at most $C_\ell\varepsilon a$, which tends to zero at fixed ε as $a\to 0$. Thus $I^{K,s} = \mathcal{I}(\widehat{\theta}_k) \in \mathbb{R}^{3m}$. As in Section 31.1 we put

$$G_j(v,w) = \mathcal{I}\big(\widehat{\Pi}_{k\leftarrow j}\widehat{\Phi}_j(v, g_{j,\cdot}w)\big), \qquad \Gamma_j(v) = D_w G_j(v,0), \qquad \omega_j = \min\{a_j/\varepsilon, \sqrt{\varepsilon/a_j}\},$$

$$Q_j^{\mathrm{Tay}} = G_j(\widehat{\theta}_{j-1}, w_j) - G_j(\widehat{\theta}_{j-1},0) - \Gamma_j(\widehat{\theta}_{j-1})w_j.$$

The Taylor remainder Q_j^{Tay} is the quantity denoted $\mathsf{R}_j^{\mathrm{cur}}$ in Section 31.1, and the vector C below is the vector G of Definition 31.1. Unless stated otherwise, constants may depend on L, γ, M, J, n_*, Θ, the analytic domains, the loops, σ, and the coarse index s (the dependence described in item (5) of Definition 4.14); they are independent of K, j, x, the lattice offset, and the classical recursion index $d_j = J(K-s-j)$. A constant indexed by s may depend on H_s. All regions are the full periodic torus.

The threshold s_0 below depends on the fixed data and is chosen before the coarse index s; the reconstruction maps do not change with s. The classical recursion index d_j is the depth $\mathfrak{d}_j$ of Section 26, not the increment $x_j - x_{j-1}$ of the heat path there.

Remark 32.2. The bounds of Theorem 31.5(4) on the circulation Taylor remainders Q_j^{Tay} come from the bound for general outputs in part (3) of that theorem, applied to

$$Z_j^a(\theta,q) = \widehat{\mathcal{E}}_j^a\big(\widehat{\Phi}_j(\theta,q)\big), \qquad G_j(\theta,w) = \mathscr{C}_{a,\varepsilon,x}\big(a_j^{-1}Z_j^a(\theta, g_{j,\cdot}w)\big),$$

with the field $\widehat{\mathcal{E}}_j^a$ of Theorem 31.3. That bound is useful only if the larger coarse/free radius, which we denote ρ^+_{joint}, and the coefficient bound, which we denote C_F^{cur}, are fixed before K, s, j, and the output resolution vary. We explain why. The only composition of growing length in Z_j^a is the field $\widehat{\mathcal{E}}_j^a$. Let C_E bound the rows and volume-normalized columns of the matrices E_i^a, let C_{src} be the constant in Theorem 31.3(4), and recall $D = \beta_J/(1-\alpha_*)$ and $q = B\alpha_*^2 < 1$. A common majorant for $\widehat{\mathcal{E}}_j^a$ is

$$\mathcal{M}_{\mathrm{ext}}(z) = C_E z + \frac{C_E C_{\mathrm{src}} C_*}{1-q}\,\frac{z^2}{(1-Dz)^2}. \tag{32.1}$$

Indeed, a remainder at scale $i > j$, with $r' = i - 1 - j$, contributes at most $C_E C_{\mathrm{src}} C_* q^{r'} z^2/(1-Dz)^2$, since $(a_j/a_i)\alpha_*^{2r'+1} = C_* q^{r'}$; for a distinguished input its column factors multiply to a^3/a_j^3, so the same series and its derivatives bound the columns. We fix a radius ρ_E inside the larger domain, with $D\rho_E < 1$, such that the reconstruction images lie strictly inside the disk of radius ρ_E. Then $\mathcal{M}_{\mathrm{ext}}(\rho_E) < \infty$, and its derivatives on the smaller domain are fixed constants. We then choose the larger coarse/free domain of radius ρ^+_{joint} so that its image under $\widehat{\Phi}_j$ lies in this disk, uniformly in the indices, as in Step 7 of the proof of Theorem 31.5. The majorant $\mathcal{M}_{\mathrm{ext}}$ and its derivatives on the smaller domain, composed with the joint coefficient bound for $\widehat{\Phi}_j$, then give the fixed constant C_F^{cur}. Both maps are equivariant and vanish at zero, so $Z_j^a(0,0) = 0$. After the substitution $q_{j,\ell} = g_{j,\ell} w_{j,\ell}$, each fluctuation factor contributes its coupling $g_{j,\ell} \le t_j$, and one derivative in the coarse field costs a fixed factor on the larger domain, which we include in C_F^{cur}. Thus neither C_F^{cur} nor ρ^+_{joint} depends on the remaining number of steps or on s; the bound for general outputs is not applied to an output chosen anew at each cutoff. This is Step 7 of the proof of Theorem 31.5.

The following proposition collects the estimates of Section 31 that are used below, together with the dependence of their constants.

Proposition 32.3. *In the setting of Definition 32.1, let s_0 be the threshold of Theorem 31.5, enlarged as in Lemma 31.8. For every $s \ge s_0$, $K \ge s$, $1 \le j \le k$, and $a \le \varepsilon \le \varepsilon_0(s)$, the following statements hold. The constants do not depend on $s \ge s_0$, except through the factors in H_s and n_s that are displayed.*

1. *Conditionally on $\mathcal{F}_{j-1}$, the vector w_j has the law $k_j(\widehat{\theta}_{j-1}, \cdot)$ on $\Omega_j = \prod_\ell \overline{B}_{\mathbb{R}^3}(0, p_{j,\ell})$, with $p_j \le p_{j,\ell} \le p_j + C_J$; this kernel does not depend on the restrictions at coarser scales once $\widehat{\theta}_{j-1}$ is fixed. Its potential satisfies $D_w^2 V_j \ge I/2$ and $\|D_w^2 V_j - I\|_{\mathrm{row+col}} \le \vartheta_j \le C[t_j p_j + t_j^2(1 + \mathsf{E}_{\mathrm{q}})]$, and $\operatorname{Var} f \le 2\mathbb{E}|\nabla f|^2$ and $\operatorname{Ent}(f^2) \le 4\mathbb{E}|\nabla f|^2$ conditionally on $\mathcal{F}_{j-1}$. Further, $m_j \le C_J(L/a_j)^3$, $|\mathbb{E}[w_{j,\ell} \mid \mathcal{F}_{j-1}]| \le C t_j b_{j-1}$, $p_j \ge 1$, $6m_j e^{-p_j^2/192} \le 1/2$, and $|\mathbb{E}[w^c_{j,\ell} \mid \mathcal{F}_{j-1}]| \le p_j/(16\sqrt{3})$.*
2. *For θ in the reconstruction domain, $\|\Gamma_j(\theta)\|_{\ell^2 \to \mathbb{R}^{3m}} \le C\omega_j$, $\|\Gamma_j(\theta)\|_{\ell^\infty \to \mathbb{R}^{3m}} \le C\sqrt{\varepsilon/a_j}$, and $\|\Gamma_j(\theta) - \Gamma_j(0)\|_{\ell^2 \to \mathbb{R}^{3m}} \le C\|\theta\|_\infty \omega_j$.*
3. *We have $|\Gamma_j(\widehat{\theta}_{j-1})\bar{w}_j + \mathbb{E}[Q_j^{\mathrm{Tay}} \mid \mathcal{F}_{j-1}]| \le C t_j b_{j-1}\sqrt{\varepsilon/a_j}$, the same bound for $|\mathbb{E}[Q_j^{\mathrm{Tay}} \mid \mathcal{F}_{j-1}]|$, and $\mathbb{E}[|Q_j^{\mathrm{Tay}} - \mathbb{E}(Q_j^{\mathrm{Tay}} \mid \mathcal{F}_{j-1})|^2 \mid \mathcal{F}_{j-1}] \le C t_j^2 p_j^2 \omega_j^2$.*
4. *Pathwise, $b_0 \le r$, $b_j \le C[r\alpha_*^j + g_3\sqrt{a_j}\, p_j]$, and $\sum_{j=1}^k b_{j-1} \le D_s$, with D_s as in Lemma 31.8 and $\sup_{s \ge s_0} D_s < \infty$. With T_s as in Lemma 31.8 and $\widetilde{N}$ the quantity denoted $\mathsf{N}_{K,s}$ there, $\sup_{\|\widehat{\theta}_0\|_\infty \le r} |T_s| \le Cr\sqrt{\varepsilon}/(g_3 H_s)$ and $\mathbb{E}|\widetilde{N}| + \sup_{\|\widehat{\theta}_0\|_\infty \le r} |T_s| \le Cr\sqrt{\varepsilon}/(g_3 H_s) + C g_3 D_s \sqrt{\varepsilon} + C\sqrt{\eta}[1 + \log(1/\eta)]^2$.*

5. *We have* $\sum_j \Gamma_j(0)\Gamma_j(0)^{\mathsf{T}} = C^{a,\varepsilon,L} \otimes I_3 - C^{\mathrm{ret}}_{s,a,\varepsilon}$ *with* $\|C^{\mathrm{ret}}_{s,a,\varepsilon}\| \le C n_s^2 \varepsilon / H_s$. *As* $a \downarrow 0$ *at fixed* ε, $C^{a,\varepsilon,L} \to C^{\varepsilon,L}$ *uniformly in* x *and the lattice offset, and* $C^{\varepsilon,L} \to \Sigma$ *as* $\varepsilon \downarrow 0$.

Proof. Parts (1)–(3) are parts (1), (2), and (4) of Theorem 31.5; the constants in part (3) are fixed by Remark 32.2. Part (4) is Lemma 31.8, and part (5) is Theorem 31.6 together with Lemma 31.2(5). By Lemma 31.10, all of these hold at the fixed coupling γ, with constants independent of $s \ge s_0$ apart from the displayed factors. □

32.2 Integration by parts and conditional characteristic functions

We now prove two finite-dimensional lemmas. The first compares one conditional increment with a Gaussian vector by an integration by parts against the density of the conditional fluctuation kernel, with a cutoff that vanishes near the boundary of the product of balls; this is the characteristic-function form of Stein's Gaussian integration by parts [147]. The second lemma assembles the one-step comparisons by telescoping conditional characteristic functions.

Lemma 32.4. *Let* $\mathcal{K} \subset \mathbb{R}^D$ *be compact and convex with nonempty interior, let* V *be a* C^2 *function on a neighborhood of* $\mathcal{K}$ *with* $D^2V \ge \kappa I$ *for some* $\kappa > 0$, *and let* $d\zeta = Z^{-1}\mathbf{1}_{\mathcal{K}} e^{-V}\,dw$. *Assume the Poincaré inequality* $\mathrm{Var}_\zeta f \le \kappa^{-1}\mathbb{E}_\zeta|\nabla f|^2$ *for every real* C^1 *function* f. *Let* Ψ *be a real* $d \times D$ *matrix with rows* ψ_b, *and set*

$$\mu = \mathbb{E}_\zeta w, \qquad \xi = \Psi(w-\mu), \qquad S = \Psi\Psi^{\mathsf{T}}, \qquad R_b = \langle \nabla V - (w-\mu), \psi_b \rangle.$$

Then for every $\chi \in C^1_c(\operatorname{int}\mathcal{K}; [0,1])$, *with* $\vartheta = \sup_{\operatorname{supp}\chi} \|D^2V - I\|_{\mathrm{op}}$, *every* $u \in \mathbb{R}^d$, *and* $1 \le b \le d$,

$$\begin{aligned}\left|\mathbb{E}_\zeta[(\xi_b - i(Su)_b)e^{iu\cdot\xi}]\right| \le{}& \frac{\sqrt{2}}{\kappa}\|\Psi\|_{\mathrm{op}}|u|\big(\vartheta|\psi_b| + \|R_b\nabla\chi\|_{L^2(\zeta)}\big)\\ &+ 2\mathbb{E}_\zeta|D_{\psi_b}\chi| + 2\mathbb{E}_\zeta[(1-\chi)|\xi_b|] + |(Su)_b|\,\zeta\{\chi < 1\}.\end{aligned}$$

The numerical coefficients do not depend on D, *on the shape of* $\mathcal{K}$, *or on its radii.*

By Proposition 32.3(1), the conditional fluctuation kernels satisfy the Poincaré hypothesis with $\kappa = 1/2$.

Proof. We write $\mathbb{E}$ for $\mathbb{E}_\zeta$ and $e_u(w) = e^{iu\cdot\xi(w)}$. Since χ has compact support in the interior of $\mathcal{K}$, we may integrate the directional derivative of $\chi e_u e^{-V}$, extended by zero, over $\mathbb{R}^D$; there is no boundary contribution. Since

$$D_{\psi_b}(u\cdot\xi) = (Su)_b, \qquad D_{\psi_b}V = \xi_b + R_b,$$

the resulting identity is

$$\mathbb{E}[\chi(\xi_b + R_b)e_u] = i(Su)_b\mathbb{E}[\chi e_u] + \mathbb{E}[(D_{\psi_b}\chi)e_u]. \tag{32.2}$$

Rearranging, we obtain

$$\mathbb{E}[(\xi_b - i(Su)_b)e_u] = \mathbb{E}[(1-\chi)(\xi_b - i(Su)_b)e_u] - \mathbb{E}[\chi R_b e_u] + \mathbb{E}[(D_{\psi_b}\chi)e_u]. \tag{32.3}$$

At $u = 0$, the identity (32.2) and $\mathbb{E}\xi_b = 0$ imply

$$\mathbb{E}[\chi R_b] = \mathbb{E}[D_{\psi_b}\chi] + \mathbb{E}[(1-\chi)\xi_b]. \tag{32.4}$$

Here it matters that R_b is defined with the mean μ of ζ.

For a real function F and a complex function H, we have $|\operatorname{Cov}(F,H)| \le (\operatorname{Var} F)^{1/2}(\mathbb{E}|H - \mathbb{E}H|^2)^{1/2}$ by the Cauchy–Schwarz inequality. We apply the Poincaré inequality to $F = \chi R_b$ and separately to $\Re e_u$ and $\Im e_u$; the sum of the squared gradients of the latter two functions is $|\Psi^{\mathsf T}u|^2 \le \|\Psi\|_{\mathrm{op}}^2|u|^2$. Further,

$$\nabla(\chi R_b) = \chi(D^2V - I)\psi_b + R_b\nabla\chi, \qquad \|\nabla(\chi R_b)\|_{L^2} \le \vartheta|\psi_b| + \|R_b\nabla\chi\|_{L^2},$$

and only the Hessian on $\operatorname{supp}\chi$ enters the last bound. Thus

$$|\operatorname{Cov}(\chi R_b, e_u)| \le \kappa^{-1}\|\Psi\|_{\mathrm{op}}|u|\big(\vartheta|\psi_b| + \|R_b\nabla\chi\|_{L^2}\big).$$

In (32.3) we write $\mathbb{E}[\chi R_b e_u] = \operatorname{Cov}(\chi R_b, e_u) + \mathbb{E}[\chi R_b]\mathbb{E}e_u$ and use (32.4). The two occurrences of each cutoff term are bounded by the corresponding absolute expectations, and the remaining term with $(Su)_b$ is bounded by $|(Su)_b|\zeta\{\chi < 1\}$. This proves the stated inequality, even with 1 in place of $\sqrt{2}$ in the first coefficient. □

Lemma 32.5. *Let $(\mathcal{F}_j)_{j=0}^k$ be a finite filtration, and let $\xi_j \in \mathbb{R}^d$ be bounded, $\mathcal{F}_j$-measurable, and conditionally centered, $\mathbb{E}[\xi_j \mid \mathcal{F}_{j-1}] = 0$. Let $S_j^0 \ge 0$ be deterministic matrices, and let $\rho_j, \eta_j \ge 0$ be integrable $\mathcal{F}_{j-1}$-measurable random variables. Suppose that for every $u \in \mathbb{R}^d$*

$$\big|\mathbb{E}[(\xi_j - iS_j^0u)e^{iu\cdot\xi_j} \mid \mathcal{F}_{j-1}]\big| \le \rho_j|u| + \eta_j(1+|u|).$$

For $0 \le q \le k$ put $M_{q,k}^0 = \sum_{j=q+1}^k \xi_j$. Then almost surely

$$\Big|\mathbb{E}[e^{iu\cdot M_{q,k}^0} \mid \mathcal{F}_q] - \exp\Big(-\frac{1}{2}u^{\mathsf T}\sum_{j=q+1}^k S_j^0 u\Big)\Big| \le \sum_{j=q+1}^k \mathbb{E}\big[\tfrac{1}{2}\rho_j|u|^2 + \eta_j|u|(1+|u|) \mid \mathcal{F}_q\big].$$

For every integrable random vector N, replacing $M_{q,k}^0$ by $M_{q,k}^0 + N$ adds at most $|u|\mathbb{E}[|N| \mid \mathcal{F}_q]$ to the bound. No independence or smallness of the increments is assumed, and the numerical constants do not depend on k, q, or the dimensions.

Proof. We set

$$\varphi_j(v) = \mathbb{E}[e^{iv\cdot\xi_j} \mid \mathcal{F}_{j-1}], \qquad \Delta_j(v) = \mathbb{E}[(\xi_j - iS_j^0v)e^{iv\cdot\xi_j} \mid \mathcal{F}_{j-1}].$$

Since ξ_j is bounded, we may differentiate along $v = \tau u$, and we find

$$\frac{d}{d\tau}\varphi_j(\tau u) = -\tau u^{\mathsf{T}} S_j^0 u\, \varphi_j(\tau u) + iu \cdot \Delta_j(\tau u).$$

The integrating factor from τ to 1 is $\exp[-(1-\tau^2)u^{\mathsf{T}} S_j^0 u/2] \le 1$. Since $\varphi_j(0) = 1$, integrating from 0 to 1, we obtain

$$|\varphi_j(u) - \varphi_j^0(u)| \le \mathsf{e}_j(u), \qquad \varphi_j^0(u) = e^{-u^{\mathsf{T}} S_j^0 u/2}, \qquad \mathsf{e}_j(u) = \tfrac{1}{2}\rho_j |u|^2 + \eta_j |u|(1+|u|). \tag{32.5}$$

Fix q, and for $q \le j \le k$ set

$$H_j = \exp\Big(iu \cdot \sum_{l=q+1}^{j} \xi_l\Big) \prod_{l=j+1}^{k} \varphi_l^0(u).$$

Then $H_q = \prod_{l=q+1}^{k} \varphi_l^0(u)$ is deterministic and $H_k = e^{iu \cdot M_{q,k}^0}$. Conditioning the difference $H_j - H_{j-1}$ first on $\mathcal{F}_{j-1}$ and then on $\mathcal{F}_q$, and using (32.5), we bound its conditional expectation given $\mathcal{F}_q$ in modulus by $\mathbb{E}[\mathsf{e}_j(u) \mid \mathcal{F}_q]$; here we used that the exponential of the past increments has modulus one and that every remaining deterministic factor lies in $[0,1]$. Telescoping proves the assertion. Finally, $|e^{iu\cdot(z+n)} - e^{iu\cdot z}| \le |u||n|$ implies the statement about N; no measurability or independence requirement on N is needed. □

32.3 Telescoping circulations and dimension-dependent cutoffs

The next lemma applies Lemma 32.4 to the conditional fluctuation kernels. The cutoff χ_j must vanish near the boundary of the product of balls, and its gradient grows like the square root of the number D_j of fluctuation variables, so the error terms carry a polynomial factor in D_j. This factor is harmless because the cutoff radius grows logarithmically in $1/t_j$, so that the probability that the cutoff is active decays faster than any power of the mesh.

Lemma 32.6. *In the setting of Definition 32.1, for every finite $K \ge s$,*

$$I^{K,s} = T_s + \sum_{j=1}^{k} \Gamma_j(\widehat{\theta}_{j-1})(w_j - \bar{w}_j) + \widetilde{N},$$

where

$$T_s = \mathcal{I}(\widehat{\Pi}_{k \leftarrow 0}\widehat{\theta}_0), \qquad \widetilde{N} = \sum_{j=1}^{k} \big\{\Gamma_j(\widehat{\theta}_{j-1})\bar{w}_j + Q_j^{\mathrm{Tay}}\big\}.$$

All zero-fluctuation continuations lie in the reconstruction domain, and the middle sum is a sum of martingale increments under $\nu_{K,s}$.

There is $s_0 < \infty$, depending only on L, γ, M, J, n_*, Θ, the analytic domains and column bounds, the loops, and σ, and not on the later index s, such that for $s \ge s_0$ the following holds at each RG step. The kernel k_j lives on m_j balls in $\mathbb{R}^3$, with $D_j = 3m_j \le 3C_J(L/a_j)^3$, and $p_j \ge 1$, $D_w^2 V_j \ge I/2$, and

$$\|D_w^2 V_j - I\|_{\mathrm{op}} \le \vartheta_j \le C\{t_j p_j + t_j^2(1+\mathsf{E}_{\mathrm{q}})\} \le \tfrac{1}{2}.$$

There is a smooth function $\chi_j : \Omega_j \to [0,1]$, equal to one on the product of the balls of half the radii and to zero outside the product of the balls of three quarters of the radii, with $|\nabla\chi_j| \le C\sqrt{D_j}/p_j$ and $\nabla\chi_j$ supported in $\{\chi_j < 1\}$. The conditional probability that the cutoff is active,

$$q_j^{\mathrm{cut}} = \mathbb{P}\{\chi_j(w_j) < 1 \mid \mathcal{F}_{j-1}\},$$

satisfies $q_j^{\mathrm{cut}} \le 6m_j e^{-p_j^2/192} \le 1/2$. Put $\widehat{\tau}_j = (1+3m_j)(6m_j)^{1/2}e^{-p_j^2/384}$. Let Ψ_j be either $\Gamma_j(\widehat{\theta}_{j-1})$ or $\Gamma_j(0)$, and let $\xi_j = \Psi_j(w_j - \bar{w}_j)$ and $S_j = \Psi_j\Psi_j^{\mathsf{T}}$. Then for every $u \in \mathbb{R}^{3m}$,

$$\big|\mathbb{E}[(\xi_j - iS_j u)e^{iu\cdot\xi_j} \mid \mathcal{F}_{j-1}]\big| \le \rho_j|u| + \eta_j(1+|u|),$$

with

$$\rho_j \le C_{3m}\vartheta_j\|\Psi_j\|_{\mathrm{op}}^2, \qquad \eta_j \le C_{3m}\|\Psi_j\|_{\mathrm{op}}(1+\|\Psi_j\|_{\mathrm{op}})\widehat{\tau}_j,$$

where C_{3m} depends only on m, J, and the ratios of the radii, and not on D_j, p_j, or the coarse field. There is a deterministic function T of the mesh such that

$$\widehat{\tau}_j \le T(a_j) \le C\big(1+(L/a_j)^3\big)(L/a_j)^{3/2}\exp\Big\{-\frac{A_{\mathrm{w}}^2}{384}\log^2\frac{1}{M^{(J-1)/2}g_3\sqrt{a_j}}\Big\}.$$

For every $r' > 0$ we have $T(h) \le C_{r'}h^{r'}$ as $h \downarrow 0$. In particular, with $A_s^{\mathrm{cut}} = \sum_{j\ge1} a_j^{-1/2}T(a_j)$ and $\Theta_{\mathrm{cut}}(v) = \sup_{0<h\le v} T(h)$,

$$\sum_{j=1}^{k}\omega_j(1+\omega_j)\widehat{\tau}_j \le C\sqrt{\varepsilon}\,A_s^{\mathrm{cut}} + C_B\Theta_{\mathrm{cut}}(\varepsilon) \longrightarrow 0 \qquad (\varepsilon \downarrow 0),$$

uniformly in K, x, the lattice offset, and d_j, and $A_s^{\mathrm{cut}} \le A_{s_0}^{\mathrm{cut}} < \infty$. The number of blocks is $m_j = O_{J,L,\gamma}(t_j^{-6})$.

Proof. The decomposition is that of Lemma 31.8, proved in Step 5 of its proof: for $F_j = \mathcal{I}(\widehat{\Pi}_{k\leftarrow j}\widehat{\theta}_j)$ we have $F_0 = T_s$, $F_k = I^{K,s}$, and $F_j - F_{j-1} = \Gamma_j(\widehat{\theta}_{j-1})w_j + Q_j^{\mathrm{Tay}}$, since $\widehat{\Pi}_{k\leftarrow j-1} = \widehat{\Pi}_{k\leftarrow j}\circ\widehat{\Phi}_j(\cdot,0)$ on the reconstruction domain, which contains all sampled fields and all zero-fluctuation continuations by Theorem 31.3. The coefficients are $\mathcal{F}_{j-1}$-measurable and $\bar{w}_j$ is the conditional mean under the same law, so the middle sum is a martingale.

We next fix the threshold, uniformly for all later coarse indices; all data in the dependence list are fixed before this choice. The largest coupling of each RG step and the cutoff radii satisfy

$$t_1(s) = g_3\sqrt{H_s/M}, \qquad t_j(s) = t_1(s)B^{-(j-1)/2}, \qquad p_j = p_1(s) + \tfrac{1}{2}A_{\mathrm{w}}(j-1)\log B. \tag{32.6}$$

By Proposition 32.3(1), the kernel k_j lives on m_j balls with radii $p_j \le p_{j,\ell} \le p_j + C_J$ and has the stated Hessian, dimension, and mean bounds. The bound on rows and columns implies the bound on the operator norm, since for a finite matrix A

$$\|A\|^2_{\ell^2\to\ell^2} \le \Big(\sup_i \sum_l |A_{il}|\Big)\Big(\sup_l \sum_i |A_{il}|\Big),$$

as follows by applying the weighted Cauchy–Schwarz inequality in each row and then summing. The Hessian error therefore tends to zero with $t_j p_j + t_j^2(1+\mathsf{E}_{\mathrm{q}})$. Since $t_1(s) \downarrow 0$, one enlargement of s_0 enforces $p_j \ge 1$ and $\vartheta_j \le 1/2$ at every level. The number of blocks satisfies

$$m_j \le C_J(L/a_j)^3 \le C_{J,L,\gamma}t_j^{-6}, \qquad a_j = t_j^2/(\lambda_B^2 g_3^2),$$

with $\lambda_B = M^{(J-1)/2}$, so $6m_j e^{-p_j^2/192} \to 0$ uniformly over all sufficiently small t_j. The same s_0 enforces the bound $1/2$ on this quantity and the bound on the means

$$|\mathbb{E}[w^c_{j,\ell} \mid \mathcal{F}_{j-1}]| \le p_j/(16\sqrt{3}), \qquad 1 \le c \le 3. \tag{32.7}$$

These are restrictions on the coarse side only; the cutoff radii and the maps are not changed.

The cutoff. Fix a smooth function $\psi : [0,\infty) \to [0,1]$, equal to one on $[0,1/2]$ and to zero on $[3/4,\infty)$, and set

$$\chi_j(w) = \prod_{\ell=1}^{m_j} \psi(|w_\ell|/p_{j,\ell}).$$

It is smooth, since each factor is constant near $w_\ell = 0$, and it has compact support in the interior of the product. The gradient of each factor has norm at most C/p_j, so $|\nabla\chi_j| \le C\sqrt{m_j}/p_j \le C\sqrt{D_j}/p_j$, and $\nabla\chi_j$ vanishes wherever $\chi_j = 1$. These bounds depend only on ψ, not on the number of balls.

The probability that the cutoff is active. We use the logarithmic Sobolev inequality $\mathrm{Ent}(f^2) \le 4\mathbb{E}|\nabla f|^2$ of Proposition 32.3(1) on the product itself, by Herbst's argument (see [123]). For a scalar coordinate $F(w) = w^c_\ell$, let $H(\lambda) = \log \mathbb{E}e^{\lambda F}$. Applying the inequality to $f = e^{\lambda F/2}$, we find $\lambda H'(\lambda) - H(\lambda) \le \lambda^2$. Integrating $(H/\lambda)' \le 1$ from zero for $\lambda > 0$, and applying the same argument to $-F$, we obtain

$$\mathbb{E}e^{\lambda(F-\mathbb{E}F)} \le e^{\lambda^2} \quad (\lambda \in \mathbb{R}), \qquad \mathbb{P}\{|F-\mathbb{E}F| \ge v\} \le 2e^{-v^2/4},$$

where the tail bound follows by taking $\lambda = v/2$ in $e^{\lambda^2 - \lambda v}$ for each of the two tails. If $\chi_j < 1$, then some $|w_\ell| > p_{j,\ell}/2 \geq p_j/2$, so some coordinate has absolute value larger than $p_j/(2\sqrt{3})$. By (32.7), its deviation from its conditional mean is at least $p_j/(4\sqrt{3})$. A union bound over the $3m_j$ coordinates gives

$$q_j^{\mathrm{cut}} = \mathbb{P}\{\chi_j < 1 \mid \mathcal{F}_{j-1}\} \leq 6m_j e^{-p_j^2/192}. \tag{32.8}$$

The error terms with the dimension retained. We suppress the index j and write $D = 3m_j$, $p = p_j$, $q = \zeta\{\chi < 1\} \leq 1/2$, $\Psi = \Psi_j$, and ζ for the conditional kernel. Both choices of Ψ are linear maps whose rows are fixed once the coarse field is fixed; neither choice changes the law, its mean, the cutoff, or the score vector $\nabla V - (w - \mu)$. The contraction $R_b = (\nabla V - (w - \mu)) \cdot \psi_b$ retains its dependence on the chosen row ψ_b. The product of balls has diameter at most $C_J p\sqrt{D}$, and by convexity the mean $\mu = \mathbb{E}w$ lies in the product. Since $\nabla R_b = (D^2 V - I)\psi_b$, with $c_b = R_b(\mu)$ we have

$$\sup_w |R_b(w) - c_b| \leq C_J \vartheta p \sqrt{D}\, |\psi_b|. \tag{32.9}$$

By the Poincaré inequality, $\mathbb{E}|\xi_b|^2 \leq 2|\psi_b|^2$. Further,

$$\mathbb{E}|D_{\psi_b}\chi| \leq C\sqrt{D}\, |\psi_b|\, q/p, \qquad \mathbb{E}[(1-\chi)|\xi_b|] \leq \sqrt{2}\, |\psi_b| \sqrt{q}.$$

Using (32.4), $\mathbb{E}\chi \geq 1/2$, and (32.9), we obtain

$$|c_b| \leq C_J |\psi_b| \big\{ \vartheta p \sqrt{D} + (\sqrt{D}/p) q + \sqrt{q} \big\}.$$

Since $\nabla\chi$ is supported in $\{\chi < 1\}$, multiplying the resulting bound on $\sup |R_b|$ by the gradient bound and by $\sqrt{q}$, and using $p \geq 1$ and $\vartheta \leq 1/2$, we find

$$\|R_b \nabla\chi\|_{L^2} \leq C_J (1 + D) |\psi_b| \sqrt{q}. \tag{32.10}$$

In particular, R_b is not bounded independently of D.

We insert these estimates into Lemma 32.4 with $\kappa = 1/2$, and use $|(Su)_b| \leq |\psi_b| \|\Psi\|_{\mathrm{op}} |u|$ and $(\sum_b |\psi_b|^2)^{1/2} \leq \sqrt{3m}\, \|\Psi\|_{\mathrm{op}}$. The Euclidean norm of the vector of errors is at most

$$C_{3m} \vartheta \|\Psi\|_{\mathrm{op}}^2 |u| + C_{3m} \|\Psi\|_{\mathrm{op}} (1 + \|\Psi\|_{\mathrm{op}})(1 + D)\sqrt{q}\, (1 + |u|).$$

All constants may depend on J and the ratios of the radii, but not on D, p, or the coarse field. By (32.8), $(1 + D)\sqrt{q} \leq \widehat{\tau}_j$, which gives the stated ρ_j and η_j.

The deterministic envelope. On $0 < h \le H_{s_0}/B$ we take

$$T(h) = C\big(1 + (L/h)^3\big)(L/h)^{3/2} \exp\Big[-\frac{A_{\mathrm{w}}^2}{384} \log^2 \frac{1}{\lambda_B g_3 \sqrt{h}}\Big], \tag{32.11}$$

with one sufficiently large C; then $\widehat{\tau}_j \le T(a_j)$, since $m_j \le C_J (L/a_j)^3$ and $p_j = A_{\mathrm{w}} \log(1/(\lambda_B g_3 \sqrt{a_j}))$. This definition uses the mesh itself, not the index j or the coarse index. To verify the decay, let $h_* = H_{s_0}/B$ and $z = \log(h_*/h) \ge 0$. The logarithm of the polynomial prefactor is at most $C + (9/2)z$. The exponent is a quadratic polynomial in z with leading coefficient $-A_{\mathrm{w}}^2/1536$. For every $r' > 0$, subtracting $\log h^{r'}$ adds only $r'z$ and a constant, and the resulting quadratic polynomial is bounded above. This proves $T(h) \le C_{r'} h^{r'}$ and $\Theta_{\mathrm{cut}}(v) \to 0$, with constants of the stated dependence.

Taking $r' = 2$ shows that $\sum_{j \ge 1} a_j^{-1/2} T(a_j) < \infty$. For $s \ge s_0$ this series is a tail of the same series along the fixed sequence of meshes, so $A_s^{\mathrm{cut}} \le A_{s_0}^{\mathrm{cut}}$. Finally $\omega_j \le 1$, and

$$\sum_{a_j > \varepsilon} \omega_j (1 + \omega_j) T(a_j) \le 2\sqrt{\varepsilon}\, A_s^{\mathrm{cut}}, \qquad \sum_{a_j \le \varepsilon} \omega_j (1 + \omega_j) T(a_j) \le \frac{2\Theta_{\mathrm{cut}}(\varepsilon)}{1 - B^{-1}}.$$

For the second bound we used that the meshes form a geometric sequence, so that $\sum_{a_j \le \varepsilon} a_j/\varepsilon \le (1 - B^{-1})^{-1}$. Truncating either sum at k only decreases it. This proves the summability and uniformity assertions. □

32.4 Gaussian approximation of the circulations

We first record how characteristic-function estimates are converted into estimates in the bounded-Lipschitz distance d_{BL}, which uses test functions bounded by one with Lipschitz constant at most one. The argument also covers a singular limiting covariance.

Lemma 32.7. *Let P' and P be probability measures on $\mathbb{R}^d$, with characteristic functions $\widehat{P}'(u) = \int e^{iu\cdot z} P'(dz)$ and $\widehat{P}$. For all $A > 0$ and $\delta > 0$,*

$$d_{\mathrm{BL}}(P', P) \le P'\{|z| > A\} + P\{|z| > A\} + 4\delta \mathbb{E}|Z_d| + \frac{|B_{\mathbb{R}^d}(0, A+1)|}{(2\pi)^d} \int_{\mathbb{R}^d} e^{-\delta^2 |u|^2/2} |\widehat{P}'(u) - \widehat{P}(u)|\, du, \tag{32.12}$$

where Z_d is a standard Gaussian vector in $\mathbb{R}^d$. In particular, if probability measures P_l are uniformly tight and their characteristic functions converge pointwise to that of P, then $d_{\mathrm{BL}}(P_l, P) \to 0$. If $d = 3m$, the same convergence holds after applying $\mathfrak{q}(v) = (|v_i|^2/8)_{i=1}^m$, provided the tails of the P_l and of P vanish uniformly as the radius tends to infinity; quantitatively, for every $A > 0$,

$$d_{\mathrm{BL}}(\mathfrak{q}_* P', \mathfrak{q}_* P) \le \max\{1, A/4\}\, d_{\mathrm{BL}}(P', P) + 2P'\{|v| > A\} + 2P\{|v| > A\}. \tag{32.13}$$

The constants depend only on d and on the chosen radii A and δ.

Proof. Let f satisfy $\|f\|_\infty \le 1$ and $\operatorname{Lip} f \le 1$, and let $\chi_A(z) = \min\{1, (A+1-|z|)_+\}$ and $h = f\chi_A$. Then h is supported in the ball of radius $A+1$, is bounded by one, and has Lipschitz constant at most two. If φ_δ is the centered Gaussian density with covariance $\delta^2 I_d$, then $\|h * \varphi_\delta - h\|_\infty \le 2\delta \mathbb{E}|Z_d|$. The Fourier transform of a Gaussian density gives $\varphi_\delta(z) = (2\pi)^{-d} \int e^{iu\cdot z} e^{-\delta^2|u|^2/2}\, du$. Inserting this formula into the convolution and using Fubini's theorem, which is justified since h and the Gaussian in u are integrable, we obtain, with $\widehat{h}(u) = \int h(z) e^{-iu\cdot z}\, dz$,

$$P'(h*\varphi_\delta) - P(h*\varphi_\delta) = (2\pi)^{-d} \int \widehat{h}(u) e^{-\delta^2|u|^2/2} \big(\widehat{P}'(u) - \widehat{P}(u)\big)\, du.$$

Since $|\widehat{h}(u)| \le |B_{\mathbb{R}^d}(0, A+1)|$, the modulus of the right side is at most the last term of (32.12). Restoring h costs $4\delta\mathbb{E}|Z_d|$, and restoring f costs at most $P'\{|z|>A\} + P\{|z|>A\}$, since $|f-h| \le \mathbf{1}_{\{|z|>A\}}$. The right side does not depend on f, which proves (32.12). Under the hypotheses on P_l, dominated convergence (the characteristic functions differ by at most two) shows that the last term tends to zero for fixed A and δ; we then let $A \to \infty$ and $\delta \downarrow 0$.

For the quadratic map, let π_A be the nearest-point projection onto the closed ball of radius A. It is 1-Lipschitz: for $z, z' \in \mathbb{R}^d$, the inequalities $\langle z - \pi_A z, y - \pi_A z\rangle \le 0$ for y in the ball, applied with $y = \pi_A z'$ and symmetrically, give $|\pi_A z - \pi_A z'|^2 \le \langle z - z', \pi_A z - \pi_A z'\rangle$. On the ball,

$$|\mathfrak{q}(v) - \mathfrak{q}(w)| \le \tfrac{1}{8}(|v| + |w|)|v - w| \le (A/4)|v - w|.$$

Thus, for a test function f on $\mathbb{R}^m$ bounded by one with Lipschitz constant at most one, the function $f \circ \mathfrak{q} \circ \pi_A$ is bounded by one and has Lipschitz constant at most $A/4$. Further, $f \circ \mathfrak{q}$ differs from it only outside the ball, by at most two. This proves (32.13). For the convergence, take $P' = P_l$, let $l \to \infty$, and then let $A \to \infty$. □

Theorem 32.8. *In the setting of Definition 32.1, there is an integer s_0 such that for every fixed integer $s \ge s_0$,*

$$\lim_{\varepsilon \downarrow 0} \limsup_{K \to \infty} \sup_{x \in \mathbb{T}^3_L,\, \textit{offset}} d_{\mathrm{BL}}\Big(\mathrm{Law}_{\nu_{K,s}}\, I^{K,s}(\varepsilon, x),\, N(0, \Sigma \otimes I_3)\Big) = 0,$$

where Σ is the covariance of Definition 31.1; it may be singular. The underlying estimates hold for every $K \ge s$, $1 \le j \le K - s$, and $a \le \varepsilon \le \varepsilon_0(s)$, where one may take $\varepsilon_0(s) \le \min\{cH_s, \varepsilon_{\mathrm{loop}}, c/g_3^2\}$. The constants in the bounds on the coefficients, on the variation of the covariance, and on the conditional remainders can be chosen independently of $s \ge s_0$. More explicitly, let $\kappa_* = -\log \alpha_* / \log B$, which exceeds $1/2$ since $\alpha_* < B^{-1/2}$, and let

$$\Psi_\kappa(u) = \begin{cases} u^\kappa, & \kappa < 1, \\ u(1 + |\log u|), & \kappa = 1, \\ u, & \kappa > 1, \end{cases} \qquad 0 < u \le 1.$$

Then the variation of the coefficients and the remainder satisfy

$$\sum_j \|\widehat{\theta}_{j-1}\|_\infty \omega_j^2 \le Cr\Psi_{\kappa_*}(\varepsilon/H_s) + C\sqrt{\eta}\,[1+|\log\eta|],$$

$$\mathbb{E}|\widetilde{N}| + |T_s| \le \frac{Cr}{g_3 H_s}\sqrt{\varepsilon} + Cg_3 D_s\sqrt{\varepsilon} + C\sqrt{\eta}\,[1+|\log\eta|]^2,$$

where $D_s = C\{r/(1-\alpha_*) + g_3\sqrt{H_s}(p_1(s)+1)\}$ *and* $\sup_{s\ge s_0} D_s < \infty$. *The coarse-field term may grow like* H_s^{-1}, $\varepsilon_0(s)$ *may decrease with* s, *and* s *is fixed before both limits.*

Proof. We first sum the one-step bounds over the scales (Steps 1–3), then replace the coefficients by their values at the zero field (Step 4), then bound the characteristic functions (Step 5), and finally pass to the bounded-Lipschitz distance (Step 6).

Step 0: the threshold. We take the threshold of Lemma 32.6 and enlarge it, if necessary, to that of Proposition 32.3. All constants in the coefficient, potential-derivative, and conditional variance bounds are independent of the later s. Indeed, the maps for coarse index s are those of the fixed sequence at the absolute levels $s+j$, with recursion indices $J(K-s-j)$, and the output class is that of Remark 32.2. We use only the mean and variance bounds of Proposition 32.3(3); the local bound (31.13) is not needed. The domain and zero-fluctuation statements come from Theorem 31.3. The law of the coarse field may depend on s; since every estimate holds for every coarse field, no comparison of these laws is needed. We take the range of ε in the statement, shrinking c if necessary so that $\eta < 1$ and $p(\varepsilon) = A_{\mathrm{w}}\log(1/(\lambda_B g_3\sqrt{\varepsilon})) \ge 1$; this is possible with c depending only on M, J, and A_{w}.

Step 1: sums over the scales. Since the meshes a_j decrease by the ratio B, splitting at $a_j = \varepsilon$ gives

$$\sum_{j=1}^{k} \omega_j^2 \le \frac{1}{1-B^{-1}} + \frac{1}{1-B^{-2}} = C_B^{(2)}. \tag{32.14}$$

For $a_j > \varepsilon$ the summands are ε/a_j, and reading them from the last coarse scale backward bounds their sum by the first geometric series; for $a_j \le \varepsilon$ they are a_j^2/ε^2, bounded by the second series. The estimate holds also if either part is empty. For $h \le \varepsilon$ write

$$p(h) = p(\varepsilon) + \tfrac{1}{2}A_{\mathrm{w}}\log(\varepsilon/h),$$

so that $p_j = p(a_j)$. For each fixed $v > 0$, geometric summation gives

$$\sum_{a_j \le \varepsilon} (a_j/\varepsilon)^v (1+p(a_j)) \le C_{B,v,A_{\mathrm{w}}}(1+p(\varepsilon)). \tag{32.15}$$

Indeed, the first ratio $z = a_{j_0}/\varepsilon \le 1$ need not be one, and the sum is at most $z^v \sum_{l\ge 0} B^{-vl}[1 + p(\varepsilon) + (A_{\mathrm{w}}/2)(\log(1/z) + l\log B)]$; we use $z^v \le 1$,

$\sup_{0<z\le 1} z^v \log(1/z) < \infty$, and the convergence of $\sum_l B^{-vl}$ and $\sum_l lB^{-vl}$. For $a_j > \varepsilon$ we have $p(a_j) \le p(\varepsilon)$ and $\sum_{a_j>\varepsilon} a_j^{-1/2} \le C_B \varepsilon^{-1/2}$. It follows that

$$g_3 \sum_j \sqrt{a_j}(1+p_j)\omega_j^2 \le C g_3 \sqrt{\varepsilon}\,(1+p(\varepsilon)) \le C\sqrt{\eta}\,(1+|\log\eta|), \tag{32.16}$$

where on the fine scales we used (32.15) with $v = 5/2$, and on the coarse scales the sum of inverse square roots. Here and below the constants may depend on γ and on H_{s_0}, but not on the later s. Since $p_j \ge 1$ and $t_j \le t_1(s_0)$, the Hessian error satisfies $\vartheta_j \le C g_3 \sqrt{a_j}(1+p_j)$. Thus

$$\sum_j \vartheta_j \omega_j^2 \le C\sqrt{\eta}\,(1+|\log\eta|). \tag{32.17}$$

Step 2: the variation of the coefficients. We write $b_j = \|\widehat{\theta}_j\|_\infty$. The bound of Proposition 32.3(4) is pathwise, with a coefficient independent of H_s and of all later $s \ge s_0$; we use this uniform coefficient rather than a bound with a constant depending on H_s. Its conditions hold here: all fields and zero-fluctuation continuations lie in the reconstruction domain, and $t_1(s) \le t_1(s_0)$ satisfies the required upper bound for every later s. With $b_0 \le r$, it implies

$$b_{j-1} \le C\big\{ r(a_j/H_s)^{\kappa_*} + g_3\sqrt{a_j}(1+p_j)\big\}, \qquad 1 \le j \le k. \tag{32.18}$$

For $j \ge 2$ we used $a_{j-1} = Ba_j$, $p_{j-1} \le p_j$, and $\alpha_*^{j-1} = \alpha_*^{-1}(a_j/H_s)^{\kappa_*}$; for $j = 1$ we used $b_0 \le r$ and absorbed α_*^{-1} into C. The deterministic part of the weighted sum $\sum_j b_{j-1}\omega_j^2$ over the coarse scales is

$$Cr\varepsilon H_s^{-\kappa_*} \sum_{a_j>\varepsilon} a_j^{\kappa_*-1}.$$

If $\kappa_* < 1$, summing from the last coarse mesh bounds this by $Cr(\varepsilon/H_s)^{\kappa_*}$. If $\kappa_* = 1$, every summand is one and there are at most $C_B(1+\log(H_s/\varepsilon))$ of them, which gives the logarithmic case of Ψ_{κ_*}; this case cannot be bounded by $C\varepsilon/H_s$. If $\kappa_* > 1$, summing from the largest mesh bounds it by $Cr\varepsilon/H_s$. On the fine scales the sum is

$$CrH_s^{-\kappa_*}\varepsilon^{-2} \sum_{a_j\le\varepsilon} a_j^{\kappa_*+2} \le Cr(\varepsilon/H_s)^{\kappa_*}.$$

In all three cases this is bounded by $Cr\Psi_{\kappa_*}(\varepsilon/H_s)$. For the fluctuation part of (32.18) we use (32.16). This proves, pathwise, the first estimate of the theorem:

$$\sum_j b_{j-1}\omega_j^2 \le Cr\Psi_{\kappa_*}(\varepsilon/H_s) + C\sqrt{\eta}\,(1+|\log\eta|). \tag{32.19}$$

Step 3: the remainder. Let $\mathcal{D}_j = Q_j^{\mathrm{Tay}} - \mathbb{E}[Q_j^{\mathrm{Tay}} \mid \mathcal{F}_{j-1}]$. By the conditional mean and variance bounds of Proposition 32.3(3), the tower property, $\mathbb{E}|\mathcal{D}_j| \le (\mathbb{E}|\mathcal{D}_j|^2)^{1/2}$, and the triangle inequality, we have, without any independence,

$$\mathbb{E}|\widetilde{N}| \le C \sum_j t_j \, \mathbb{E} b_{j-1} \sqrt{\varepsilon / a_j} + C \sum_j t_j p_j \omega_j. \tag{32.20}$$

In the first sum we apply the pathwise bound inside the expectation:

$$\sum_j t_j \, \mathbb{E} b_{j-1} \sqrt{\varepsilon / a_j} = \lambda_B g_3 \sqrt{\varepsilon} \, \mathbb{E}\Big[\sum_j b_{j-1}\Big] \le \lambda_B g_3 \sqrt{\varepsilon} \, D_s.$$

On the fine scales the second sum is $\lambda_B g_3 \varepsilon^{-1} \sum_j a_j^{3/2} p_j$, which is at most $C\sqrt{\eta}(1 + p(\varepsilon))$ by (32.15). On the coarse scales each term is $\lambda_B \sqrt{\eta}\, p_j$; there are at most $C_B[1 + \log(H_{s_0}/\varepsilon)]$ such scales, and each $p_j \le p(\varepsilon)$. For fixed g_3 and H_{s_0} both factors are at most $C(1 + |\log \eta|)$. Adding the bound on T_s from Proposition 32.3(4), we obtain

$$\mathbb{E}|\widetilde{N}| + \sup_{\|\widehat{\theta}_0\|_\infty \le r} |T_s| \le \frac{Cr}{g_3 H_s} \sqrt{\varepsilon} + C g_3 D_s \sqrt{\varepsilon} + C\sqrt{\eta}\,(1 + |\log \eta|)^2, \tag{32.21}$$

which is also the estimate of Lemma 31.8. The quantity D_s is the sum of the bounds on b_{j-1}, with a coefficient independent of s, and $\sup_{s \ge s_0} D_s < \infty$ follows from (32.6): $p_1(s)$ grows linearly in s, and $\sqrt{H_s}$ decreases by the factor $B^{-1/2}$ at each increment of s.

Step 4: coefficients at the zero field. We now replace the coefficient matrices by their values at the zero field, keeping the centered fluctuation variables $e_j = w_j - \bar{w}_j$ of the conditioned measure. Let

$$M_k = \sum_j \Gamma_j(\widehat{\theta}_{j-1}) e_j, \qquad M_k^0 = \sum_j \Gamma_j(0) e_j, \qquad S_j^0 = \Gamma_j(0)\Gamma_j(0)^{\mathsf{T}}.$$

The reconstruction domain gives a fixed deterministic bound $b_j \le b_{\max} < \infty$. By the conditional Poincaré inequality and the bound on $\Gamma_j(\theta) - \Gamma_j(0)$ in Proposition 32.3(2), we have

$$\mathbb{E}\big[|(\Gamma_j(\widehat{\theta}_{j-1}) - \Gamma_j(0))e_j|^2 \mid \mathcal{F}_{j-1}\big] \le C_{3m} b_{j-1}^2 \omega_j^2.$$

Since these differences are martingale increments for the same measure, conditioning on the earlier variables makes all cross terms vanish. With (32.19) we obtain

$$\mathbb{E}|M_k - M_k^0|^2 \le C_{3m} \sum_j \mathbb{E} b_{j-1}^2 \omega_j^2 \le C_{3m} b_{\max} \big\{ Cr \Psi_{\kappa_*}(\varepsilon / H_s) + C\sqrt{\eta}\,(1 + |\log \eta|) \big\} \longrightarrow 0, \tag{32.22}$$

uniformly in K at fixed s.

Step 5: characteristic functions. We apply Lemma 32.6 with $\Psi_j = \Gamma_j(0)$, under the same conditional kernels at the coarse fields $\widehat{\theta}_{j-1}$; the kernel at the zero field is not used. The bound $\|\Gamma_j(0)\|_{\mathrm{op}} \le C\omega_j$ implies the deterministic bounds

$$\rho_j^0 \le C\vartheta_j\omega_j^2, \qquad \eta_j^0 \le C\omega_j(1+\omega_j)\widehat{\tau}_j,$$

whose sums tend to zero by (32.17) and Lemma 32.6. Lemma 32.5 with $q = 0$, followed by (32.22) and (32.21), bounds the error in the characteristic function of the circulation by

$$\begin{aligned}\Big|\mathbb{E}e^{iu\cdot I^{K,s}} - e^{-u^{\mathsf{T}}(\Sigma\otimes I_3)u/2}\Big| \le |u|\Big\{\mathbb{E}|T_s + \widetilde{N}| + (\mathbb{E}|M_k - M_k^0|^2)^{1/2}\Big\} \\ + \sum_j \Big\{\tfrac{1}{2}\rho_j^0|u|^2 + \eta_j^0|u|(1+|u|)\Big\} \\ + \tfrac{1}{2}|u|^2\Big\|\sum_j S_j^0 - \Sigma\otimes I_3\Big\|_{\mathrm{op}}.\end{aligned} \tag{32.23}$$

In the last term we used $|e^{-x} - e^{-y}| \le |x-y|$ for $x, y \ge 0$. The last term is deterministic. By Proposition 32.3(5),

$$\sum_j S_j^0 = C^{a,\varepsilon,L}\otimes I_3 - C^{\mathrm{ret}}_{s,a,\varepsilon}, \qquad \|C^{\mathrm{ret}}_{s,a,\varepsilon}\| \le Cn_s^2\varepsilon/H_s,$$

and the first covariance converges to $C^{\varepsilon,L}\otimes I_3$ as $K\to\infty$ and then to $\Sigma\otimes I_3$ as $\varepsilon\downarrow 0$, uniformly in x and the lattice offset. This identification concerns the linearization of the reconstruction at the origin and the linearized coarse field; the nonlinear reconstruction is never conditioned to have zero coarse field. At each fixed s, every term on the right of (32.23) therefore vanishes in the stated iterated limit, uniformly in x and the lattice offset. In particular,

$$\lim_{\varepsilon\downarrow 0}\limsup_{K\to\infty}\sup_{x,\,\mathrm{offset}}\Big|\mathbb{E}e^{iu\cdot I^{K,s}} - e^{-u^{\mathsf{T}}(\Sigma\otimes I_3)u/2}\Big| = 0. \tag{32.24}$$

No random covariance and no compensated exponential is needed.

Step 6: the bounded-Lipschitz distance. By the conditional Poincaré inequality, we have $\mathbb{E}[|\Gamma_j(0)e_j|^2 \mid \mathcal{F}_{j-1}] \le 2\,\mathrm{tr}\,S_j^0$, and orthogonality together with (32.14) gives $\mathbb{E}|M_k^0|^2 \le C_{3m}$. With (32.22) and (32.21), this gives a bound on $\mathbb{E}|I^{K,s}|$ that is uniform in K, x, the lattice offset, and ε in a sufficiently small range at the fixed s; by Markov's inequality the tails of $I^{K,s}$ vanish uniformly. We apply (32.12) with $P' = \mathrm{Law}_{\nu_{K,s}} I^{K,s}$ and $P = N(0, \Sigma\otimes I_3)$. Its last term is bounded by the integral against $e^{-\delta^2|u|^2/2}$ of the minimum of two and the right side of (32.23), which does not depend on x or the lattice offset. By dominated convergence, this integral vanishes in the iterated limit $K\to\infty$, then $\varepsilon\downarrow 0$, for fixed A and δ. Letting then $A\to\infty$ and $\delta\downarrow 0$ proves the theorem, also for singular Σ. The dependence on s of the coarse-field constant and of the range of ε is exactly the one in the statement; no choice of s depending on ε has been made. □

Remark 32.9. Lemmas 32.4 and 32.5 are abstract finite-dimensional statements. Their application to the circulations fixes the coupling $\gamma > 0$ before s_0 is chosen, and gives estimates with the dependence described in item (5) of Definition 4.14; it does not give constants uniform as $\gamma \to 0$ at a fixed side, as would be needed for item (6). The proof of Theorem 32.8 uses no tightness of the linear and quadratic flow data; these enter in Lemma 32.11 and in the passage to the continuum measure.

The same proof applies conditionally on the first q RG steps, with error bounds that do not depend on the values of these steps. This uniformity is what makes the asymptotic independence in Section 32.8 possible; it does not follow from Theorem 32.8 itself.

Lemma 32.10. *In the setting of Definition 32.1, fix $s \geq s_0$. Write $\|h\|_{\mathrm{BL}} = \max\{\|h\|_\infty, \operatorname{Lip} h\}$. Fix an integer $q \geq 0$, and for $K - s \geq q$ let $\mathcal{F}_q = \sigma(\widehat{\theta}_0, w_1, \dots, w_q)$ be the σ-field generated by the coarse field and the fluctuation variables of the first q RG steps. Let $C \sim N(0, \Sigma \otimes I_3)$ and $\mathfrak{q}(v) = (|v_i|^2/8)_{i=1}^m$. Regular conditional probabilities can be chosen so that*

$$\lim_{\varepsilon \downarrow 0} \limsup_{K \to \infty} \sup_{x,\, \mathit{offset}} \operatorname*{ess\,sup}_{\nu_{K,s}} d_{\mathrm{BL}}\Big(\operatorname{Law}\big(I^{K,s}(\varepsilon, x) \mid \mathcal{F}_q\big), \operatorname{Law}(C)\Big) = 0. \tag{32.25}$$

The same holds with $I^{K,s}$ and C replaced by $\mathfrak{q}(I^{K,s})$ and $\mathfrak{q}(C)$. In particular, if $|B_{K,q}| \leq 1$ is any real $\mathcal{F}_q$-measurable random variable, then

$$\lim_{\varepsilon \downarrow 0} \limsup_{K \to \infty} \sup_{x,\, \mathit{offset}} \sup_{\|f\|_{\mathrm{BL}} \leq 1} \Big| \mathbb{E}_{\nu_{K,s}}\big[f(\mathfrak{q}(I^{K,s}))B_{K,q}\big] - \mathbb{E} f(\mathfrak{q}(C))\, \mathbb{E}_{\nu_{K,s}} B_{K,q} \Big| = 0. \tag{32.26}$$

The constants may depend on s and q and otherwise have the dependence of item (5) of Definition 4.14. The variable $B_{K,q}$ may depend on K, and no regularity in the values of the first q steps is required. Nothing is asserted uniformly in q.

Proof. We follow the proof of Theorem 32.8 conditionally on $\mathcal{F}_q$, and check that every error bound is deterministic and does not depend on the values of the first q steps.

Step 1: the decomposition after q steps. Since all spaces of coarse fields and fluctuation variables are finite-dimensional compact metric spaces, the explicit normalized kernels give regular conditional probabilities. Fix a realization of the first q steps. By Proposition 32.3(1), the later conditional kernels are the same kernels as before conditioning, since the restrictions at coarser scales do not alter them once their coarse field is fixed. Every such field lies in the reconstruction domain and satisfies $e^{\widehat{\theta}_{j-1}} \in B_r$, as noted in Section 31.1. The maps at the absolute levels $s + q + 1, \dots, K$ are the same reconstruction maps, with the same recursion indices. By Theorem 31.3, every zero-fluctuation continuation is defined. Thus the decomposition starting at q is

$$I^{K,s} = T_q + \sum_{j=q+1}^{K-s} \Gamma_j(\widehat{\theta}_{j-1})(w_j - \bar{w}_j) + N_q,$$

where

$$T_q = \mathcal{I}\big(\widehat{\Pi}_{K-s\leftarrow q}\widehat{\theta}_q\big), \qquad N_q = \sum_{j=q+1}^{K-s} \{\Gamma_j(\widehat{\theta}_{j-1})\bar{w}_j + Q_j^{\mathrm{Tay}}\},$$

and $\bar{w}_j$ is still the conditional mean under the conditioned Wilson measure. This is a restriction of the same telescoping sum, with no change of measure.

Step 2: bounds uniform in the first q steps. The field $\widehat{\mathcal{E}}_q^a$ of Theorem 31.3 vanishes at zero and has bounded derivative on the reconstruction domain, so $\|\widehat{\mathcal{E}}_q^a(\widehat{\theta}_q)\|_\infty \le C b_{\max}$. By its identity for circulations, the contraction of the heat semigroup, and the length bound, we have, with $a_q = H_{s+q}$,

$$|T_q| \le \frac{C b_{\max}}{g_3 a_q}\sqrt{\varepsilon}.$$

Here $b_{\max}$ is the fixed bound for the reconstruction domain. We keep the pathwise bounds of Proposition 32.3(4) and (32.19), which hold after conditioning as well; they are not restarted at $\widehat{\theta}_q$. Using the mean and variance bounds of Proposition 32.3(3), which hold for every coarse field, and the tower property, we obtain

$$\mathbb{E}[|N_q| \mid \mathcal{F}_q] \le C g_3 D_s \sqrt{\varepsilon} + C \sum_{j>q} t_j p_j \omega_j \le C g_3 D_s \sqrt{\varepsilon} + C\sqrt{\eta}\,(1 + |\log \eta|)^2.$$

For the means we used $t_j\sqrt{\varepsilon/a_j} = \lambda_B g_3 \sqrt{\varepsilon}$ and the deterministic bound on $\sum_j b_{j-1}$; for the centered part, the conditional variance and the conditional Cauchy–Schwarz inequality. These bounds vanish at fixed s and q and do not depend on the values of the first q steps. The cutoff estimates of Lemma 32.6 hold at every later coarse field. For the replacement of the coefficients by their values at the zero field, we set

$$B_{s,\varepsilon} = C r \Psi_{\kappa_*}(\varepsilon/H_s) + C\sqrt{\eta}\,(1 + |\log \eta|).$$

By the conditional Poincaré inequality and the orthogonality of martingale increments, we have

$$\begin{aligned}\mathbb{E}\Big[\Big|\sum_{j>q}\big(\Gamma_j(\widehat{\theta}_{j-1}) - \Gamma_j(0)\big)(w_j - \bar{w}_j)\Big|^2 \;\Big|\; \mathcal{F}_q\Big] &\le C\,\mathbb{E}\Big[\sum_{j>q} b_{j-1}^2 \omega_j^2 \;\Big|\; \mathcal{F}_q\Big] \\ &\le C b_{\max} B_{s,\varepsilon}.\end{aligned}$$

The last inequality follows from the pathwise bound (32.19), which holds on every sample path; its right side is deterministic and tends to zero at fixed s. Lemma 32.5 applies to this tail of the sum.

Step 3: the covariance of the tail. The coefficients $\Gamma_j(0)$ for $j > q$ are exactly the coefficients at the zero field for the coarse index $s+q$, since their defining maps are the same restrictions of the fixed family. By Theorem 31.6 at index $s+q$,

$$\sum_{j>q} \Gamma_j(0)\Gamma_j(0)^{\mathsf{T}} = C^{a,\varepsilon,L} \otimes I_3 - C^{\mathrm{ret}}_{s+q,a,\varepsilon}, \qquad \|C^{\mathrm{ret}}_{s+q,a,\varepsilon}\| \le C n^2_{s+q} \varepsilon / H_{s+q},$$

and by Lemma 31.2 the first term has the same limit $\Sigma \otimes I_3$. For every u, the conditional error in the characteristic function is therefore bounded almost surely by the sum of these deterministic remainder, coefficient, cutoff, and covariance errors, as in (32.23). This bound does not depend on the first q steps, and it vanishes in the stated order at fixed s and q. The factors $1/a_q$ and n^2_{s+q}/H_{s+q} grow with q, which is why q is fixed before the limits.

Step 4: conditional laws. By the conditional Poincaré inequality, the conditional second moment of the tail $\sum_{j>q} \Gamma_j(0)(w_j - \bar{w}_j)$ also has a deterministic bound, and the conditional first-moment bounds of Step 2 then give uniform conditional tails for $I^{K,s}$. We apply (32.12) to these conditional laws: its Fourier integral is bounded by the same deterministic envelope for the characteristic functions, and its truncation terms by these conditional tails. Choosing one null set for all rational u and using the continuity of each conditional characteristic function, we obtain an almost sure bound that does not depend on the version of the conditional law or on the test function. This proves (32.25).

Step 5: the quadratic map. By (32.13) applied to the conditional laws, with the projection onto a ball of radius A on which $\mathfrak{q}$ has Lipschitz constant at most $A/4$, and with the conditional tails outside the ball vanishing uniformly as $A \to \infty$, the statement for $\mathfrak{q}(I^{K,s})$ follows; we let $K \to \infty$ and $\varepsilon \downarrow 0$ before $A \to \infty$. Multiplying by $B_{K,q}$ and using the tower property proves (32.26). □

32.5 Wilson flow and removal of the conditioning

We now compare the normalized Wilson-loop deficits of the flowed fine configuration with the squared circulations, and remove the conditioning on the small-field event. The comparison has two parts. The first is an expansion of the trace of a product of $\mathrm{SU}(2)$ matrices to second order, with a remainder controlled by the total variation and independent of the number of links. The second is the local theory of the Wilson flow of Theorem 24.5, which writes the flowed field as the linear heat evolution plus the quadratic Picard term plus a smaller remainder. The Wilson flow is the one introduced by Lüscher [128], with time measured in physical units as in Section 2.1.

Lemma 32.11. *The following statements hold.*

1. *For every finite sequence $v_e \in \mathbb{R}^3$, with $D = \sum_e |v_e|$ and $Y = \sum_e v_e$, and every $s' > 0$,*

$$\Big| \frac{1 - \frac{1}{2}\operatorname{tr} \prod_e e^{s' v_e^a \tau_a}}{(s')^2} - \frac{|Y|^2}{8} \Big| \le \frac{s' D^3}{48} e^{s' D/2}.$$

The same bound holds for an ordered exponential along a path of finite length, with D the total variation of the integrated coefficient. The bound does not depend on the number of links.

2. *Fix $1/2 < \alpha_{\mathrm{fl}} < 2/3$ and a horizon $T_0 > 0$, and put $\beta_{\mathrm{fl}} = \alpha_{\mathrm{fl}} - 1/2$ and $\kappa_{\mathrm{fl}} = 1 - 3\alpha_{\mathrm{fl}}/2$. For the reconstruction of Definition 32.1, let $\mathfrak{x} = P^a_\cdot A^{K,s}$ be the linear heat evolution of the initial potential $A^{K,s} = a^{-1}\widehat{\theta}_k$, let $\mathfrak{y} = \mathcal{Q}_a(\mathfrak{x},\mathfrak{x})$ be its quadratic Picard term, and let $\mathcal{B}_{K,s} = \mathsf{X}^a_{\alpha_{\mathrm{fl}}}(\mathfrak{x}) + \mathsf{Y}^a_{\alpha_{\mathrm{fl}}}(\mathfrak{y})$ be the norm of the linear and quadratic flow data of Definition 4.8. For every $R < \infty$ there are $T_R \le T_0$, $a_R > 0$, $\varepsilon_R > 0$, and C_R such that, on $\{\mathcal{B}_{K,s} \le R\}$ and for $a \le \varepsilon \le \varepsilon_R$, $a \le a_R$, and $\sigma\varepsilon^2 < T_R$, the representative A_{fl} of the Wilson flow in the damping gauge of Theorem 24.5 satisfies*

$$A_{\mathrm{fl}} = \mathfrak{x} + \mathfrak{y} + v, \qquad \|v(t)\|_\infty \le C_R (t + a^2)^{\kappa_{\mathrm{fl}}}.$$

Write $Y_i = (a/\sqrt{\eta}) \sum_{e \in \ell_{i,\varepsilon,a,x}} \operatorname{sgn}(e) A_{\mathrm{fl},e}(\sigma\varepsilon^2)$ and $D_i = (a/\sqrt{\eta}) \sum_{e \in \ell_{i,\varepsilon,a,x}} |A_{\mathrm{fl},e}(\sigma\varepsilon^2)|$. Then, uniformly in x, the lattice offset, K, and s, whenever the same radius and domains apply,

$$\max_i |Y_i - I_i^{K,s}| \le C_R \varepsilon^{3/2 - 2\alpha_{\mathrm{fl}}}, \qquad \max_i \big(D_i + |I_i^{K,s}|\big) \le C_R \varepsilon^{-\beta_{\mathrm{fl}}},$$

$$\max_i \Big| \frac{1 - \frac{1}{2}\operatorname{tr} \operatorname{Hol}_{\ell_{i,\varepsilon,a,x}} \Psi^{(N_K)}_{\sigma\varepsilon^2} U}{\eta} - \frac{|I_i^{K,s}|^2}{8} \Big| \le C_R \varepsilon^{2 - 3\alpha_{\mathrm{fl}}}.$$

The representative stays in the logarithmic chart on the whole time interval:

$$a \sup_{t \le T_R} \|A_{\mathrm{fl}}(t)\|_\infty \le C_R \big\{ a^{1-\alpha_{\mathrm{fl}}} + a^{2-2\alpha_{\mathrm{fl}}} + a (T_R + a^2)^{\kappa_{\mathrm{fl}}} \big\} \longrightarrow 0 \qquad (a \to 0).$$

3. *Enlarge s_0 so that n_{s_0} also satisfies the requirement on the coarse side in Lemma 28.10 for the interval $\{\gamma\}$, the horizon T_0, and the exponent α_{fl}. For each fixed $s \ge s_0$, $\rho_s(R) = \sup_{K \ge s} \nu_{K,s}\{\mathcal{B}_{K,s} > R\} \to 0$ as $R \to \infty$. Let*

$$Z_{\varepsilon,K} = \Big(\frac{1 - \frac{1}{2}\operatorname{tr} \operatorname{Hol}_{\ell_{i,\varepsilon,a,x}} \Psi^{(N_K)}_{\sigma\varepsilon^2} U}{\eta} \Big)_{i=1}^{m}$$

be the vector of normalized Wilson-loop deficits on the fine lattice, and $\mathfrak{q}(I) = (|I_i|^2/8)_{i=1}^m$. For every $f : \mathbb{R}^m \to \mathbb{R}$ with $\|f\|_\infty \le 1$ and $\operatorname{Lip} f \le 1$,

$$\big| \mathbb{E}_{\mu_{N_K,\gamma}} f(Z_{\varepsilon,K}) - \mathbb{E}_{\nu_{K,s}} f(\mathfrak{q}(I^{K,s})) \big| \le 2\mu_{N_K,\gamma}(S^c_{N_K,n_s,\gamma}) + 2\rho_s(R) + C_R \varepsilon^{2 - 3\alpha_{\mathrm{fl}}}.$$

The constants have the dependence described in items (5) and (7) of Definition 4.14, with additional dependence on R, T_0, and α_{fl}. No expectation of an unbounded function is transferred between the two measures.

Proof. Part (1) is an algebraic expansion (Step 1). Part (2) follows from the local theory of the Wilson flow and part (1) (Steps 2–4), and part (3) combines part (2) with the tightness of the flow data and Lemma 5.5 (Step 5).

Step 1: the trace expansion. Let $B_e = v_e^a \tau_a$. Then $\|B_e\|_{\mathrm{op}} = |v_e|/2$, and $|\operatorname{tr} T|/2 \le \|T\|_{\mathrm{op}}$ for every 2×2 matrix T. In the product of the exponential series, the sum of the norms of all terms that are homogeneous of degree p is at most

$$\sum_{\sum_e p_e = p} \prod_e \frac{(s'|v_e|/2)^{p_e}}{p_e!} = \frac{(s'D/2)^p}{p!},$$

by the multinomial identity; this bound has no constant depending on the number of links. The trace of the term of degree one vanishes. The identity $\operatorname{tr}(B_e B_f)/2 = -v_e \cdot v_f/4$ gives the half-trace of the terms of degree two,

$$-\frac{(s')^2}{8} \sum_e |v_e|^2 - \frac{(s')^2}{4} \sum_{e<f} v_e \cdot v_f = -\frac{(s')^2}{8} |Y|^2.$$

The norms of all terms of degree at least three sum to at most $(s'D/2)^3 e^{s'D/2}/6$. Dividing by $(s')^2$ gives the first assertion. For an integrable connection coefficient along a path of finite length, the term of degree p of the ordered exponential series has norm at most $(s'D/2)^p/p!$, since the ordered integral is bounded by $1/p!$ times the integral of the symmetric product of the absolute coefficients. The linear term has trace zero, and the half-trace of the quadratic term is $-(s')^2 |\int v|^2/8$, since the dot product is symmetric on the two ordered halves of the square. The same remainder bound therefore proves the assertion for ordered exponentials, with $D = \int |v|$.

Step 2: the flow. Fix R, T_0, and α_{fl}, and abbreviate $\alpha = \alpha_{\mathrm{fl}}$, $\beta = \beta_{\mathrm{fl}} = \alpha - 1/2$, and $\kappa = \kappa_{\mathrm{fl}} = 1 - 3\alpha/2$. The event $\{\mathcal{B}_{K,s} \le R\}$ controls exactly the linear heat evolution, the quadratic Picard term, and all first differences required in Theorem 24.5. Indeed, the linear part is $P_\cdot^a A^{K,s}$, and the quadratic part is the ordered quadratic term of the damped Wilson equation on the same fine lattice. Restricting the horizon only decreases these norms, and the difference arrays include every forward and backward difference in the norm required by that theorem. We use its bound on the remainder of one solution and its identification with the Wilson flow, reducing its lifespan to $T_R \le T_0$ if necessary. It gives the decomposition and the bound on v, and it identifies $e^{aA_{\mathrm{fl}}}$ with the Wilson flow up to a time-dependent periodic lattice gauge transformation. The trace of a closed loop is unchanged by this gauge transformation.

The chart condition holds on the whole interval, not only at time zero. Indeed, by the two bounds on the flow data and the remainder bound, we have

$$a \sup_{t \le T_R} \|A_{\mathrm{fl}}(t)\|_\infty \le C_R\{a^{1-\alpha} + a^{1-2\beta} + a(T_R + a^2)^\kappa\}.$$

Since $1 - 2\beta = 2 - 2\alpha > 0$ and $\kappa > 0$, all terms tend to zero as $a \to 0$. The last term takes its maximum at the final time, where it is $O_R(a)$ for fixed T_R. We choose a_R below the threshold of the chart and $\varepsilon_R \le 1$ with $\sigma\varepsilon_R^2 < T_R$.

Step 3: the circulation of the flowed field. At $t_\varepsilon = \sigma\varepsilon^2$ and $a \le \varepsilon$ we have $\sigma\varepsilon^2 \le t_\varepsilon + a^2 \le (\sigma + 1)\varepsilon^2$. By the definitions of the norms and the remainder bound, we have

$$\|\mathfrak{x}(t_\varepsilon)\|_\infty \le C_\sigma R\varepsilon^{-\alpha}, \qquad \|\mathfrak{y}(t_\varepsilon)\|_\infty \le C_\sigma R\varepsilon^{-2\beta}, \qquad \|v(t_\varepsilon)\|_\infty \le C_{R,\sigma}\varepsilon^{2\kappa}. \tag{32.27}$$

The physical length of the cycle divided by $\sqrt{\eta}$ is at most $C_\ell\sqrt{\varepsilon}/g_3$. Since $I_i^{K,s} = (a/\sqrt{\eta})\sum_e \mathrm{sgn}(e)\mathfrak{x}_e(t_\varepsilon)$, multiplying the last two estimates by this factor, we obtain

$$\max_i |Y_i - I_i^{K,s}| \le C_R\{\varepsilon^{1/2-2\beta} + \varepsilon^{1/2+2\kappa}\} \le C_R\varepsilon^{3/2-2\alpha},$$

where we used $1/2 - 2\beta = 3/2 - 2\alpha$ and $1/2 + 2\kappa = 5/2 - 3\alpha > 3/2 - 2\alpha$. Multiplying all three estimates in (32.27) by the same factor, we find $D_i + |I_i^{K,s}| \le C_R\varepsilon^{-\beta}$. These constants depend on the fixed $g_3 > 0$, as allowed.

Step 4: the Wilson-loop deficit. For each oriented link we take $v_e = \mathrm{sgn}(e)aA_{\mathrm{fl},e}/\sqrt{\eta}$ and $s' = \sqrt{\eta}$ in the trace expansion of Step 1. A link traversed against its orientation contributes the inverse of the positive link variable, whose logarithm is the negative of the positive one. The resulting D and Y are exactly D_i and Y_i. In particular,

$$\sqrt{\eta}\, D_i \le C_R\varepsilon^{1-\alpha}, \qquad \sqrt{\eta}\, D_i^3 \le C_R\varepsilon^{2-3\alpha},$$

and the exponential in the trace bound is bounded for small ε. Further,

$$\big||Y_i|^2 - |I_i^{K,s}|^2\big| \le (|Y_i| + |I_i^{K,s}|)|Y_i - I_i^{K,s}| \le C_R\varepsilon^{2-3\alpha}.$$

This proves the bound on the deficit. It is deterministic on the event $\{\mathcal{B}_{K,s} \le R\}$ and uses only the length bound on the cycles, so it is uniform over x, the lattice offset, K, and s for which the same radius and domains apply.

Step 5: radius tightness and removal of the conditioning. For each fixed $s \ge s_0$, we apply Lemma 28.10, in particular (28.18), with coarse side n_s, remaining depth $K - s$, and $I = \{\gamma\}$; the enlargement of s_0 in part (3) makes n_s an admissible coarse side for that lemma. Its fine potential is $A^{K,s} = a^{-1}\widehat{\theta}_{K-s}$, by the definition of the reconstruction, and no interpolation is involved at the fine lattice. Its tightness statement on the horizon T_0 is exactly $\rho_s(R) \to 0$, at fixed s and fixed positive coupling.

Finally, $Z_{\varepsilon,K}$ is a gauge-invariant function of the fine configuration, so on the small-field event it takes the same value whether it is evaluated on the link variables of the fine configuration or on the reconstructed representative. Lemma 5.5, applied to the bounded function $f(Z_{\varepsilon,K})$, shows that replacing $\mu_{N_K,\gamma}$ by $\nu_{K,s}$ costs at most $2\mu_{N_K,\gamma}(S^c_{N_K,n_s,\gamma})$; the event has positive probability, since $\nu_{K,s}$ is defined. Under $\nu_{K,s}$, the difference between $f(Z_{\varepsilon,K})$ and $f(\mathfrak{q}(I^{K,s}))$ is at most $C_R\varepsilon^{2-3\alpha}$ on $\{\mathcal{B}_{K,s} \le R\}$, where the dimension m is absorbed into C_R, and at most two on its complement. Adding these bounds proves the last inequality. □

The next lemma restates the Gaussian limits in the form in which they are applied below. Since every input of the preceding proofs is available at each fixed coupling $0 < \gamma \le \Gamma$ by Lemma 31.10, it requires no new argument.

Lemma 32.12. *In the setting of Lemma 31.10, every fixed $s \ge s_0$ satisfies the conclusion of Theorem 32.8. Moreover, for every fixed $q \ge 0$ the conclusions of Lemma 32.10 hold, including the essential supremum over the values of the first q RG steps, with $\mathcal{F}_q = \sigma(\widehat{\theta}_0, w_1, \dots, w_q)$. In particular, with $C \sim N(0, \Sigma \otimes I_3)$,*

$$\lim_{\varepsilon\downarrow 0} \limsup_{K\to\infty} \sup_{x,\,\mathit{offset}} \operatorname{ess\,sup} d_{\mathrm{BL}}\big(\mathrm{Law}(I^{K,s} \mid \mathcal{F}_q), \mathrm{Law}(C)\big) = 0,$$

and the same holds after applying $\mathfrak{q}(v) = (|v_i|^2/8)_{i=1}^m$. The constants have the dependence described in item (5) of Definition 4.14, with additional dependence on q; nothing is asserted for q growing with ε or K. Definition 32.1 and the conclusions of Lemmas 32.4 to 32.6 and 32.11 also hold in this setting; for the last one, only the radius tightness at a fixed coarse side is used.

Proof. We check the inputs of the local tools. Lemmas 32.4 and 32.5 are finite-dimensional statements; the conditional fluctuation kernels satisfy the Poincaré hypothesis by Proposition 32.3(1). The decomposition in Lemma 32.6 is an exact finite sum, and its cutoff estimates use the conditions on the number of blocks and on the means, and the decay of the cutoff error, which hold by Step 1 of the proof of Theorem 31.5 and (31.9). Hence every cutoff estimate holds with the same constants. Lemma 32.11 uses Theorem 24.5 for the linear and quadratic flow data on the fine lattice, the identity of Theorem 15.13 between the reconstructed field and the fine configuration, and the trace expansion; these deterministic arguments need no bound on γ, and the removal of the radius uses (28.18). None of these checks uses a limiting random variable for the flow data.

By Lemma 31.10, all five inputs of Proposition 32.3 hold at this fixed coupling, with the stated independence of s. The proofs of Theorem 32.8 and Lemma 32.10 therefore apply with these inputs. In the conditional proof, the pathwise bounds of Proposition 32.3(4) are kept, not restarted; the coarse-field term after q steps is bounded by $Cb_{\max}\sqrt{\varepsilon}/(g_3 a_q)$, and the coarse covariance by $Cn_{s+q}^2\varepsilon/H_{s+q}$. Thus q remains fixed before both limits. □

32.6 The continuum limit

We now pass to the continuum measure, with the limits in the order displayed at the beginning of the section. The final limit removes the conditioning error, whose available bound $F_\Gamma(n_s)$ tends to zero as $s \to \infty$ and is independent of K. In the theorem below, the class $[n_*]$ in the subscript of $\lambda_{L,\gamma,[n_*]}$ is the class $[n_*]_M$ of Theorem 29.28.

Theorem 32.13. *Fix $L > 0$, an odd integer $M \geq 3$, an equivalence class $[n_*]_M$ of lattice sides, and any $\gamma > 0$. Choose $\Gamma \geq \gamma$ and the parameters of Theorem 23.5, and let $\lambda_{L,\gamma,[n_*]}$ be the continuum measure of Theorem 2.3. For every finite family of smooth closed loops $\ell_1, \dots, \ell_m$ in $\mathbb{R}^3$ and every $\sigma > 0$, put $g_3^2 = \gamma / L$ and*

$$Z_\varepsilon(x) = \Big(\frac{1 - W_{x+\varepsilon\ell_i, \sigma\varepsilon^2}}{g_3^2 \varepsilon} \Big)_{i=1}^m .$$

Then

$$\lim_{\varepsilon \downarrow 0} \sup_{x \in \mathbb{T}_L^3} d_{\mathrm{BL}}\big(\mathrm{Law}_{\lambda_{L,\gamma,[n_*]}} Z_\varepsilon(x), \mathrm{Law}\, Z_G \big) = 0, \qquad Z_G = (|C_i|^2/8)_{i=1}^m,$$

where the three color components of C are independent centered Gaussian vectors with covariance

$$\Sigma_{ih} = (2\pi)^{-3} \int_{\mathbb{R}^3} \frac{e^{-2\sigma|k|^2}}{|k|^2} \overline{\widehat{J}_i(k)} \cdot \widehat{J}_h(k)\, dk, \qquad \widehat{J}_i(k) = \int_0^1 \dot{\ell}_i(v) e^{-ik\cdot \ell_i(v)}\, dv.$$

Degenerate covariances and repeated or reversed loops are allowed. Every sufficiently large fixed coarse index satisfies the conclusion of Lemma 32.12 for the circulations. The limits are taken in the order described above. The constants have the dependence described in item (5) of Definition 4.14; no rate uniform in the coupling, in the coarse index, or as $\sigma \downarrow 0$ is asserted.

Proof. By Lemma 31.2(1), $k \cdot \widehat{J}_i(k) = 0$ and $|\widehat{J}_i(k)| \leq C \min\{|k|, 1\}$, so Σ is finite, real, symmetric, and positive semidefinite, and its positive square root constructs the three color vectors. This is the covariance of Definition 31.1, and Lemma 31.10 shows that the results of Section 31 apply at this coupling.

Let $F_\Gamma(n_s)$ be the supremum over $0 < \gamma' \leq \Gamma$ of the bound in Theorem 23.10 at coarse side n_s; by that theorem, $F_\Gamma(n_s) \to 0$ as $s \to \infty$. At fixed s, let $\rho_s(R)$ be the radius tail of Lemma 32.11, which tends to zero by (28.18) with $I = \{\gamma\}$. Let $Z_{\varepsilon,K}(x)$ be the vector of normalized Wilson-loop deficits of Lemma 32.11 for the lattice cycles approximating $x + \varepsilon\ell_i$. By that lemma and the triangle inequality, for every function f with $\|f\|_\infty \leq 1$ and $\mathrm{Lip}\, f \leq 1$,

$$\big| \mathbb{E}_{\mu_{N_K,\gamma}} f(Z_{\varepsilon,K}(x)) - \mathbb{E} f(Z_G) \big| \leq 2F_\Gamma(n_s) + 2\rho_s(R) + C_R \varepsilon^{2-3\alpha_{\mathrm{fl}}} + d_{\mathrm{BL}}\big(\mathrm{Law}_{\nu_{K,s}}\, \mathfrak{q}(I^{K,s}), \mathrm{Law}\, Z_G \big).$$

For each fixed $\varepsilon > 0$ and x, the joint convergence of flowed Wilson loops, Theorems 29.23 and 29.24, implies that $\mathbb{E}_{\mu_{N_K,\gamma}} f(Z_{\varepsilon,K}(x)) \to \mathbb{E}_{\lambda_{L,\gamma,[n_*]}} f(Z_\varepsilon(x))$ as $K \to \infty$; the lattice cycles are admissible approximations of the loops $x + \varepsilon\ell_i$. The bound above is uniform in x and the lattice offset. To see that the identification at fixed ε is compatible with this uniformity, we translate the lattice sequence by a lattice vector so that the base point is near a vertex, and use the allowed lattice approximation of the translated loops; the additional swept area is $O(\varepsilon a)$, a connecting path and its inverse do not change the trace, and the laws of the fine lattice and of the continuum are invariant under translations. At fixed ε all deficits lie in the compact cube $[0, 2/(g_3^2\varepsilon)]^m$, so a finite net of test functions with $\|f\|_\infty \le 1$ and $\operatorname{Lip} f \le 1$ makes this passage to the limit uniform over all such test functions. We let $K \to \infty$, and then $\varepsilon \downarrow 0$, using the statement for $\mathfrak{q}(I^{K,s})$ in Lemma 32.12 and $2 - 3\alpha_{\mathrm{fl}} > 0$. What remains is $2F_\Gamma(n_s) + 2\rho_s(R)$. We let $R \to \infty$ at fixed s, and only then $s \to \infty$. This proves the theorem. For the full class $[n_*]_M$, the continuum measure was identified in Theorem 29.28; the argument above needs only one subsequence $N_K = n_* B^K$. □

32.7 A uniform short-distance variance lower bound

Corollary 32.14. *In Theorem 32.13 take $m = 1$, write $\ell = \ell_1$ and $v = \Sigma_{11}$, and let $D_{\varepsilon,x} = (1 - W_{x+\varepsilon\ell,\sigma\varepsilon^2})/(g_3^2\varepsilon)$. Then*

$$\liminf_{\varepsilon\downarrow 0} \inf_x \operatorname{Var}_{\lambda_{L,\gamma,[n_*]}} D_{\varepsilon,x} = \liminf_{\varepsilon\downarrow 0} \inf_x \frac{\operatorname{Var}_{\lambda_{L,\gamma,[n_*]}} W_{x+\varepsilon\ell,\sigma\varepsilon^2}}{(g_3^2\varepsilon)^2} \ge \frac{3v^2}{32}. \tag{32.28}$$

If $\widehat{J}_1 \not\equiv 0$, then $v > 0$, and for every sufficiently small fixed ε the observable $W_{x+\varepsilon\ell,\sigma\varepsilon^2}$ is not almost surely constant, for every x. The threshold for ε may depend on the data listed in item (5) of Definition 4.14.

Proof. For independent copies D and D' of a random variable with finite variance, $\operatorname{Var} D = \mathbb{E}(D - D')^2/2$. At each fixed scale the variance is finite, since $0 \le D_{\varepsilon,x} \le 2/(g_3^2\varepsilon)$. By Theorem 32.13, the laws of pairs of independent copies converge, uniformly in x, to the law of independent copies Z and Z' of $v\chi_3^2/8$, where χ_3^2 is a chi-square variable with three degrees of freedom: on compact sets, approximate a bounded continuous function of two variables by finite sums of products, and use the uniform tails of the marginals on the complement. Applying this to the bounded continuous function $\min\{A, (u-u')^2\}$ and then letting $A \to \infty$, we find that the left side of (32.28) is at least $\mathbb{E}(Z - Z')^2/2 = \operatorname{Var} Z = 3v^2/32$. A nonzero continuous function $\widehat{J}_1$ is nonzero on an open set, on which the positive weight in the integral defining v has positive integral, so $v > 0$. The strict lower bound then gives a common threshold below which the observable is not constant. No moment is transferred from the Wilson measure. □

32.8 Asymptotic independence from macroscopic Wilson loops

The small-loop deficits are asymptotically independent of fixed macroscopic flowed Wilson loops. The reason is that a macroscopic flowed Wilson loop is approximated, on the same probability space, by a function of the first q RG steps, while the Gaussian limit of Lemma 32.10 holds uniformly conditionally on these steps. The approximation must have constants independent of the higher derivatives of the finite-scale reconstruction, which grow with q; this is provided by the stability estimate Corollary 25.11.

Lemma 32.15. *In the setting of Definition 32.1, fix $s \geq s_0$, finitely many piecewise C^1 closed loops Γ_r in $\mathbb{T}^3_L$, times $t_r > 0$, and characters χ_r of finite-dimensional representations of $\mathrm{SU}(2)$, $1 \leq r \leq b$. Use lattice approximations $\Gamma_{r,K}$ of bounded physical length and swept area $O(a)$, and let*

$$V_{K,r} = \chi_r\big(\mathrm{Hol}_{\Gamma_{r,K}} \Psi_{t_r}^{(N_K)}(U)\big), \qquad \mathbf{V}_K = (V_{K,r})_{r=1}^{b}$$

be the vector of flowed Wilson loops of the fine configuration under $\nu_{K,s}$. There are $\mathcal{F}_q$-measurable random vectors $\mathbf{V}_K^{[q]}$ on the same probability space such that

$$\lim_{q\to\infty} \limsup_{K\to\infty} \mathbb{E}_{\nu_{K,s}} \min\big\{2, |\mathbf{V}_K - \mathbf{V}_K^{[q]}|\big\} = 0. \tag{32.29}$$

The vector $\mathbf{V}_K^{[q]}$ consists of the flowed Wilson loops of the finite-scale reconstruction $U_K^{[q]} = \exp(a I_{a_q \to a} A_q)$, with the same times and lattice paths, where $A_q = \widehat{\theta}_q / a_q$, $a_q = H_s B^{-q}$, and $I_{a_q\to a}$ is the cardinal interpolation of Lemma 28.10. The approximation does not depend on ε, x, or any test function of the small loops. The constants have the dependence described in item (7) of Definition 4.14, at fixed coupling and with s fixed.

Proof. We use the cardinal interpolation and the notation of Lemma 28.10. On the fine lattice the linear and quadratic flow data of the finite-scale reconstruction are

$$x_q = P_\cdot^a I_{a_q\to a} A_q, \qquad y_q = \mathcal{Q}_a(x_q, x_q).$$

This is the cardinal interpolation of the field at index q; we do not claim that it equals the nonlinear zero-fluctuation continuation. Its link variables and their Wilson flow are defined without any small-field event of their own. At fixed q the field A_q ranges over a fixed compact set and its cardinal interpolation is smooth, as in Lemma 28.4. The construction uses only $\widehat{\theta}_q$, so it is $\mathcal{F}_q$-measurable.

Fix $1/2 < \alpha < 2/3$ and a horizon $T_0 > 0$, and set

$$d_{K,q} = \mathsf{X}_\alpha^a(x_{K-s} - x_q) + \mathsf{Y}_\alpha^a(y_{K-s} - y_q), \qquad \mathcal{B}_{K,s} = \mathsf{X}_\alpha^a(x_{K-s}) + \mathsf{Y}_\alpha^a(y_{K-s}).$$

Both norms include every first difference on the common lattice. The exact bilinear decomposition of $y_{K-s} - y_q$ and the estimates of Lemma 28.10 on the linear term and on the two mixed terms and the quadratic term imply, for every $\delta > 0$,

$$\lim_{q\to\infty} \sup_{K \geq s+q} \nu_{K,s}\{d_{K,q} > \delta\} = 0. \tag{32.30}$$

The linear part is bounded by Markov's inequality and the tail estimate for the linear term; the quadratic part is bounded by the sum of the tail estimates for the mixed terms and the quadratic term, each with threshold $\delta/3$. The radius tail $\rho_s(R) = \sup_{K \geq s} \nu_{K,s}\{\mathcal{B}_{K,s} > R\}$ tends to zero by (28.18).

Fix R and $0 < \delta \leq 1$. On the event $\{\mathcal{B}_{K,s} \leq R,\ d_{K,q} \leq \delta\}$, both pairs of flow data lie in the ball of radius $R+1$. Let

$$0 < u_R < \tfrac{1}{4} \min\{T_{R+1}, T_0, \min_r t_r\}.$$

By the estimate of Theorem 24.5 for differences on the same lattice, we have, at this early time,

$$\|A_a(u_R) - A_a^{[q]}(u_R)\|_{C_a^1} \leq C_{R,u_R} d_{K,q}, \qquad \|A_a(u_R)\|_{C_a^1} + \|A_a^{[q]}(u_R)\|_{C_a^1} \leq K_R < \infty.$$

Both damping gauges start at the identity. By Theorems 15.13 and 24.5, the first damped solution represents the Wilson flow of the fine configuration, and the second represents the Wilson flow started from $U_K^{[q]}$. Since each character is gauge invariant, both flows may be restarted from these damped fields at time u_R for the purpose of evaluating their later traced loops.

We apply Corollary 25.11 with radius $R+1$, input horizon T_0, early time $u = u_R$, $\tau = \min_r t_r$, $T = \max_r t_r$, the given characters, and the fixed bounds on the lengths of the paths. Both pairs of flow data lie in that ball on the stated event, in the same initial gauge, and the discrepancy in that corollary is exactly $d_{K,q}$. It gives

$$|\mathbf{V}_K - \mathbf{V}_K^{[q]}| \leq C_{R,u_R,\mathbf{t},\mathbf{\Gamma},\chi}\, d_{K,q}, \tag{32.31}$$

for the whole vector of characters, including the normalized fundamental traces. The constant in (32.31) depends on the radius and on the fixed waiting time, but not on the higher derivatives of the finite-scale reconstruction, which grow with q; the threshold for the mesh depends on R, u_R, and the loops, but not on q. For all sufficiently fine meshes it follows that

$$\mathbb{E} \min\{2, |\mathbf{V}_K - \mathbf{V}_K^{[q]}|\} \leq 2\rho_s(R) + 2\nu_{K,s}\{d_{K,q} > \delta\} + C_R\delta. \tag{32.32}$$

We let $q \to \infty$ at fixed s, R, and δ, using (32.30), then $\delta \downarrow 0$, and finally $R \to \infty$. This proves the claim on the same finite probability spaces, without coupling different cutoffs. □

Theorem 32.16. *Assume the setting of Theorem 32.13. Fix, independently of ε and x, a finite vector $\mathbf{V} = (\chi_r(\mathrm{Hol}_{\Gamma_r} X(t_r)))_{r=1}^b$ of characters of holonomies of the trajectory X around piecewise C^1 closed loops Γ_r in $\mathbb{T}_L^3$ at times $t_r > 0$. Then*

$$\limsup_{\varepsilon \downarrow 0} \sup_x \sup_{\|f\|_{\mathrm{BL}}, \|g\|_{\mathrm{BL}} \leq 1} \left| \mathbb{E}_{\lambda_{L,\gamma,[n_*]}}[f(Z_\varepsilon(x)) g(\mathbf{V})] - \mathbb{E} f(Z_G)\, \mathbb{E}_{\lambda_{L,\gamma,[n_*]}} g(\mathbf{V}) \right| = 0, \tag{32.33}$$

where $\|h\|_{\mathrm{BL}} = \max\{\|h\|_\infty, \operatorname{Lip} h\}$. *The constants have the dependence described in items (5) and (7) of Definition 4.14. Nothing is asserted uniformly in a growing family of macroscopic loops, as* $\gamma \downarrow 0$, *as* $\sigma \downarrow 0$, *or as* $\min_r t_r \downarrow 0$.

Proof. On the probability space of $\nu_{K,s}$, let $\mathbf{V}_K$ be the vector of flowed Wilson loops of the fine configuration and $\mathbf{V}_K^{[q]}$ the $\mathcal{F}_q$-measurable approximation of Lemma 32.15. By (32.32),

$$a_{K,s,q} = \mathbb{E}_{\nu_{K,s}} \min\{2, |\mathbf{V}_K - \mathbf{V}_K^{[q]}|\} \le 2\rho_s(R) + 2\nu_{K,s}\{d_{K,q} > \delta\} + C_R\delta.$$

Let $\Delta_{K,s,q}(\varepsilon)$ be the deterministic bound on the conditional bounded-Lipschitz distance for the squared circulations from Lemma 32.12. Multiplying by $g(\mathbf{V}_K^{[q]})$, which is $\mathcal{F}_q$-measurable and bounded by one, and using the tower property, we obtain an error of at most $\Delta_{K,s,q}(\varepsilon)$ against the independent Gaussian factor. Replacing $g(\mathbf{V}_K^{[q]})$ by $g(\mathbf{V}_K)$, in the product and in its separate expectation, costs at most $2a_{K,s,q}$, since $|g(\mathbf{V}_K) - g(\mathbf{V}_K^{[q]})| \le \min\{2, |\mathbf{V}_K - \mathbf{V}_K^{[q]}|\}$. Replacing $f(\mathfrak{q}(I^{K,s}))$ by the deficits $f(Z_{\varepsilon,K}(x))$ costs at most $2\rho_s(R) + C_R\varepsilon^{2-3\alpha_{\mathrm{fl}}}$, by Lemma 32.11. Finally, two applications of Lemma 5.5, to the product and to the expectation of $g(\mathbf{V}_K)$, transfer from $\nu_{K,s}$ to $\mu_{N_K,\gamma}$ at a cost of at most $4F_\Gamma(n_s)$. Thus the error under the Wilson measure is at most

$$4F_\Gamma(n_s) + 2\rho_s(R) + C_R\varepsilon^{2-3\alpha_{\mathrm{fl}}} + 2a_{K,s,q} + \Delta_{K,s,q}(\varepsilon).$$

For fixed ε, x, f, and g, the joint law of the deficits and of $\mathbf{V}_K$ under $\mu_{N_K,\gamma}$ converges to the corresponding joint law under $\lambda_{L,\gamma,[n_*]}$, by Theorems 29.23 and 29.24 applied to the union of the two families of loops. The bound above does not depend on x, f, or g, so it also bounds their supremum after this identification. We let $K \to \infty$, then $\varepsilon \downarrow 0$ at fixed s, R, q, and δ. Next we let $q \to \infty$, using (28.17) to bound $\sup_{K \ge s+q} \nu_{K,s}\{d_{K,q} > \delta\}$, then $\delta \downarrow 0$, then $R \to \infty$ at this s, and finally $s \to \infty$. The bound vanishes. □

32.9 Asymptotic independence from bounded Borel functions

The last theorem extends the asymptotic independence to every fixed bounded Borel function on the trajectory space. In the terminology of Rényi, as discussed by Aldous and Eagleson [4], it says that $Z_\varepsilon(x)$ converges mixingly relative to the Borel σ-field of $\mathcal{X}_L$, uniformly in x and over test functions with $\|f\|_{\mathrm{BL}} \le 1$: the limit is independent of that σ-field. This only names the mode of convergence.

Theorem 32.17. *Assume the setting of Theorem 32.16, with* $Z_\varepsilon(x)$ *and* Z_G *as there. For every bounded Borel function* $H : \mathcal{X}_L \to \mathbb{R}$, *chosen independently of* ε *and* x,

$$\lim_{\varepsilon \downarrow 0} \sup_{x \in \mathbb{T}_L^3} \sup_{\|f\|_{\mathrm{BL}} \le 1} \left| \mathbb{E}_{\lambda_{L,\gamma,[n_*]}}[f(Z_\varepsilon(x))H] - \mathbb{E} f(Z_G)\, \mathbb{E}_{\lambda_{L,\gamma,[n_*]}} H \right| = 0.$$

In particular this holds for $H = h \circ i^{1,2}$, for every bounded Borel function h on the space of Sobolev trajectories, where $i^{1,2}$ is the map of Definition 29.1. The approximations in the proof may depend on H and $\lambda_{L,\gamma,[n_*]}$. There is no supremum over H, and nothing is asserted for H depending on ε or x.

Proof. Let $\lambda = \lambda_{L,\gamma,[n_*]}$. By Theorem 29.3, the Borel σ-field of $\mathcal{X}_L$ is generated by the determining coordinates w_j, $j \geq 1$, which are normalized fundamental Wilson loops. We first approximate H in $L^1(\lambda)$ by a bounded Lipschitz function of finitely many of these coordinates.

The events A whose indicators can be approximated in $L^1(\lambda)$ by $[0,1]$-valued Borel functions of finitely many coordinates form a σ-field. It contains the events determined by finitely many coordinates. It is closed under complements, and under finite unions by the Lipschitz map $(s_1, s_2) \mapsto \max\{s_1, s_2\}$ on $[0,1]^2$; for a countable union, we first truncate to a finite union whose indicator has small L^1 error, by continuity of λ from below. Hence it contains every Borel event, and approximating a bounded H by simple functions gives approximations bounded by $\|H\|_\infty$.

Next, a bounded Borel function of $(w_1, \dots, w_q)$ can be approximated by a bounded Lipschitz function. The law λ_q of $(w_1, \dots, w_q)$ is a Borel probability measure on the compact cube $[-1,1]^q$, so each Borel set A has a compact subset K_A and a relatively open superset O_A with $\lambda_q(O_A \setminus K_A)$ arbitrarily small; indeed, the sets with this property contain the compact sets, by continuity from above along decreasing open neighborhoods, and they form a σ-field, by choosing the outer errors summably and keeping finitely many inner compact sets. If the relative complement of O_A is nonempty, it has positive distance d_A from K_A, and $\max\{0, 1 - \operatorname{dist}(\cdot, K_A)/d\}$ with $0 < d < d_A$ is Lipschitz, equals one on K_A, and vanishes outside O_A; in the remaining cases we use constants. Its $L^1(\lambda_q)$ distance to $\mathbf{1}_A$ is at most $\lambda_q(O_A \setminus K_A)$. Applying this to the indicators of a simple function, extending the resulting Lipschitz function from the cube to $\mathbb{R}^q$ by the distance-cone extension, and truncating at $\|H\|_\infty$, we find for every $\eta' > 0$ a bounded Lipschitz function $g_{\eta'} : \mathbb{R}^q \to \mathbb{R}$ with

$$H_{\eta'} = g_{\eta'}(w_1, \dots, w_q), \qquad \mathbb{E}_\lambda |H - H_{\eta'}| < \eta'.$$

Both q and the Lipschitz constant are fixed before the loops shrink.

Let $\mathbf{V} = (2w_1, \dots, 2w_q)$. Its components are fundamental characters, so $\mathbf{V}$ satisfies the hypotheses of Theorem 32.16. We apply that theorem to the function $z \mapsto g_{\eta'}(z/2)/A_{\eta'}$, where $A_{\eta'} = \max\{1, \|g_{\eta'}\|_\infty, \operatorname{Lip} g_{\eta'}\}$. This function is bounded by one and has Lipschitz constant at most one, and its value at $\mathbf{V}$ is $H_{\eta'}/A_{\eta'}$. Multiplying by $A_{\eta'}$, we find that the expression in the statement with $H_{\eta'}$ in place of H tends to zero, uniformly in x and in f with $\|f\|_{\mathrm{BL}} \leq 1$. Replacing $H_{\eta'}$ by H costs at most

$$\mathbb{E}_\lambda |H - H_{\eta'}| + |\mathbb{E} f(Z_G)| \, \mathbb{E}_\lambda |H - H_{\eta'}| \leq 2\eta',$$

uniformly in these variables and in ε. We let $\varepsilon \downarrow 0$ and then $\eta' \downarrow 0$. Finally, by Theorem 30.5 the map $i^{1,2}$ is Borel, so $h \circ i^{1,2}$ is an admissible H; no continuity of $i^{1,2}$ is used. □

Proof of Theorem 2.8. Let $\lambda = \lambda_{L,\gamma,[n]_M}$ with n divisible by four. Part (1) is Theorem 32.13, applied with $n_* = n$ and any $\Gamma \geq \gamma$; its covariance Σ is the matrix in (2.6). Part (2) is Corollary 32.14. Part (3) is Theorem 32.17, applied to the bounded Borel function G. □

PART XI

Weak-coupling asymptotics near flat connections

SECTION 33

Laplace asymptotics near flat connections

This section begins the analysis of weak coupling. We fix the side n of the coarse lattice and let $\gamma \to 0$. Then every scale of the renormalization group is weakly coupled. The law of the coarsest field V^{JK} under the conditioned Wilson measure is the stopped measure $\widehat{\nu}$ of Theorem 14.8, and it concentrates near the flat configurations on Λ_n. We study $\widehat{\nu}$ by Laplace's method on the finite-dimensional space $\mathcal{U}_n$, uniformly in the number of averaging steps that precede the coarse lattice. The results are used in Sections 34 to 36 to prove Theorems 2.9 to 2.11; nothing in Sections 31 and 32 depends on this section.

We prove four main results. Throughout, $g^2 = \gamma/n$ and $E_0 = 4\sum_p q(V_p)$ is the Wilson action on Λ_n.

1. Theorem 33.10 shows that the partition function of $\widehat{\nu}$ is comparable to γ^{3n^3-1}, uniformly in the depth, for sufficiently small $\gamma \in (0, \gamma_0]$, and that the integral of $e^{-\kappa E_0/g^2}$ over all of $\mathcal{U}_n$ is $O(g^{6n^3-2})$.
2. Theorem 33.8 constructs coordinates near the trivial connection in which the $6n^3 - 6$ nonconstant directions transverse to the gauge orbits are nondegenerate for the effective classical action E_d, uniformly in d, and integrates these directions out by Laplace's method. What remains is an integral over the nine constant coordinates in the Lie algebra, in which E_d has no positive quadratic part; this integral is analyzed in Section 36.
3. Theorem 33.11 computes, in the continuum and on the lattice, the covariance Σ_θ of the linearization of the flowed cycle logarithms at a regular flat connection, under the Gaussian measure defined by the quadratic part of the Yang–Mills action.
4. Proposition 33.12 shows that, transverse to a compact patch of regular flat configurations, $\widehat{\nu}$ is Gaussian up to errors of order $\sqrt{\gamma}$. It also shows that the lattice covariance Σ_θ^N decomposes exactly into a contribution of the coarse lattice and contributions of the normalized fluctuation variables of each RG step.

The tools are an analysis of the cone of commuting triples in $\mathfrak{su}(2)^3$ (Lemma 33.2) and a Laplace estimate in normal coordinates that is uniform in an arbitrary tangential weight (Lemma 33.3 and Corollary 33.4).

The inputs from earlier sections are the stopped density and its estimates (Theorem 14.8), the description of flat configurations and of their refinements (Lemma 14.9), bounds and symmetries of the effective classical actions (Theorems 10.11 and 11.2

and Lemma 10.8), the triangular change of variables of one RG step (Theorem 12.13), and the reconstruction maps $\widehat{\mathscr{R}}$ (Theorem 15.12).

The exponent. We work modulo based gauge transformations, that is, lattice gauge transformations equal to the identity at a fixed root. This quotient still carries the simultaneous conjugation of the cycle holonomies; see Section 33.1. The exponent $6n^3 - 2$ in Theorem 33.10 comes from the following count of directions.

Directions	Dimension	Factor in $\widehat{Z}$
Based gauge quotient of $\mathcal{U}_n$	$6n^3 + 3$	ambient space
Regular flat configurations	$5 = 3 + 2$	tangential volume
Normal to a regular flat configuration	$6n^3 - 2$	g^{6n^3-2}
Nonconstant transverse directions near I	$6n^3 - 6$	g^{6n^3-6}
Normal to a nonzero commuting triple	4	g^4
Constant modes with $\lvert X\rvert \le \sqrt{g}$	9	$g^{9/2}$

The five flat directions are the three holonomy angles and the two directions in which simultaneous conjugation moves the common axis of the holonomies. Near a regular flat configuration the normal integral directly gives g^{6n^3-2}. Near the trivial connection the count is less direct. We write the constant modes as $X \in \mathfrak{su}(2)^3 \simeq \mathbb{R}^9$. On the constant configurations $e^{X/n}$ the Wilson action is comparable to $Q(X)/n$, where $Q(X) = 2^{-1}\sum_{i<j}|x_i \times x_j|^2$, and Q vanishes exactly on the cone $\mathcal{M}$ of commuting triples. Near a commuting triple of radius ϱ, the volume element of $\mathcal{M}$ is proportional to $\varrho^4\, d\varrho$, and in each of the four normal directions Q grows like $\varrho^2|b|^2/2$ (Lemma 33.2). Each normal Gaussian width is then of order g/ϱ, and the product $\varrho^4(g/\varrho)^4\, d\varrho = g^4\, d\varrho$ integrates to $O(g^4)$ over a bounded range of radii. The ball of radius $\sqrt{g}$ contributes only $O(g^{9/2})$. With the factor g^{6n^3-6} from the nonconstant directions, we again obtain $g^{6n^3-2} = (\gamma/n)^{3n^3-1}$. The same count indicates that the measure $e^{-Q(Y)}dY$ on $\mathbb{R}^9$ has infinite total mass. This divergence of the bosonic three-matrix SU(2) integral is known [7, 121, 122]; see also Section 36. In this section e^{-Q} is only integrated over bounded sets.

Two normalizations. Two normalizations of the exponent occur. In Section 33.5 we write the exponent of $\widehat{\nu}$ as E_d/g^2 and use the Laplace parameter $g^2 = \gamma/n$. In Sections 33.6 and 33.8 we write it as nE_d/γ and use the Laplace parameter γ. These are the same exponent, since

$$\frac{E_d}{g^2} = \frac{nE_d}{\gamma}.$$

Accordingly the normal Hessians H_d in Lemma 33.9 and Proposition 33.12 are Hessians of nE_d.

Constants. Constants in results about $\widehat{\nu}$ may depend on n, L, M, J, the parameter tuple Θ, the coupling bound γ_0, and on fixed patches, charts, and test functions, all chosen before

γ; this is the dependence described in item (6) of Definition 4.14. They do not depend on the depth d or on $\gamma \in (0, \gamma_0]$. All spectral gaps are proved at the fixed side n, and we prove no bound that is uniform in n. The general Laplace estimates of Section 33.4 state their own finite-dimensional dependence, as in item (1) of Definition 4.14.

Earlier work. Laplace's method in the directions normal to a manifold of critical points is rooted in Bott's theory of nondegenerate critical manifolds [31]; see Wong [155] for the asymptotic analysis of integrals. We use no specific theorem from these works. The estimates we need are uniform in the depth, the coupling, and an arbitrary tangential weight; they are proved in Section 33.4, and the singular tip of the cone of commuting triples is treated separately. The special role of the constant modes on a finite periodic torus in weak-coupling analysis is well known in the physics literature; see Lüscher [127] and the computation of the zero-momentum contribution to Wilson loops by Coste, González-Arroyo, Jurkiewicz, and Korthals Altes [62]. For the gradient flow on a four-dimensional periodic torus, Fodor, Holland, Kuti, Nógrádi, and Wong [91] separate constant and nonconstant modes and their flowed observables. These works do not treat the fixed-side three-dimensional normalization or the covariance of flowed based cycle logarithms. The decomposition of the covariance across scales in Proposition 33.12 is completion of squares for Gaussian measures; the work lies in matching it with the constrained coordinates of the renormalization group.

33.1 Preliminaries

Lie-algebra conventions. We use the conventions of Section 4. Let $\tau_a = -i\sigma_a/2$, where σ_a are the Pauli matrices, and write $X = x^a \tau_a \in \mathfrak{su}(2)$. Then $[\tau_a, \tau_b] = \epsilon_{abc}\tau_c$, $\langle X, Y\rangle = -2\,\mathrm{tr}(XY)$, and $|X| = |x|$, so that the bracket corresponds to the cross product in $\mathbb{R}^3$. We identify $\mathfrak{su}(2)^3$ with $\mathbb{R}^9$ by $X = (x_1, x_2, x_3)$ and use the Euclidean norm $|X|$. In exponential coordinates

$$dH(e^X) = \frac{1}{16\pi^2}\,\mathrm{sinc}^2(|X|/2)\,d^3X, \qquad q(e^X) = 1 - \cos(|X|/2) = \frac{|X|^2}{8} + O(|X|^4),$$

by (4.2). The logarithm Log is the inverse of exp on $\{|X| < 2\pi\}$.

Based gauge transformations. Fix a root $x_* \in \Lambda_n$. A lattice gauge transformation k is *based* if $k_{x_*} = I$. The group of based gauge transformations acts freely on $\mathcal{U}_n$, and we call the quotient the based quotient. Constant gauge transformations are not divided out: they act on the based quotient, and on the holonomies around the three coordinate cycles based at x_* they act by simultaneous conjugation. In the proof of Theorem 33.8 we show, using a spanning tree, that the based quotient is diffeomorphic to $\mathrm{SU}(2)^{2n^3+1}$, of dimension $6n^3 + 3$, and that the based gauge transformations carry Haar measure of total mass one. A configuration V is flat if $V_p = I$ for every plaquette p.

Smooth charts. We use the following routine facts about local coordinates several times. We include the short proofs because the dependence of the constants matters below.

Lemma 33.1. *1. Let F be a smooth map from a neighborhood of $p \in \mathbb{R}^k$ into $\mathbb{R}^k$ such that $T = DF(p)$ is invertible. Then there exist a closed ball $\overline{B}$ about p and an open neighborhood W of $F(p)$ such that F maps an open subset of $\overline{B}$ diffeomorphically onto W. The radii of $\overline{B}$ and W and the bounds for every fixed derivative of the inverse depend only on $\|T^{-1}\|$ and on bounds for the derivatives of F on a fixed neighborhood of p.*

2. Let $\mathcal{Q}$ be a smooth Riemannian manifold, for instance an open subset of $\mathbb{R}^k$ with the Euclidean metric or a compact Lie group with a bi-invariant metric, and let Exp *be its exponential map. Let $\Sigma \subset \mathcal{Q}$ be a smooth embedded submanifold and let $P \subset \Sigma$ be compact. Then there exists $r_0 > 0$ such that the normal exponential map $(y, v) \mapsto \mathrm{Exp}_y(v)$, defined for y in a compact neighborhood of P in Σ and $v \perp T_y\Sigma$ with $|v| < r_0$, is injective and is a local diffeomorphism with smooth positive Jacobian. Further, there exist finitely many open sets $W_l \Subset W_l^+ \subset \Sigma$ with $P \subset \bigcup_l W_l$ and smooth orthonormal frames $(\nu_{l,1}, \dots, \nu_{l,k'})$ of the normal bundle over W_l^+ such that all derivatives of fixed order of the maps $(y, v) \mapsto \mathrm{Exp}_y(\sum_\alpha v_\alpha \nu_{l,\alpha}(y))$, $v \in \mathbb{R}^{k'}$, and of their inverses are bounded on the closures of $\{(y, v) : y \in W_l,\ |v| \le r_0/2\}$. The transitions between these trivializations preserve y and are orthogonal in v, so integrals over the tube $\{\mathrm{Exp}_y(v) : y \in P,\ |v| < r_0/2\}$ can be computed with a partition of unity depending only on y. In $\mathbb{R}^k$ with the Euclidean metric, $\mathrm{Exp}_y(v) = y + v$.*

Proof. For (1), we translate p to zero and write $T^{-1}(F(h) - F(0)) = h + r(h)$, where $Dr(0) = 0$. On a sufficiently small closed ball $\overline{B}$ we have $\|Dr\| \le 1/2$. For $|z|$ less than half the radius of $\overline{B}$, the iterates $h_{k+1} = z - r(h_k)$, $h_0 = 0$, stay in $\overline{B}$, and their successive differences decrease by the factor $1/2$. Their limit is the unique solution h in $\overline{B}$ of $h + r(h) = z$. Differentiating this identity, we find that the inverse is smooth with $\|Dh\| \le 2$, and repeated differentiation bounds every fixed derivative in terms of those of r.

For (2), we take a point of P, an orthonormal tangent frame of Σ near it, and fixed smooth vector fields of $\mathcal{Q}$ whose projections onto the normal spaces are linearly independent at this point. The Gram–Schmidt formulas applied to these projections give a smooth orthonormal normal frame, since their denominators stay positive near the point. Since the differential of Exp_y at 0 is the identity, the derivative of $(y, v) \mapsto \mathrm{Exp}_y(\sum_\alpha v_\alpha \nu_\alpha(y))$ at $v = 0$ consists of the tangent and normal frames. It is invertible, with determinant one in orthonormal coordinates. By (1), applied in a chart of $\mathcal{Q}$, the map is a local diffeomorphism near $v = 0$, and its Jacobian is smooth and positive. Since P is compact, finitely many such charts cover a compact neighborhood P' of P in Σ, and we choose open sets $W_l \Subset W_l^+$ inside them, covering P, and a common normal radius. All maps extend smoothly past the closures of the smaller sets, and their derivatives of every fixed order are bounded there. It remains to prove injectivity for a common radius. If it failed

on $\{(y,v) : y \in P',\ |v| < 1/k\}$ for every k, there would be distinct points (y_k, v_k) and (y'_k, v'_k) of the normal bundle with $|v_k|, |v'_k| < 1/k$ and $\mathrm{Exp}_{y_k}(v_k) = \mathrm{Exp}_{y'_k}(v'_k)$. Passing to subsequences, $y_k \to y$ and $y'_k \to y'$ in P', and the common image converges both to y and to y'. Then $y = y'$, and both preimages converge to $(y, 0)$, near which the map is a local diffeomorphism and hence injective; this is a contradiction. Thus, for a small r_0, the base point y is a function on the tube, the transitions between the orthonormal frames act on v by orthogonal matrices depending on y, and a partition of unity in y handles overlaps. □

33.2 The stopped measure at a fixed side

Fix $L > 0$, $n \in 4\mathbb{N}$, an odd integer $M \geq 3$, an integer $J \geq 1$, and the tuple Θ of construction parameters of Theorem 23.2. Let ρ, r, and E_* be the analytic radius, the radius of the small-field domains $B_r \subset D_r$, and the bound for the effective interactions in Theorem 14.8. For a depth $d = kJ$, $k \geq 0$, and $\gamma > 0$, we set $g^2 = \gamma/n$ and consider the stopped measure

$$d\widehat{\nu}_{n,d,\gamma}(V) = \widehat{Z}^{-1}_{n,d,\gamma} \mathbf{1}_{D_r}(V) \exp\Big(-\frac{E_{d,\mathrm{sat}}(V)}{g^2} - \overline{R}_{d,\gamma}(V)\Big) dH_n(V), \qquad \overline{R}_{d,\gamma} = R_{d,\gamma} - R_{d,\gamma}(I), \tag{33.1}$$

of Theorem 14.8, with the indicator of D_r and the Haar disintegration factors of the construction. Here $E_{d,\mathrm{sat}}$ and the subscript sat in general denote the gauge-invariant extension from B_r to D_r, $R_{d,\gamma}$ is the effective interaction, $\overline{R}_{d,\gamma}$ is the centered effective interaction, and $\widehat{Z}_{n,d,\gamma}$ is the partition function. The depths $d = kJ$ are those at which the recursion of Theorem 14.8 defines an effective interaction. Subtracting $R_{d,\gamma}(I)$ fixes the normalization constant. If Z^{raw} denotes the partition function before centering, that is, the integral with $R_{d,\gamma}$ in place of $\overline{R}_{d,\gamma}$, then $\widehat{Z}_{n,d,\gamma} = e^{R_{d,\gamma}(I)} Z^{\mathrm{raw}}$ (Theorem 33.10).

For $d = JK$ and $N = nB^K$, the measure $\widehat{\nu}_{n,JK,\gamma}$ is the law of the stopping field V^{JK} under the conditioned Wilson measure $\nu_{N,n,\gamma}$ (Theorem 14.8). For a stopped measure at an intermediate side this identification fails, since the conditioned Wilson measure also imposes the remaining coarser restrictions (Definition 4.4). Our results concern the density (33.1) and make no identification of the latter kind.

We use the following properties. All constants and domains in them are independent of d and of $\gamma \in (0, \gamma_0]$.

(P1) There exists $\kappa > 0$ such that $E_{d,\mathrm{sat}} \geq \kappa E_0$ on D_r for every integer $d \geq 0$, whether or not an effective interaction is attached to d (Theorem 14.8; see also Theorem 11.2).

(P2) The effective classical action satisfies $E_d \geq 0$ (Theorem 11.2). It is invariant under lattice gauge transformations and exactly invariant under lattice translations on a fixed chart (Lemma 10.8). It vanishes at constant commuting configurations satisfying

the smallness condition of Lemma 33.7, as proved there. Its derivatives through order five are bounded uniformly in d on a fixed larger link chart (Theorem 10.11).

(P3) The centered effective interaction satisfies $|\overline{R}_{d,\gamma}| \le C_n$ on D_r (Theorem 14.8), and its first derivatives in fixed charts are bounded on the larger chart (Lemma 33.6).

(P4) The coupling bound $\gamma_0 > 0$ satisfies $\sqrt{\gamma_0/n} \le g_*$, where g_* is the coupling bound of Theorem 14.8, and, with $t_0 = \sqrt{\gamma_0/(Mn)}$ and $p(t) = A_{\mathrm{w}} \log(1/t)$,

$$p(t) \ge p_0, \qquad C_J t p(t) < \frac{1}{2}, \qquad \frac{C_J(tp(t)^3 + tp(t))}{1 - C_J t p(t)} \le \sigma_0 \qquad (0 < t \le t_0), \tag{33.2}$$

where p_0, C_J, and σ_0 are the constants of Theorem 12.13.

Since the largest coupling of an RG step with output side $m \ge n$ is $\sqrt{\gamma/(Mm)} \le t_0$, the conditions (33.2) contain the coupling conditions of Theorem 12.13 for all these steps. Once n, M, J, and Θ are fixed, (P4) holds for all sufficiently small $\gamma_0 > 0$: the function p is decreasing, $t \log^a(1/t) \to 0$ as $t \to 0$ for $a = 1, 3$, and these two functions are increasing in t when $\log(1/t) > a$. Thus γ_0 is chosen after n, M, J, and Θ, and before γ, and no separate condition is imposed for an individual coupling or depth.

33.3 The cone of commuting triples

Since two elements of $\mathfrak{su}(2)$ commute if and only if they are parallel, the commuting triples in $\mathfrak{su}(2)^3 \simeq \mathbb{R}^9$ are the triples $(\vartheta_1 u, \vartheta_2 u, \vartheta_3 u)$ with $\boldsymbol{\vartheta} \in \mathbb{R}^3$ and $u \in S^2$. If we regard $X \in \mathbb{R}^9$ as the real 3×3 matrix with columns x_1, x_2, x_3, these are exactly the matrices of rank at most one. The following lemma collects the geometry of this cone and the behavior of the quartic Q near it. The distance to the set of matrices of rank at most one is computed from the singular values, as in the rank-one case of the theorem of Eckart and Young [80].

Lemma 33.2. *Set*

$$Q(X) = \tfrac{1}{2} \sum_{i<j} |x_i \times x_j|^2, \qquad \mathcal{M} = \{(\vartheta_i u)_{i=1}^3 : \boldsymbol{\vartheta} \in \mathbb{R}^3,\ u \in S^2\}.$$

Then the following statements hold.

1. *The set $\mathcal{M} \setminus \{0\}$ is a smooth submanifold of $\mathbb{R}^9$ of dimension five. The map $(\boldsymbol{\vartheta}, u) \mapsto (\vartheta_i u)_i$ identifies exactly $(\boldsymbol{\vartheta}, u)$ with $(-\boldsymbol{\vartheta}, -u)$. At $y = (\vartheta_i u)_i$ with $\varrho = |\boldsymbol{\vartheta}| > 0$ and $\omega = \boldsymbol{\vartheta}/\varrho$, the normal space and the induced volume are*

$$\mathcal{N}_y = \Big\{ b = (b_1, b_2, b_3) : b_i \perp u,\ \sum_i \vartheta_i b_i = 0 \Big\}, \qquad \dim \mathcal{N}_y = 4,$$

$$d\mathrm{vol}_{\mathcal{M}} = \tfrac{1}{2} \varrho^4 \, d\varrho \, d\Omega_\omega \, d\Omega_u.$$

Note that $|y| = \varrho$.

2. *There exists an absolute constant $c \in (0,1)$ such that $(y,b) \mapsto y+b$, for $y \in \mathcal{M} \setminus \{0\}$, $b \in \mathcal{N}_y$, and $|b| \le c\varrho$, is injective and is a local diffeomorphism (a normal tube), with Euclidean Jacobian $1 + O(|b|/\varrho)$. The implicit constant is absolute; in particular it is uniform in the directions ω and u.*
3. *For $y \in \mathcal{M} \setminus \{0\}$ and $b \in \mathcal{N}_y$,*

$$Q(y+b) = \tfrac{1}{2}\varrho^2|b|^2 + \tfrac{1}{2}\sum_{i<j}|b_i \times b_j|^2,$$

and for every $X \in \mathbb{R}^9$,

$$Q(X) \ge \tfrac{1}{6}|X|^2 \operatorname{dist}(X,\mathcal{M})^2.$$

4. *Let f be a nonnegative C^5 function on a fixed ball about 0 that vanishes on $\mathcal{M}$ in that ball. Then $Df(0) = 0$, $D^2f(0) = 0$, and $D^3f(0) = 0$. On a smaller fixed ball,*

$$\|D^2f(X)\| \le C|X|^2, \qquad \|D^3f(X)\| \le C|X|,$$

and, for $y \in \mathcal{M} \setminus \{0\}$ and $b \in \mathcal{N}_y$ with $y+b$ in the smaller ball,

$$f(y+b) = \tfrac{1}{2}b^{\mathsf{T}}D^2_\perp f(y)b + O(\varrho|b|^3 + |b|^4),$$

where $D^2_\perp f(y)$ is the Hessian of f at y restricted to $\mathcal{N}_y$. If f_4 is the homogeneous quartic Taylor polynomial of f at 0 and $y = \varrho\widehat{y}$ with $|\widehat{y}| = 1$, then $D^2_\perp f(\varrho\widehat{y}) = \varrho^2 D^2_\perp f_4(\widehat{y}) + O(\varrho^3)$. If, in addition, $f \ge c_0 Q$ on the ball, then $D^2_\perp f_4(\widehat{y}) \ge c_0 I_4$. The constants depend only on the radii of the two balls, on $\|f\|_{C^5}$, and, in the last assertion, on c_0.

The last hypothesis $f \ge c_0 Q$ cannot be omitted: the function Q^2 is nonnegative and vanishes on $\mathcal{M}$, but its normal Hessian vanishes on all of $\mathcal{M}$.

Proof. We begin with part (1). The tangent vectors at $y_i = \vartheta_i u \neq 0$ have the form

$$t_i = \eta_i u + \vartheta_i v, \qquad \eta \in \mathbb{R}^3,\ v \perp u.$$

These five parameters are independent, and orthogonality to every η and every v gives exactly the asserted normal space. In the parameters $(\boldsymbol{\vartheta}, u)$ the induced metric is

$$\sum_i |d(\vartheta_i u)|^2 = |d\boldsymbol{\vartheta}|^2 + \varrho^2|du|^2.$$

Each nonzero matrix of rank one has exactly two preimages: a nonzero column determines the common line, and the two unit vectors on this line determine all three coefficients. We obtain the volume element $\varrho^2\, d^3\boldsymbol{\vartheta}\, d\Omega_u/2$, which is the displayed formula after polar coordinates in $\boldsymbol{\vartheta}$.

For part (2), the tube is taken over the nonzero stratum, and its radius is proportional to $|y|$. We first restrict to $1/2 < |y| < 2$. By Lemma 33.1(2), finitely many coordinate patches

of this compact piece of $\mathcal{M}$ carry smooth orthonormal normal frames with bounded first derivatives on smaller patches. In such a frame the derivative of $(y, b) \mapsto y + b$ at $b = 0$ is the orthogonal sum of the tangent and normal frames, and its volume determinant is one. At $b \neq 0$ its tangent columns differ by $O(|b|)$, and the determinant is $1 + O(|b|)$. We now check that the base point is unique. If $b \in \mathcal{N}_y$, the matrix $X = y + b$ satisfies

$$XX^{\mathsf{T}} = \varrho^2 uu^{\mathsf{T}} + bb^{\mathsf{T}}, \qquad bb^{\mathsf{T}}u = 0,$$

since $\sum_i \vartheta_i b_i = 0$ and $b_i \perp u$. If $|b| < c\varrho$ with $c < 1$, the largest eigenvalue ϱ^2 of XX^{T} is simple, and its eigenline is exactly $\mathbb{R}u$. Projecting the columns of X onto this line recovers y, and the two choices of sign of u give the same matrix y. Together with the local invertibility of the derivative, this proves that the map is a normal tube. Since the map commutes with the dilations $(y, b) \mapsto (\lambda y, \lambda b)$, the bound on the unit stratum implies the Jacobian bound $1 + O(|b|/\varrho)$ with an absolute constant.

For part (3), let $b \in \mathcal{N}_y$ and expand

$$(\vartheta_i u + b_i) \times (\vartheta_j u + b_j) = u \times (\vartheta_i b_j - \vartheta_j b_i) + b_i \times b_j.$$

The first summand is perpendicular to u and the second is parallel to u, so they are orthogonal. Since $\vartheta_i b_j - \vartheta_j b_i \perp u$, we have $|u \times (\vartheta_i b_j - \vartheta_j b_i)| = |\vartheta_i b_j - \vartheta_j b_i|$, and the Lagrange identity gives

$$\sum_{i<j} |\vartheta_i b_j - \vartheta_j b_i|^2 = |\boldsymbol{\vartheta}|^2 |b|^2 - \Big|\sum_i \vartheta_i b_i\Big|^2 = \varrho^2 |b|^2.$$

This proves the formula for $Q(y + b)$. For the global bound, let $\sigma_1 \geq \sigma_2 \geq \sigma_3 \geq 0$ be the singular values of X. Since $|x_i \times x_j|^2$ is the sum of the squares of the 2×2 minors in the columns i and j, the quantity $2Q(X)$ is the sum of the squares of all 2×2 minors of X. This sum is invariant under left and right multiplication by orthogonal matrices, and evaluating it on a diagonal matrix gives

$$2Q(X) = \sigma_1^2\sigma_2^2 + \sigma_1^2\sigma_3^2 + \sigma_2^2\sigma_3^2.$$

For a fixed unit vector u, the closest matrix with all columns parallel to u has columns $(u \cdot x_i)u$, and its squared distance to X is $|X|^2 - u^{\mathsf{T}}XX^{\mathsf{T}}u$. Diagonalizing XX^{T}, we see that the minimum over u is $\sigma_2^2 + \sigma_3^2 = \operatorname{dist}(X, \mathcal{M})^2$. Since $\sigma_1^2 \geq |X|^2/3$, we obtain

$$Q(X) \geq \tfrac{1}{2}\sigma_1^2(\sigma_2^2 + \sigma_3^2) \geq \tfrac{1}{6}|X|^2 \operatorname{dist}(X, \mathcal{M})^2.$$

For part (4), since the origin is a minimum of f, we have $Df(0) = 0$, and $D^2 f(0)$ is positive semidefinite. Since $\mathcal{M}$ is a cone, the restriction of f to every line through a matrix of rank one vanishes near zero, and the quadratic form $D^2 f(0)$ vanishes on every matrix

of rank one. If a positive semidefinite form H satisfies $v^{\mathsf{T}} H v = 0$, then $Hv = 0$, as one sees by diagonalizing H. Since the matrices with a single nonzero entry have rank one and span $\mathbb{R}^9$, we conclude that $D^2 f(0) = 0$. The cubic Taylor term vanishes as well, that is, $D^3 f(0) = 0$: on each line through the origin it would otherwise take opposite signs on the two sides of zero, contradicting nonnegativity, and a cubic form that vanishes on every line is zero.

By Taylor's formula with integral remainder, we have, on a smaller concentric ball,

$$\|D^2 f(X)\| \le C|X|^2, \qquad \|D^3 f(X)\| \le C|X|, \qquad D^2 f(X) = D^2 f_4(X) + O(|X|^3).$$

For example, the last error is at most $\sup\|D^5 f\||X|^3/6$; the other constants use the bounds for the fourth and fifth derivatives on the larger ball. Since $f(y) = 0$ is a minimum at every $y \in \mathcal{M}$ in the ball, we have $Df(y) = 0$. Using Taylor's formula on the segment from y to $y + b$ and the bound for $D^3 f$, we find a cubic remainder at most $C(\varrho + |b|)|b|^3$, which proves the normal expansion. The Hessian of the quartic f_4 is homogeneous of degree two, and $\mathcal{N}_{\varrho\widehat{y}} = \mathcal{N}_{\widehat{y}}$; this proves the expansion at $y = \varrho\widehat{y}$. If $f \ge c_0 Q$, the function $f - c_0 Q$ is nonnegative and vanishes at y, and its Hessian at this point is positive semidefinite. By the exact normal formula in part (3), the normal Hessian of Q at y is $\varrho^2 I_4$, and we obtain

$$D^2_\perp f(\varrho\widehat{y}) \ge c_0 \varrho^2 I_4.$$

Dividing by ϱ^2 and letting $\varrho \downarrow 0$, we obtain $D^2_\perp f_4(\widehat{y}) \ge c_0 I_4$. This completes the proof. □

33.4 Laplace asymptotics in normal coordinates

We now prove the Laplace estimates used in the normal directions of the regular flat configurations and in the nonconstant directions near the trivial connection. The main point is uniformity. The phase, the amplitude, and the tangential weight may depend on an arbitrary index, which in the applications records the depth and the coupling, and the tangential weight need not converge or have any regularity. We therefore prove the estimates for each fixed tangential point and then integrate them against the tangential marginal of the measure itself.

Lemma 33.3. *Let P be a compact patch of a smooth manifold with a smooth volume measure $d\mathrm{vol}$, and let a Euclidean vector bundle of rank $d \ge 1$ over P be given with a finite atlas of smooth orthonormal trivializations. Fix $0 < b_1 < b_0$ and a cutoff $\chi_y(b)$ with $0 \le \chi \le 1$, jointly Borel in every trivialization, equal to one for $|b| \le b_1$ and supported in a compact subset of the tube $\{|b| < b_0\}$. Let ι range over an arbitrary index set and let $0 < \delta \le \delta_0$. For each ι and δ let $V_\iota(y, b)$ and $a_{\iota,\delta}(y, b)$ be real functions on the tube, jointly Borel in every trivialization, and*

assume that the Hessian $L_\iota(y) = D_b^2 V_\iota(y,0)$ exists and is a measurable function of y. Assume that on the support of χ

$$\begin{aligned} V_\iota(y,0) = D_b V_\iota(y,0) = 0, \qquad & c_0 I \le L_\iota(y) \le C_0 I, \\ |V_\iota(y,b) - \tfrac{1}{2} b^{\mathsf T} L_\iota(y) b| \le C_0 |b|^3, \qquad & V_\iota(y,b) \ge c_0 |b|^2, \\ c_0 \le a_{\iota,\delta}(y,b) \le C_0, \qquad & |a_{\iota,\delta}(y,b) - a_{\iota,\delta}(y,0)| \le C_0 |b|. \end{aligned}$$

The amplitude $a_{\iota,\delta}$ includes the Jacobian of the tube coordinates, so that the reference measure is $d\mathrm{vol}(y)\, db$, where db is Lebesgue measure in an orthonormal trivialization. Let $h_{\iota,\delta} \ge 0$ be any measurable function on P with $0 < \int_P h_{\iota,\delta}\, d\mathrm{vol} < \infty$; no regularity in y and no convergence as ι or δ varies is assumed. Let

$$d\mathsf P_{\iota,\delta} = Z_{\iota,\delta}^{-1} h_{\iota,\delta}(y) \chi_y(b) a_{\iota,\delta}(y,b) e^{-V_\iota(y,b)/\delta}\, d\mathrm{vol}(y)\, db$$

be the normalized measure, and set

$$z = \delta^{-1/2} L_\iota(y)^{1/2} b, \qquad \alpha_{\iota,\delta}(y) = \frac{a_{\iota,\delta}(y,0)}{\sqrt{\det L_\iota(y)}}.$$

Let G_d be a standard Gaussian vector in $\mathbb R^d$. Then for every family $P_y(z)$ of polynomials of a fixed degree whose coefficients are bounded measurable functions of y, and every bounded measurable function f on P,

$$\begin{aligned} Z_{\iota,\delta} \mathbb E_{\mathsf P_{\iota,\delta}}[f(y) P_y(z)] &= (2\pi\delta)^{d/2} \Big[\int_P f\, h_{\iota,\delta}\, \alpha_{\iota,\delta}\, \mathbb E P_y(G_d)\, d\mathrm{vol} + \mathcal R_{\iota,\delta}(f,P) \Big], \\ |\mathcal R_{\iota,\delta}(f,P)| &\le C_P \sqrt{\delta} \int_P |f|\, h_{\iota,\delta}\, d\mathrm{vol}. \end{aligned} \tag{33.3}$$

The error is additive, also when $\mathbb E P_y(G_d) = 0$. For $y \in P$ let $\mathsf P_{\iota,\delta}(\cdot \mid y)$ be the probability measure on the fiber with density proportional to $\chi_y(b) a_{\iota,\delta}(y,b) e^{-V_\iota(y,b)/\delta}$. It is defined for every y, also where $h_{\iota,\delta}(y) = 0$, and it is a version of the conditional law of b given y under $\mathsf P_{\iota,\delta}$. Moreover, the following hold.

1. *For every $y \in P$, $|\mathbb E_{\mathsf P_{\iota,\delta}}[P_y(z) \mid y] - \mathbb E P_y(G_d)| \le C_P \sqrt{\delta}$, and $\mathbb E_{\mathsf P_{\iota,\delta}}[|z|^k \mid y] \le C_k$ for every fixed real $k \ge 0$.*
2. *Let $d = 4$ and $q_\iota = b^{\mathsf T} L_\iota(y) b/2$. Then for $j = 0, 1, 2$,*

$$|\mathbb E_{\mathsf P_{\iota,\delta}}[f(y)(q_\iota/\delta)^j] - m_j \mathbb E_{\mathsf P_{\iota,\delta}} f(y)| \le C_j \|f\|_\infty \sqrt{\delta}, \qquad (m_0, m_1, m_2) = (1, 2, 6).$$

3. *Let $d = 4$, let L_∞ be a measurable field of symmetric matrices with $c_0 I \le L_\infty(y) \le C_0 I$, and let $q_\infty = b^{\mathsf T} L_\infty(y) b/2$. Then the estimate in (2) holds with q_∞ in place of q_ι, up to the additional error $C_j \|f\|_\infty \|L_\iota - L_\infty\|_\infty$.*

The constants depend only on d, on b_0, b_1, and the atlas, on c_0 and C_0, and on the degree and the coefficient bounds of P_y (respectively on k and j). They are independent of ι, δ, and δ_0, and of $h_{\iota,\delta}$, its total mass, and its variation. In applications at a fixed side n, the geometric data may depend on n.

Corollary 33.4. *Assume the hypotheses of Lemma 33.3. For $y \in P$ let $r_{\iota,\delta,y}$ be the Lebesgue density of $z = \delta^{-1/2} L_\iota(y)^{1/2} b$ under $\mathsf{P}_{\iota,\delta}(\cdot \mid y)$, and let $\phi_d(z) = (2\pi)^{-d/2} e^{-|z|^2/2}$. For every real $s \geq 0$ there exists $C_s < \infty$ such that, for all $0 < \delta \leq \delta_0$,*

$$\sup_{\iota,y} \int_{\mathbb{R}^d} (1 + |z|^s) |r_{\iota,\delta,y}(z) - \phi_d(z)| \, dz \leq C_s \sqrt{\delta}. \tag{33.4}$$

The density $r_{\iota,\delta,y}$ is defined by its normal integral at every y, also where the tangential weight vanishes, and assertions integrated against the tangential marginal of $\mathsf{P}_{\iota,\delta}$ hold almost everywhere with respect to that marginal; no assumption on the behavior of this marginal as ι and δ vary is made. The constant C_s has the dependence described in Lemma 33.3, and in addition depends on s.

Suppose in addition that $V_\iota(y,b) \geq c|b|^2$ and $c \leq a_{\iota,\delta}(y,b) \leq C$ for all $|b| < b_0$, with $c, C > 0$ independent of ι, y, and δ. In the following whole-tube conclusions, the constants C_s may additionally depend on c and C; they remain independent of ι, y, δ, δ_0, and the tangential weight. Then there exists $c' > 0$, depending only on the data of Lemma 33.3 and on c and C, such that for $0 < \delta \leq 1$

$$\int_{|b|<b_0} (1 + |z|^s)(1 - \chi_y(b)) a_{\iota,\delta}(y,b) e^{-V_\iota(y,b)/\delta} \, db \leq C_s \delta^{d/2} e^{-c'/\delta}. \tag{33.5}$$

Let $r^{\mathrm{tube}}_{\iota,\delta,y}$ be defined as $r_{\iota,\delta,y}$, but with χ_y replaced by the indicator of the tube $\{|b| < b_0\}$. Then $\int (1 + |z|^s) |r^{\mathrm{tube}}_{\iota,\delta,y} - r_{\iota,\delta,y}| \, dz \leq C_s e^{-c'/\delta}$ for $0 < \delta \leq 1$, and (33.4) holds for $r^{\mathrm{tube}}_{\iota,\delta,y}$ for all $0 < \delta \leq \delta_0$.

In the application of Proposition 33.12, the rank is $6n^3 - 2$, $\delta = \gamma$, the phase is $nE_{JK}(V(y,v))$, and $L = H^{\mathrm{act}}_K(y) = D^2_v[nE_{JK}(V(y,v))]|_{v=0}$. In this application the additional hypotheses on the whole tube hold, and all constants are independent of K.

Both results follow from an estimate at a fixed tangential point, which we prove first.

Lemma 33.5. *Assume the hypotheses of Lemma 33.3. Fix a trivialization of the atlas, a point y in its domain, and the parameters ι and δ. Write $L = L_\iota(y)$ and $a_0 = a_{\iota,\delta}(y,0)$. Let*

$$u_y(z) = \chi_y(b) a_{\iota,\delta}(y,b) e^{-V_\iota(y,b)/\delta}, \qquad b = \delta^{1/2} L^{-1/2} z,$$

extended by zero outside the tube, and let $Z_y = \int u_y(z) \, dz$ and $r_y = u_y / Z_y$. Then $Z_y > 0$, and for every real $s \geq 0$ there exist $C_s < \infty$ and $c > 0$, with the dependence described in Lemma 33.3 and additionally on s, such that the following hold for all $0 < \delta \leq \delta_0$.

1. $\int (1+|z|^s)\,|u_y(z) - a_0 e^{-|z|^2/2}|\,dz \le C_s\sqrt{\delta}$.
2. *If* $\delta \le 1$, *then* $Z_y \ge c$.
3. $\int (1+|z|^s)\,|r_y(z) - \phi_d(z)|\,dz \le C_s\sqrt{\delta}$.
4. $\int |z|^s r_y(z)\,dz \le C_s$.

Proof. Let $\varepsilon = \sqrt{\delta}$. On the support of χ we set

$$A(z) = V_\iota(y, \varepsilon L^{-1/2} z)/\delta, \qquad B(z) = |z|^2/2.$$

Since $|b| \le \varepsilon|z|/\sqrt{c_0}$ and $|z|^2 = b^{\mathsf T} L b/\delta$, the hypotheses imply, with constants determined by c_0 and C_0, that

$$A(z) \ge c|z|^2, \qquad B(z) \ge c|z|^2, \qquad |A(z) - B(z)| \le C\varepsilon|z|^3, \qquad |a_{\iota,\delta}(y,b) - a_0| \le C\varepsilon|z|.$$

The identity $e^{-A} - e^{-B} = -(A-B)\int_0^1 e^{-[(1-t)B + tA]}\,dt$ yields

$$|e^{-A} - e^{-B}| \le |A - B| e^{-\min(A,B)}. \tag{33.6}$$

This bound does not require $|A-B|$ to be small. Here the lower bound $V_\iota \ge c_0|b|^2$ on the whole support of χ enters, since the cubic Taylor bound alone would not control the integrand far from $b = 0$. On the support of χ we obtain

$$|a_{\iota,\delta}e^{-A} - a_0 e^{-B}| \le a_{\iota,\delta}|e^{-A} - e^{-B}| + |a_{\iota,\delta} - a_0|e^{-B} \le C\varepsilon(|z| + |z|^3)e^{-c|z|^2}.$$

We have $u_y - a_0 e^{-B} = \chi(a_{\iota,\delta}e^{-A} - a_0 e^{-B}) - (1-\chi)a_0 e^{-B}$, and the last term is supported where $|b| > b_1$, hence where $|z| \ge \sqrt{c_0}\, b_1/\varepsilon$. For $0 < \delta \le 1$ we have

$$\begin{aligned}\int (1+|z|^s)\,|u_y - a_0 e^{-B}|\,dz &\le C\varepsilon \int (1+|z|^s)(|z| + |z|^3)e^{-c|z|^2}\,dz \\ &\quad + C_0 \int_{|z| \ge \sqrt{c_0} b_1/\varepsilon} (1+|z|^s) e^{-|z|^2/2}\,dz \le C_s\varepsilon.\end{aligned}$$

In the last inequality, we used polar coordinates and $\int_0^\infty \varrho^m e^{-c\varrho^2}\,d\varrho < \infty$ for $m > -1$ for the first integral; for the second, we absorbed half of the exponential into the polynomial to obtain the bound $C_s e^{-c'/\delta}$, and we used that $u^{-1}e^{-c'/u^2}$ is bounded for $u \in (0,1]$. This proves (1) for $\delta \le 1$. If $\delta > 1$, then u_y is supported in $|z| \le C_0^{1/2} b_0$ and $0 \le u_y \le C_0$, since $V_\iota \ge 0$ on the support of χ. Both $\int (1+|z|^s)u_y\,dz$ and $a_0\int (1+|z|^s)e^{-|z|^2/2}\,dz$ are then bounded by a constant C_s, and $C_s \le C_s\sqrt{\delta}$. This proves (1) in general. Note that no dependence on δ_0 enters.

For (2), let $0 < \delta \le 1$ and set $\varrho_0 = \min(b_1/2, \sqrt{\delta})$. On the ball $|b| \le \varrho_0$ we have $\chi = 1$, $a_{\iota,\delta} \ge c_0$, and $V_\iota \le C_0|b|^2/2 + C_0|b|^3 \le C_0(1/2 + b_0)\delta$. Changing variables, we obtain

$$Z_y = \delta^{-d/2}(\det L)^{1/2} \int \chi_y a_{\iota,\delta} e^{-V_\iota/\delta}\,db \ge \delta^{-d/2} c_0^{d/2}\, c_0\, e^{-C_0(1/2+b_0)}\, \omega_d \varrho_0^d \ge c,$$

where ω_d is the volume of the unit ball and we used $\varrho_0^d \delta^{-d/2} \geq \min(b_1/2, 1)^d$. The same integral over $|b| \leq b_1/2$ shows that $Z_y > 0$ for every δ.

For (3) with $\delta \leq 1$, let $A_0 = a_0(2\pi)^{d/2}$, so that $a_0 e^{-|z|^2/2} = A_0 \phi_d(z)$. Then

$$r_y - \phi_d = \frac{u_y - a_0 e^{-|z|^2/2}}{Z_y} + a_0 e^{-|z|^2/2}\Big(\frac{1}{Z_y} - \frac{1}{A_0}\Big).$$

By (1) with $s = 0$ we have $|Z_y - A_0| \leq C\sqrt{\delta}$, and $Z_y \geq c$ by (2) and $A_0 \geq c_0(2\pi)^{d/2}$. Inserting these bounds and (1) into the last display, we obtain (3). For $\delta > 1$, we use that r_y and ϕ_d are probability densities and that r_y is supported in $|z| \leq C_0^{1/2} b_0$. Then the left side of (3) is at most $1 + (C_0^{1/2} b_0)^s + \int (1 + |z|^s)\phi_d \leq C_s \leq C_s\sqrt{\delta}$. Finally, (4) follows from (3) for $\delta \leq 1$, and from the bound on the support of r_y for $\delta > 1$. □

Proof of Lemma 33.3. We first check that all densities and conditional laws are well defined. On the spectral interval $[c_0, C_0]$ the maps $L \mapsto L^{1/2}$ and $L \mapsto L^{-1/2}$ are continuous: their binomial series in $I - L/C_0$ converge uniformly because $\|I - L/C_0\| \leq 1 - c_0/C_0 < 1$, and all partial sums are polynomials in the matrix entries. Since the Hessian is measurable, so are z, $\det L_\iota$, and $\alpha_{\iota,\delta}$. Since V_ι, $a_{\iota,\delta}$, and χ are jointly Borel, every normal integrand below is jointly measurable. Integrals over the fiber of nonnegative integrands are measurable functions of y, by integration of nonnegative simple functions followed by monotone limits; signed polynomial integrands are treated through their positive and negative parts, once the bounds below establish absolute integrability. Thus Fubini's theorem applies to the weight $h_{\iota,\delta}$ without any continuity in y.

Next we prove the formula at a fixed tangential point. Fix a trivialization and y, and let u_y, Z_y, and r_y be as in Lemma 33.5. The change of variables $b = \delta^{1/2} L^{-1/2} z$ has Jacobian $\delta^{d/2}(\det L)^{-1/2}$, so with

$$I_y(P) = \int \chi_y(b) a_{\iota,\delta}(y,b) e^{-V_\iota(y,b)/\delta} P_y(z)\, db$$

we have $I_y(P) = \delta^{d/2}(\det L)^{-1/2} \int u_y P_y\, dz$. Since $|P_y(z)| \leq C_P(1 + |z|^{\deg P})$, part (1) of Lemma 33.5 implies that $|\int u_y P_y\, dz - a_0(2\pi)^{d/2} \mathbb{E} P_y(G_d)| \leq C_P\sqrt{\delta}$. Since $(\det L)^{-1/2} \leq c_0^{-d/2}$, we obtain, uniformly in y and ι,

$$I_y(P) = (2\pi\delta)^{d/2}\big[\alpha_{\iota,\delta}(y)\mathbb{E} P_y(G_d) + \mathcal{E}_y(P)\big], \qquad |\mathcal{E}_y(P)| \leq C_P\sqrt{\delta}. \tag{33.7}$$

We multiply (33.7) by $f(y)h_{\iota,\delta}(y)$ and integrate. By Fubini's theorem, the left side becomes $Z_{\iota,\delta}\mathbb{E}_{\mathsf{P}_{\iota,\delta}}[f P_y(z)]$ on the domain of the trivialization, and the error is bounded by $C_P\sqrt{\delta}\int |f| h_{\iota,\delta}$, also when the Gaussian mean vanishes. Orthogonal changes of the normal frame preserve db, the law of G_d, and the positive square root, and they act on z by orthogonal maps. Hence the formula does not depend on the trivialization, and a finite nonnegative partition of unity on P subordinate to the atlas proves (33.3). We

obtain such a partition by choosing coordinate balls whose smaller concentric balls cover P, placing a smooth bump equal to one on each smaller ball, and dividing by the positive sum of the bumps; only the atlas enters its constants. No derivative or convergence of $h_{\iota,\delta}$ has been used.

For the conditional statements, note that $I_y(1) > 0$ for every y by Lemma 33.5(2). The density $\chi_y a_{\iota,\delta} e^{-V_\iota/\delta}/I_y(1)$ of $\mathsf{P}_{\iota,\delta}(\cdot \mid y)$ is jointly Borel, and its product with the tangential density $Z_{\iota,\delta}^{-1} h_{\iota,\delta}(y) I_y(1)$ is the joint density of $\mathsf{P}_{\iota,\delta}$. Thus $\mathsf{P}_{\iota,\delta}(\cdot \mid y)$ is a version of the conditional law, including on the set where $h_{\iota,\delta}$ vanishes. Since z has density r_y under this law, we have

$$|\mathbb{E}[P_y(z) \mid y] - \mathbb{E}P_y(G_d)| \le C_P \int (1 + |z|^{\deg P}) |r_y - \phi_d| \, dz \le C_P \sqrt{\delta}$$

by Lemma 33.5(3), and the moment bound in (1) is Lemma 33.5(4).

For (2), let $d = 4$. Then $q_\iota/\delta = |z|^2/2$ exactly. For independent one-dimensional standard Gaussians, integration by parts gives $\mathbb{E}G_i^2 = 1$ and $\mathbb{E}G_i^4 = 3$. This implies

$$\mathbb{E}(|G_4|^2/2) = 2, \qquad \mathbb{E}(|G_4|^2/2)^2 = \tfrac{1}{4}(4 \cdot 3 + 12) = 6.$$

By (1), the conditional expectations of $(q_\iota/\delta)^j$ given y differ from m_j by at most $C_j\sqrt{\delta}$, uniformly in y. Integrating against the tangential marginal of $\mathsf{P}_{\iota,\delta}$, multiplied by f, we obtain (2).

For (3), let $\eta = \|L_\iota - L_\infty\|_\infty$. Since $|b|^2 \le \delta |z|^2/c_0$, we have pointwise

$$|q_\iota - q_\infty|/\delta \le C\eta |z|^2, \qquad |q_\iota|/\delta + |q_\infty|/\delta \le C|z|^2,$$

and both constants depend only on c_0 and C_0, because L_∞ obeys the same spectral bounds as L_ι. The case $j = 0$ is trivial. For $j = 1$ the first bound and the bounded second moment give the additional error $C\|f\|_\infty \eta$. For $j = 2$ we write $x^2 - y^2 = (x - y)(x + y)$ and use the bounded fourth moment from (1). All constants have the stated dependence. This completes the proof. □

Proof of Corollary 33.4. In a trivialization of the atlas, the density of z under $\mathsf{P}_{\iota,\delta}(\cdot \mid y)$ is $r_{\iota,\delta,y} = r_y$ of Lemma 33.5, and (33.4) is part (3) of that lemma. Since orthogonal changes of the normal frame act on z by orthogonal maps and preserve ϕ_d and $|z|$, the left side of (33.4) does not depend on the trivialization. The density is jointly measurable by the Borel hypotheses and integration over the fiber, as in the proof of Lemma 33.3. Since the estimate holds at every y, integrating it against the tangential marginal of $\mathsf{P}_{\iota,\delta}$ requires no assumption on this marginal. We note that the constant in part (3) of Lemma 33.5 does not depend on δ_0: for $\delta \le 1$ the proof uses the lower bound $Z_y \ge c$, valid on all of $(0, 1]$, and for $\delta > 1$ it uses only that r_y is supported in a fixed ball.

We turn to the additional statements on the whole tube. Let $0 < \delta \le 1$, and let Z^{tube} and Z^χ be the integrals of $a_{\iota,\delta} e^{-V_\iota/\delta}$ over $|b| < b_0$, without and with the factor χ_y. By the

proof of Lemma 33.5(2) we have $Z^{\mathrm{tube}} \geq Z^{\chi} \geq c\delta^{d/2}$. On the region where $\chi_y(b) \neq 1$ we have $|b| \geq b_1$, and the lower bound $V_\iota \geq c|b|^2$ on the whole tube bounds the integrand by $C(1+|z|^s)e^{-c|b|^2/\delta}$, with $|z| \leq C|b|/\sqrt{\delta}$. Absorbing half of the exponential, we obtain

$$\begin{aligned}\int_{b_1 \leq |b| < b_0} (1 + C\delta^{-s/2}|b|^s) C e^{-c|b|^2/\delta}\, db &\leq C(1+\delta^{-s/2}) e^{-cb_1^2/(2\delta)} \int e^{-c|b|^2/(2\delta)}\, db \\ &\leq C_s \delta^{d/2} e^{-c'/\delta},\end{aligned}$$

which is (33.5). Let p^{tube} and p^{χ} be the two normalized fiber densities. Then

$$\int w|p^{\mathrm{tube}} - p^{\chi}| \leq \frac{1}{Z^{\mathrm{tube}}} \int w(1-\chi_y) a_{\iota,\delta} e^{-V_\iota/\delta} + \frac{|Z^{\mathrm{tube}} - Z^{\chi}|}{Z^{\mathrm{tube}}} \int w p^{\chi},$$

with $w = 1 + |z|^s$. By (33.5), the lower bound for Z^{tube}, and the bounded moments of p^{χ} from Lemma 33.5(4), the right side is at most $C_s e^{-c'/\delta}$. Since $e^{-c'/\delta} \leq C\sqrt{\delta}$ for $\delta \leq 1$, (33.4) holds for r^{tube} when $\delta \leq 1$. When $\delta > 1$, the density r^{tube} is supported in $|z| \leq C_0^{1/2} b_0$, and the argument for part (3) of Lemma 33.5 with $\delta > 1$ applies.

The final assertion concerns the stopped measures near a compact patch of regular flat configurations. We prove it at the end of Section 33.8, after the normal coordinates of that application have been constructed. That proof uses Lemma 33.3, but not the present corollary. □

33.5 Based coordinates near the trivial connection

In this section we construct coordinates on the based quotient near the class of the identity, separate the nine constant directions from the $6n^3 - 6$ nonconstant directions transverse to the gauge orbits, and integrate out the latter by Lemma 33.3. We first record the derivative bounds for the effective interaction and the domain conditions for small commuting configurations that the integration requires.

Lemma 33.6. *Let $R = R_{d,\gamma}$ be the effective interaction in* (33.1)*, at a depth $d = kJ$ and with $0 < \gamma \leq \gamma_0$, and let $\overline{R} = R - R(I)$. Fix $r < r_1 < \min(\rho, \pi)$ and put $\eta = 1 - r_1/\rho$. There exist constants C_j, independent of d and γ, such that in link logarithm coordinates $\xi = (\xi_e)$ with $\max_e |\xi_e| \leq r_1$,*

$$\|D_\xi^j \overline{R}(e^\xi)\|_{\mathrm{root}} \leq C_j E_* \rho^{2-j} \eta^{-j}, \qquad j \geq 1, \tag{33.8}$$

where $\|\cdot\|_{\mathrm{root}}$ is the weighted absolute coefficient norm of Definition 4.6 with one index fixed, followed by the supremum over the fixed index. In particular, let $K_1 = C_1 E_* \rho \eta^{-1}$. Then at every point of the coordinates $V(X,s) = e^{X/n+s}$ of Theorem 33.8 whose link logarithms lie in B_{r_1},

$$|D_X \overline{R}(e^{X/n+s})| \leq 3n^2 K_1, \qquad |D_s \overline{R}(e^{X/n+s})| \leq 3n^{3/2} K_1, \tag{33.9}$$

where both norms are Euclidean and the derivative in s is taken in the subspace $\mathcal{S}_n$.

Further, let $\mathcal{K} \subset D_r$ be compact. There exist finitely many based gauge transformations and an open cover of $\mathcal{K}$ such that each member of the cover, together with a larger neighborhood, is mapped into B_{r_1} by one of these gauge transformations. Let $W \Subset W^+$ be open sets of parameters and let $\Psi : W^+ \to \mathcal{U}_n$ be smooth, extend smoothly to a neighborhood of $\overline{W}$, and satisfy $\Psi(\overline{W}) \subset \mathcal{K}$. Then for every $j \geq 1$,

$$\|D^j(\overline{R}_{\mathrm{sat}} \circ \Psi)\|_{L^\infty(W)} \leq C_{n,j,\mathcal{K},\Psi,r_1,\rho,\eta} E_*, \tag{33.10}$$

where the constant depends on the suprema over $\overline{W}$ of the derivatives of Ψ through order j, which are finite by smooth extension and compactness, but not on d or γ. The gauge transformations, the subcharts, and the constants are chosen independently of d and γ. For charts of the based quotient, Ψ denotes a fixed smooth lift to configurations. These bounds concern only the effective interactions $R_{d,\gamma}$, $d = kJ$, of the stopped densities (33.1).

Proof. By Theorem 14.8, the effective interaction of (33.1) satisfies $\mathcal{B}_{\rho,a_{\mathrm{sp}}}(R) \leq E_*$ and $DR(I) = 0$, and its local expressions in different gauges agree on the overlaps of their domains in the common outer ball. That theorem also contains the bounds (33.8) and their transfer to fixed charts. We recall the argument and verify the conditions on the charts in the form used below. The constant $R(I)$ does not enter derivatives of positive order. Set

$$A_k = \frac{\rho^{k-2}}{k!} \|D^k R(0)\|_{a_{\mathrm{sp}},\mathrm{root}}, \qquad \sum_{k \geq 2} A_k \leq E_*, \qquad q = r_1/\rho = 1 - \eta.$$

We fix one index of a differentiated coefficient, sum over the contracted indices, and use $|\xi_e| \leq r_1$. The spatial weights are at least one, and deleting contracted indices does not increase the length of a shortest connecting network of the remaining indices. By the absolute Taylor expansion, we have

$$\|D^j R(e^\xi)\|_{\mathrm{root}} \leq C_j \rho^{2-j} \sum_{k \geq \max(2,j)} A_k \frac{k!}{(k-j)!} q^{k-j},$$

where the fixed conventions for color coordinates contribute only the factor C_j. For $k \geq j$ the binomial identity implies

$$\binom{k}{j} \eta^j q^{k-j} \leq \sum_{l=0}^{k} \binom{k}{l} \eta^l q^{k-l} = 1,$$

so that $k! q^{k-j}/(k-j)! \leq j! \eta^{-j}$. This summable majorant also justifies differentiating the series term by term in the interior, and it proves (33.8).

There are $9n^3$ scalar link and color coordinates, and each first partial derivative of $\overline{R}$ is at most K_1, by (33.8) with $j = 1$. Then the Euclidean gradient is at most $3n^{3/2} K_1$, and its restriction to the subspace $\mathcal{S}_n$ has no larger norm. In the coordinates (X, s) we have

$\xi_i(x) = X_i/n + s_i(x)$. For each of the nine components of X, the chain rule expresses the derivative as a sum of n^3 partial derivatives with coefficient $1/n$, which is at most n^2K_1 in absolute value. The Euclidean norm of the gradient in X is then at most $3n^2K_1$. This proves (33.9).

For the transfer, let $U_0 \in \mathcal{K}$ and choose a lattice gauge transformation k_0 with $U_0^{k_0} \in B_r$. It can be taken based: replacing $k_0(x)$ by $k_0(x_*)^{-1}k_0(x)$ conjugates the transformed configuration by one constant matrix, which preserves every link logarithm norm. We keep this gauge transformation fixed. By continuity there exist neighborhoods $O_0 \Subset O_0^+$ of U_0, with closures inside an ambient smooth coordinate chart, whose images under k_0 lie in B_{r_1} even on $\overline{O_0^+}$. To find them, we take an open neighborhood with image in B_{r_1} and then two smaller coordinate balls with closures inside it. Finitely many of the sets O_0 cover $\mathcal{K}$. They depend on $\mathcal{K}$ and on $r < r_1$, but not on the effective interaction. The action of a fixed gauge transformation is smooth on all of $\mathcal{U}_n$ and an isometry for the product metric; in particular, it extends past each of these closures.

By the agreement of the local expressions, we have, on the larger neighborhood O_l^+ of a member of this cover,

$$\overline{R}_{\mathrm{sat}}(U) = R\big(e^{\xi^{(l)}(U)}\big) - R(I), \qquad \xi^{(l)}(U)_e = \mathrm{Log}\big((U^{k_l})_e\big).$$

Since $r_1 < \pi$, the logarithm and all its derivatives of fixed order are bounded on $\{|\mathrm{Log}| \le r_1\}$. Indeed, the transverse eigenvalue of the differential of the exponential map has modulus $2\sin(|\xi|/2)/|\xi|$, which is bounded away from zero on this closed ball. Repeated differentiation of the inverse function identity then bounds every higher derivative. We refine the parameter subcharts so that the closure of each is contained in $W^+ \cap \Psi^{-1}(O_l^+)$ for one l; this is possible because the sets O_l cover $\Psi(\overline{W})$ and $\overline{W}$ is compact. The maps $\xi^{(l)} \circ \Psi$ then extend smoothly past these closures, and for every fixed j their derivatives through order j are bounded there. This verifies, at each use, the condition on compact subcharts in Theorem 14.8. By the chain rule, the derivative of order j of $\overline{R}_{\mathrm{sat}} \circ \Psi$ is a finite sum of contractions of $D^a R$, $1 \le a \le j$, with derivatives of $\xi^{(l)} \circ \Psi$. The bound (33.8) and the conversion from the norm $\|\cdot\|_{\mathrm{root}}$ to Euclidean norms at the fixed side n bound every term. Since the local expressions agree on overlaps, these bounds concern one smooth function $\overline{R}_{\mathrm{sat}}$ on a neighborhood of $\mathcal{K}$. This proves (33.10). We note that no derivative of a gauge transformation chosen as a function of U was taken. □

The next lemma is a local version of Lemma 14.9 for small constant commuting configurations. Unlike that result, it requires no condition on the side m. It is used for the chart of Theorem 33.8 and for the lower bound in Theorem 33.10.

Lemma 33.7. *There exists $\epsilon_{\mathrm{loc}} > 0$, depending only on the fixed domains of the classical background fields, of the local constraint coordinates and Haar disintegration densities, and of the based gauge transformations used in Theorem 12.13, and in particular independent of the*

preceding depth and of γ, with the following property. Let $m \geq 4$, let $H_1, H_2, H_3 \in \mathfrak{su}(2)$ commute, and suppose that $\epsilon = \max_i |H_i|/m < \epsilon_{\mathrm{loc}}$. Let c be the configuration on Λ_m with $c_e = e^{H_i/m}$ on every link e in direction i. Then c and all its commuting refinements, together with their representatives in the block axial gauge, lie in the interior of these domains for one RG step, with a margin independent of m, of the depth, and of γ. For every depth $d \geq 0$ we have $E_d(c) = 0$. In the free logarithmic coordinates relative to the coarse-field lift $U_0(c)$, the refinement has $z = 0$; this point is the conditional constrained minimizer $z_d^*(c)$, and the corresponding normalized fluctuation variable is $w = 0$. The lemma imposes no condition on the other flat configurations on Λ_m.

Proof. We check the domain conditions directly, without using a neighborhood of the small-field event. We use the identities for commuting roots in Lemma 14.9, but not its condition on the minimum side. For one averaging step, let

$$a_i = e^{H_i/(Mm)}, \qquad c_i = a_i^M,$$

where a denotes the constant configuration on Λ_{Mm} with these link variables. In the block averaging map (4.3), every translated path with endpoint connectors $F_{c,x}$ has the same transport a_i^M as the reference path C_c, since all factors commute and the paths have the same displacement. Hence the logarithms of all based loop holonomies vanish, $T_M a = c$, and no exceptional value of T_M occurs.

We write $M = 2R_M + 1$. In a centered block with center v, the based gauge transformation to the block axial gauge at $x = v + r$ is $k(x) = \prod_j a_j^{r_j}$, where $|r_j| \leq R_M$. By commutativity, we have

$$|\mathrm{Log}\, k(x)| \leq \frac{3R_M}{M}\epsilon, \qquad \max_e |\mathrm{Log}\, a_e| \leq \epsilon/M, \qquad \max_e |\mathrm{Log}\, U_0(c)_e| \leq \epsilon. \tag{33.11}$$

A transformed link in the interior of a block is the identity. On a link between two blocks in direction i, the offsets r_i at its endpoints differ by $1 - M$, and the transformed link is $a_i^M = c_i$. Thus the configuration in the block axial gauge is exactly the coarse-field lift $U_0(c)$ of Section 4, and all free logarithmic coordinates and the logarithms on the eliminated edges e_c^* vanish. Since the derivative of the block averaging constraint with respect to the eliminated edge is $M^{-2} I_3$ there, the point lies in the domain of the local constraint coordinates, with positive Jacobian. The Haar factors are positive on the small link ball.

We now choose the margin. Let $b_* > 0$ be smaller than r, than the radii r_* and r_{sym} and the constant κ_{sym} of Theorem 10.11 and Lemma 10.8, than the radius r_{lift} of the C^1 ball of fine potentials in Lemma 10.8, and than the fixed radii of the coarse-field, constraint, Haar disintegration, and gauge domains of one RG step in Theorem 12.13. These are the radii used in the choice of r_{flat} in Lemma 14.9. There are only finitely many types of words in the construction of one RG step. Let $C_{\mathrm{geo},J} \geq 1 + 3R_M/M$ be a bound for their

lengths and for the sums of the offsets in their based gauge transformations, measured in units of the output lattice of the RG step. This bound does not depend on the side, since the words are translates of the words in one fixed block, and there are only J successive block sizes. Finally, we require

$$4C_{\mathrm{geo},J}\epsilon_{\mathrm{loc}} < b_*.$$

The logarithm of a product of commuting small factors is bounded by its word length times the largest logarithm of a factor. Thus (33.11) and this choice verify every intermediate condition on coarse fields, tree gauges, and gauge transformations, with a fixed margin. At a finer side mM^l the link bound is ϵM^{-l}, and none of these inequalities becomes worse with the number of averaging steps. The gauge identity of Lemma 10.8 applies, because both representatives lie in its ball of radius r_{sym} and the logarithms of the gauge transformations are below κ_{sym}.

We prove that the effective classical action vanishes by induction on d, simultaneously for all sides $m \geq 4$ and all constant commuting configurations as in the statement. The comparison below concerns real configurations and real free coordinates. No minimum and no positive Hessian is asserted for complex coarse fields. The continuation in a complex parameter below concerns only the analytic identity for the minimizer, after it has been proved near real parameter values. For $d = 0$, the Wilson action vanishes at the flat configuration c. Suppose that the claim holds at depth d. The refinement a has side Mm and satisfies the smaller bound ϵ/M. By the induction hypothesis, we have $E_d(a) = 0$, and by the gauge invariance just checked, $E_d(U_0(c)) = E_d(a) = 0$. By the definition of the effective classical action in Section 4, for the actions and minimizers of Theorem 12.13, we have

$$E_{d+1}(c) = MF_d(c, z_d^*(c)) = M \min_z F_d(c, z), \qquad F_d(c, z) = E_d(b(c, z)),$$

where the minimum is over the domain of the classical background field. The free point $z = 0$ lies in this domain by the margins verified above; this does not presuppose that $z = 0$ lies in a fluctuation cutoff domain centered at $z_d^*(c)$. Since $F_d(c, 0) = 0$, the minimum is at most zero, and nonnegativity (Theorem 11.2) implies that $E_{d+1}(c) = 0$. This completes the induction, and it also shows that $E_d(U_0(c)) = 0$ at every depth. In other words, the iteration uses exact commuting roots, whose potential in units of the coarse lattice is H_i/m at every side and whose first spatial differences vanish; no loss of domain accumulates.

It remains to identify $z = 0$ with the conditional constrained minimizer. In the coordinates of Theorem 12.13, z_d^* is the analytic branch of constrained minimizers through $z_d^*(I) = 0$. Since the point $z = 0$ attains the minimum of $F_d(c, \cdot)$, we have $D_z F_d(c, 0) = 0$. At $c = I$ the constrained Hessian $K_d(I)$ is positive. By Lemma 33.1(1), applied to $D_z F_d$, the critical point near 0 is then locally unique for c near I. For each fixed side and depth, we find $z_d^*(e^{tH/m}) = 0$ for real t near zero. The minimizer is holomorphic on the common

domain of coarse fields of Theorem 12.13, and the factor four in the choice of ϵ_{loc} keeps $e^{tH/m}$ in this domain for complex $|t| < 2$. Each component of $t \mapsto z_d^*(e^{tH/m})$ is therefore holomorphic on $|t| < 2$ and vanishes on an interval around zero. Its Taylor coefficients at zero vanish, and continuation through overlapping discs gives $z_d^*(e^{tH/m}) = 0$ for $|t| < 2$, in particular at $t = 1$. The radius of local uniqueness at the origin need not be uniform; the common domain and the margins are. Since the normalization $z - z_d^*(c) = g_d K_d^{-1/2} w$ is invertible, $z = z_d^*(c)$ corresponds to $w = 0$, which lies in the interior of every fluctuation cutoff domain. By Theorem 15.12, the reconstruction maps $\widehat{\mathscr{R}}$, whose gauge transformations are based at the coarse vertices, preserve these properties. This completes the proof. □

Theorem 33.8. *Consider the stopped measures of Section 33.2, with L, $n \in 4\mathbb{N}$, M, J, Θ, and γ_0 fixed before γ, and let $g = \sqrt{\gamma/n}$. Let d_0 denote the forward lattice gradient on Λ_n (not a depth) and d_0^* its adjoint, the discrete divergence, both acting componentwise on $\mathfrak{su}(2)$-valued functions and link arrays, and let*

$$\mathcal{S}_n = \Big\{ s = (s_i(x)) \in \mathfrak{su}(2)^{\mathcal{E}_n} : d_0^* s = 0,\ \sum_x s_i(x) = 0 \ (i = 1,2,3) \Big\},$$

and $d_n = \dim \mathcal{S}_n = 6n^3 - 6$. There exist $\rho_n, s_n, c_n, C_n > 0$ such that the following hold.

1. *The based quotient of $\mathcal{U}_n$ is a compact manifold of dimension $6n^3 + 3$, and the based gauge transformations carry Haar measure of total mass one. The map $(X, s) \mapsto V(X, s) = e^{X/n+s}$, which assigns $\exp(X_i/n + s_i(x))$ to the link from x to $x + a_n e_i$, defined for $X \in \mathbb{R}^9$ with $|X| < \rho_n$ and $s \in \mathcal{S}_n$ with $|s| < s_n$, induces coordinates on a neighborhood of the class of the identity in the based quotient. In these coordinates the image of H_n is $J_n(X, s)\, dX\, ds$, where J_n is smooth and strictly positive. The configurations $V(X, s)$ lie in $B_r \subset D_r$. Simultaneous conjugation at the root is not divided out.*
2. *Let $F_d(X, s) = E_d(e^{X/n+s})$, $f_d(X) = F_d(X, 0)$, and $A_d(X) = D_s^2 F_d(X, 0)$. For every integer $d \geq 0$,*

$$D_s F_d(X, 0) = 0, \qquad F_d(X, s) = f_d(X) + \tfrac{1}{2}\langle s, A_d(X) s \rangle + O_n(|s|^3),$$
$$c_n I \leq A_d(X) \leq C_n I, \qquad F_d(X, s) \geq f_d(X) + c_n |s|^2.$$

3. *For $d = kJ$ and $0 < \gamma \leq \gamma_0$, write $\overline{R}_{d,\gamma}(X, s) = \overline{R}_{d,\gamma}(V(X, s))$. Then, uniformly in X, d, and γ,*

$$\int_{|s|<s_n} e^{-F_d(X,s)/g^2 - \overline{R}_{d,\gamma}(X,s)} J_n(X, s)\, ds = (2\pi)^{d_n/2} g^{d_n} e^{-f_d(X)/g^2} a_{d,\gamma}(X) \big[1 + O_n(g)\big],$$

$$a_{d,\gamma}(X) = \frac{e^{-\overline{R}_{d,\gamma}(X,0)} J_n(X, 0)}{\sqrt{\det A_d(X)}}.$$

The amplitude $a_{d,\gamma}$ has positive upper and lower bounds and a C^1 bound, uniformly in d and γ.

The constants may depend on n, L, M, J, Θ, γ_0, and on the larger chart and the bounds in (P2) and (P3), but not on d, on the total number of averaging steps, or on $\gamma \in (0, \gamma_0]$.

No positive Hessian is asserted in the nine constant directions X: at the identity the quadratic part of E_0 vanishes on constant configurations.

Proof. The proof has five steps. We construct the based quotient and the coordinates (X, s), fix the radii, prove the stationarity in s and the gap at the fixed side n, and then apply Lemma 33.3 in the variable s at each fixed X.

Step 1: inputs. All bounds in this proof are at the fixed side n. The lower bound (P1) holds at every integer $d \geq 0$, whether or not an effective interaction is attached to d. In the statements involving $\overline{R}_{d,\gamma}$, we have $d = kJ$, and $R_{d,\gamma}$ is the effective interaction of the density (33.1), with the value bound and the analytic norm of that density. Its first derivatives in the chart are obtained from Lemma 33.6, on the relatively compact subcharts chosen in Step 3 and with the identity gauge transformation, which extends past their closures. They do not follow from the value bound. The derivative bounds for the classical actions in fixed charts come from Theorem 10.11: restricted to the finitely many coordinates at side n, its coefficient bounds give bounds for ordinary derivatives, with constants depending on n. The exact translation invariance of E_d is Lemma 10.8. The vanishing of E_d and the domain conditions for small constant commuting configurations are proved in Lemma 33.7, with no condition on the minimum side. Finally, (P4) allows us to apply Theorems 12.13 and 14.8 for every $0 < \gamma \leq \gamma_0$.

Step 2: the based quotient. We fix a periodic spanning tree of the lattice graph Λ_n. There exists a unique based gauge transformation that makes every tree link the identity. It is obtained successively from the root, by prescribing its value at a new vertex from the tree link leading to that vertex. The remaining links are $3n^3 - (n^3 - 1) = 2n^3 + 1$ independent non-tree links. This change of variables has an exact interpretation for the measure. We condition on the preceding tree variables and use a left or right translation of Haar measure at the next tree link. This replaces that link by the value of the gauge transformation at the new vertex, with Haar measure. At each non-tree link the two endpoint factors are determined by the tree variables, and its change of variables is again a Haar translation. By Fubini's theorem, the image of H_n is the product of Haar probability measures in the $n^3 - 1$ values of the based gauge transformation and in the $2n^3 + 1$ non-tree link variables. Integrating out the gauge variables gives one. In particular the based quotient is the compact product $\mathrm{SU}(2)^{2n^3+1}$, of dimension $6n^3 + 3$, and no conjugation at the root has been divided out from the non-tree link variables.

Step 3: the coordinates and the radii. The gradient is injective on $\mathfrak{su}(2)$-valued vertex functions that vanish at the root: if the gradient of such a function vanishes, the function is constant on the connected graph and hence zero. The image of these gradients has

dimension $3(n^3-1)$, and its orthogonal complement in the $9n^3$-dimensional space of link arrays is $\ker d_0^*$, of dimension $6n^3+3$. The nine arrays that are constant in position lie in this complement, and their orthogonal complement within it is $\mathcal{S}_n$, of dimension $6n^3-6$. The orthogonal decomposition can be constructed explicitly. For an array A, the equation $d_0^* d_0 \xi = d_0^* A$ has a unique solution ξ with mean zero, by diagonalization of this positive matrix on mean-zero vertex functions. Subtracting $d_0\xi$ and then the spatial means of the three components, we obtain the component in $\mathcal{S}_n$.

We consider the map that sends (X,s) to $e^{X/n+s}$ and then to the non-tree link variables of its representative in the tree gauge. At $(0,0)$ its derivative is the projection along gradients onto the non-tree link coordinates. Indeed, the linearized tree gauge fixing sends a link logarithm array A to $A - d_0\xi$, where ξ vanishes at the root and $A - d_0\xi$ vanishes on the tree, and then reads off the non-tree links. The kernel of the derivative is the image of d_0 on functions vanishing at the root. The derivative is therefore injective on the complement $\mathbb{R}^9 \oplus \mathcal{S}_n$ constructed above, and invertible there, since the dimensions agree. By Lemma 33.1(1), the map is a diffeomorphism near $(0,0)$. Pulling back the product of Haar measures on the non-tree links, whose density in exponential coordinates is smooth and positive near the identity, we obtain a smooth strictly positive density $J_n(X,s)$. Its bounds and the bounds for its derivatives of fixed order on smaller closed coordinate balls depend only on n and on these balls.

We now fix the radii, independently of d and γ. We shrink the balls so that $\max_{x,i} |X_i/n + s_i(x)| < r/2$, and choose slightly larger balls with the same property. We also require $2\rho_n/n < \epsilon_{\mathrm{loc}}$, with ϵ_{loc} from Lemma 33.7, and put the larger balls inside the charts of radii r_* and r_{sym} of Theorem 10.11 and Lemma 10.8. More precisely, we choose the product $\mathcal{C}$ of the two coordinate balls in the statement and a larger product $\mathcal{C}^+$ with $\overline{\mathcal{C}} \subset \mathcal{C}^+$, such that $\overline{\mathcal{C}^+}$ lies in the chart just constructed and satisfies all these strict bounds on link logarithms. These finitely many conditions are compatible with positive radii. The map $(X,s) \mapsto e^{X/n+s}$ and the quotient chart extend smoothly to a neighborhood of $\overline{\mathcal{C}^+}$, and the gauge transformation used here is the identity. Every derivative of fixed order of the chart is therefore bounded on this closure, with constants depending only on n. This verifies the condition on compact subcharts in Theorem 14.8 and Lemma 33.6, both for the integration in s and for the derivative of the amplitude in X. The configurations $V(X,s)$ lie in $B_r \subset D_r$, with link logarithms in the ball B_{r_1} of Lemma 33.6, for a fixed $r_1 \in (r, \min(\rho,\pi))$; in particular $\eta = 1 - r_1/\rho$ is fixed. Every commuting point X used here satisfies $\max_i |X_i|/n < \epsilon_{\mathrm{loc}}$, so E_d vanishes there at every depth.

Step 4: stationarity and the gap. Fix a constant array of logarithms $A_i(x) = X_i/n$. Translation by any lattice vector fixes this array. Differentiating the exact translation invariance of E_d, we find that the gradient $DE_d(e^A)$ in link logarithm coordinates is constant in position for each direction and color. Its pairing with every array of spatial

mean zero vanishes, and

$$D_s F_d(X,0) = 0 \tag{33.12}$$

for every d and every X in the chart. This argument concerns E_d only, and it does not set any derivative of the effective interaction or of the Haar density to zero.

We now prove the gap at the fixed side. The expansion of a plaquette variable at the identity in link logarithms is $d_0 A + O(|A|^2)$, and $4q(e^Y) = |Y|^2/2 + O(|Y|^4)$. It follows that

$$E_0(e^A) = \tfrac{1}{2} \sum_{x,\, i<j} |A_j(x+e_i) - A_j(x) - A_i(x+e_j) + A_i(x)|^2 + O_n(|A|^3),$$

where e_i denotes one lattice step. At the Fourier mode $m \in \mathbb{Z}^3/n\mathbb{Z}^3$, let $\eta_i(m) = e^{2\pi i m_i/n} - 1$. For each color,

$$\sum_{i<j} |\eta_i a_j - \eta_j a_i|^2 = |\eta|^2|a|^2 - |\eta^* a|^2.$$

Since the zero mode is absent on $\mathcal{S}_n$ and $\eta^* a = 0$ there, the Hessian of E_0 at the identity is at least $\lambda_n I$ on $\mathcal{S}_n$, where $\lambda_n = 4\sin^2(\pi/n) > 0$. All inequalities between functions and Hessians here concern real configurations and real tangent vectors. Since $E_d - \kappa E_0 \geq 0$ near the identity by (P1) and vanishes at the identity, its Hessian at this point is positive semidefinite. This implies

$$D_s^2 F_d(0,0) \geq \kappa \lambda_n I.$$

By the uniform bound on third derivatives in (P2), we have

$$\|D_s^2 F_d(X,s) - D_s^2 F_d(0,0)\| \leq C_n(|X| + |s|).$$

We choose the radii so that the right side is at most $\kappa\lambda_n/2$; the upper derivative bounds in (P2) give a uniform upper bound. Then $A_d(X) = D_s^2 F_d(X,0) \geq \kappa\lambda_n I/2$, and Taylor's formula with integral remainder and (33.12) give

$$F_d(X,s) = f_d(X) + \tfrac{1}{2}\langle s, A_d(X)s\rangle + O(C_n|s|^3), \qquad F_d(X,s) - f_d(X) \geq \tfrac{1}{4}\kappa\lambda_n|s|^2.$$

This proves part (2), after decreasing c_n.

Step 5: integration in s and the amplitude. On the larger s-ball we apply Lemma 33.3, at each fixed X, with

$$V(X,s) = F_d(X,s) - f_d(X), \qquad \delta = g^2, \qquad a(X,s) = e^{-\overline{R}_{d,\gamma}(X,s)} J_n(X,s),$$

the rank d_n, and the Hessian $L = A_d(X)$. All these functions and the Hessian field are smooth in (X,s) on the fixed real chart, hence jointly Borel, and we choose a fixed smooth cutoff in s, equal to one on a smaller fixed ball and supported in the ball $|s| < s_n$. The

phase bounds were proved in Step 4. For the amplitude, let $B_n = \sup_{D_r} |\overline{R}_{d,\gamma}|$, which is bounded by (P3). By (33.9) and the mean value theorem on the convex s-ball,

$$|a(X,s) - a(X,0)| \le e^{B_n}\big(\|J_n\|_\infty 3n^{3/2}K_1 + \|D_s J_n\|_\infty\big)|s|.$$

The positive lower and upper bounds follow from $e^{-B_n} \le e^{-\overline{R}_{d,\gamma}} \le e^{B_n}$ and the positivity of J_n. Every hypothesis of Lemma 33.3 therefore holds with constants c_0, C_0 depending only on the fixed data. The case $P = 1$ of (33.7) gives the integral with the cutoff. The additive error $O(g)$ becomes a relative error because the amplitude $a(X,0)/\sqrt{\det A_d(X)}$ has a fixed positive lower bound. The lower bound $F_d - f_d \ge c_n|s|^2$ holds on the whole ball $|s| < s_n$, and so do the amplitude bounds. By (33.5), for $g \le 1$ and after factoring out $e^{-f_d(X)/g^2}$, the difference between the integral with the cutoff and the integral over the whole ball is at most $Cg^{d_n}e^{-c'/g^2}$, which is $O_n(g^{d_n+1})$. If $\gamma_0/n > 1$, then for $1 < g^2 \le \gamma_0/n$ both the integral and the main term are bounded above and below by positive constants depending only on the fixed data, and the asserted formula holds there after enlarging the constant. We obtain

$$(2\pi)^{d_n/2} g^{d_n} e^{-f_d(X)/g^2} \frac{e^{-\overline{R}_{d,\gamma}(X,0)} J_n(X,0)}{\sqrt{\det A_d(X)}} \big[1 + O_n(g)\big].$$

For the C^1 bound of the amplitude, we have

$$D_X \log a_{d,\gamma}(X) = -D_X \overline{R}_{d,\gamma}(X,0) + D_X \log J_n(X,0) - \tfrac{1}{2}\operatorname{tr}\big(A_d(X)^{-1} D_X A_d(X)\big).$$

The first term is bounded by $3n^2K_1$, by (33.9); the value bound alone would not give this estimate. The trace is bounded by $d_n \|A_d^{-1}\| \|D_X A_d\|$, and every factor is bounded uniformly, by the fixed chart, the lower bound for the Hessian, and the bound on third derivatives. This proves the bounds for the amplitude, with the phase f_d at finite depth. In particular, no limit of the classical actions as $d \to \infty$ at fixed coupling has been inserted into an exponent divided by g^2. All constants have the dependence stated in the theorem. □

33.6 Flat configurations and the partition function

We now describe the flat configurations on Λ_n away from the central triples, that is, the triples of central cycle holonomies. We then prove the two-sided bound for the partition function. Recall from Lemma 14.9 that the flat configurations modulo all periodic gauge transformations are classified by their commuting cycle holonomies modulo simultaneous conjugation. In the based quotient, where simultaneous conjugation is not divided out, the flat set is the set of commuting triples $(H_1, H_2, H_3) \in \mathrm{SU}(2)^3$. We call a flat configuration regular if its cycle holonomies are not all central. A compact regular patch is a compact subset of the flat set in the based quotient containing none of the eight configurations with central cycle holonomies.

Lemma 33.9. *1. In the based quotient at side $n \geq 4$, the set of regular flat configurations is a smooth embedded submanifold of dimension five. The Hessian of E_0 is positive definite in the normal directions at every regular flat configuration. On every compact regular patch it has a positive lower bound, and there is a finite atlas of normal coordinates $V(y,v)$, with y in the flat manifold and $v \in \mathbb{R}^{6n^3-2}$, in which the image of H_n has a smooth positive density $J(y,v)$ with respect to $d\mathrm{vol}(y)\,dv$.*

2. Consider the stopped measures of Section 33.2 and a compact regular patch. Assume either that the patch consists of configurations gauge equivalent to constant commuting links $e^{H_i/n}$ with $\max_i |H_i|/n < \epsilon_{\mathrm{loc}}$, as in Lemma 33.7, or that $2\pi/n < r_{\mathrm{flat}}$, where r_{flat} is the radius of Lemma 14.9. Assume also that the patch lies in a common larger classical link chart, after fixed gauge transformations. Then there is a normal tube over the patch, fixed independently of d and γ, on which, for every integer $d \geq 0$,

$$nE_d(V(y,v)) = \tfrac{1}{2} v^{\mathsf{T}} H_d(y) v + O(C_n|v|^3),$$
$$c_n I \leq H_d(y) \leq C_n I, \qquad nE_d(V(y,v)) \geq c_n |v|^2.$$

The normal rank is $6n^3 - 2$. The constants may depend on n, the patch, the larger chart, the constant κ of (P1), the derivative bounds of (P2), and the margins of the tube.

Proof. We use the based quotient $\mathrm{SU}(2)^{2n^3+1}$ of non-tree link variables constructed in Step 2 of the proof of Theorem 33.8. By Lemma 14.9, a flat point of the based quotient is determined by its three commuting cycle holonomies. This identification and its inverse are locally smooth. Indeed, each holonomy is a finite product of non-tree link variables. Conversely, after fixing paths in the tree, the flat transport along every non-tree link is the word in the three commuting cycle transports given by the winding numbers of the closed path that it forms with the tree. Such a word is a smooth product of integer powers.

At a regular triple we choose a noncentral member. Its quaternion vector is nonzero and, after fixing its sign, determines a smooth unit axis on a small patch. Every member of a commuting triple has its vector parallel to that axis. We choose local lifts of the three angles on the corresponding circles and two local coordinates for the axis. Differentiation in the three angles and the two axis coordinates is injective, since the chosen member has nonzero vector. Projection onto five suitable ambient coordinates therefore has invertible derivative. By Lemma 33.1(1), the regular flat set is a smooth embedded five-dimensional manifold, and its only possible singular points are the eight triples whose members are all central.

Next we determine the kernel of the Hessian, including the count of based gauge directions. By a periodic gauge transformation and a constant conjugation, we conjugate a flat representative to the constant commuting links $U_i^0 = e^{\vartheta_i \tau_3/n}$. Such transformations change neither the rank of the Hessian nor its quadratic form on the gauge quotient.

We write a variation of the links in left coordinates as $e^{ta_i(x)}U_i^0$. The derivative of the plaquette logarithm is

$$(d_U a)_{ij}(x) = \mathrm{Ad}_{U_i^0}\, a_j(x+e_i) - a_j(x) - \mathrm{Ad}_{U_j^0}\, a_i(x+e_j) + a_i(x),$$

as one sees by differentiating its four ordered factors, since the background plaquette variable is the identity. Since the quadratic part of E_0 is $\sum |d_U a|^2/2$, the kernel of the Hessian is $\{d_U a = 0\}$.

We split the colors into $\mathbb{R}\tau_3$, the neutral color, and its orthogonal plane, the charged color, which we identify with $\mathbb{C}$ so that ad_{τ_3} acts as multiplication by i. In neutral color the Fourier difference vector is $\eta_i = e^{2\pi i m_i/n} - 1$. If $\eta \neq 0$, the equations $\eta_i a_j - \eta_j a_i = 0$ imply $a = \eta\phi$, with $\phi = a_j/\eta_j$ for an index j with $\eta_j \neq 0$. These are exactly the gradient directions, and the zero mode gives three real constant neutral directions. In charged color the difference vector is

$$\eta_i = e^{i(2\pi m_i + \vartheta_i)/n} - 1.$$

It cannot vanish in all three components, since that would force every ϑ_i into $2\pi\mathbb{Z}$ and all three holonomies to be central. The same algebra $a = \eta\phi$ shows that every charged mode in the kernel is a covariant gradient. This argument includes the cases in which some ϑ_i vanish, without division by a possibly vanishing component.

The covariant gradient on vertex functions has a one-dimensional kernel, consisting of the constant neutral functions, since its charged Fourier vectors never vanish and its neutral kernel consists of constants. Its real image has dimension $3n^3 - 1$. Its restriction to functions vanishing at the root is injective, since a covariantly constant function vanishing at one point vanishes everywhere by transport along links. Hence the image of the based gradients has dimension $3n^3 - 3$, and after dividing out the based gradients, the kernel has dimension

$$(3n^3 - 1) + 3 - (3n^3 - 3) = 5.$$

Two of these directions are infinitesimal simultaneous conjugations at the root, and three are the constant neutral directions. They are exactly the tangent directions of the five-dimensional manifold parametrized above. Since the Hessian is a nonnegative symmetric matrix with no further kernel, it is positive definite on a normal complement. Its least normal eigenvalue has a positive minimum on a compact regular patch, since continuous unit normal vectors over that compact set form a compact set on which the quadratic form does not vanish.

For integration, we give the based quotient $\mathrm{SU}(2)^{2n^3+1}$ its product Riemannian metric, which is bi-invariant, and let $\mathcal{F}$ be the manifold of regular flat configurations. We use the normal exponential map

$$V(y, v) = \mathrm{Exp}_y(v), \qquad y \in \mathcal{F},\ v \perp T_y\mathcal{F},$$

of Lemma 33.1(2). Over a compact neighborhood of a compact regular patch, it is injective for a common small normal radius. We choose finitely many smooth orthonormal trivializations of the normal bundle of $\mathcal{F}$, with working subcharts relatively compact in larger charts. Since their transitions preserve y and are orthogonal in v, a partition of unity on the base extends consistently to the tube. The maps $V(y,v)$, their lifts to configurations, and the normal frames extend smoothly past the closures of the working subcharts, so all derivatives of fixed order of the charts are bounded there. Since the Haar measure of the product group is a constant multiple of its Riemannian volume, its pullback $J(y,v)$ is smooth and positive with respect to $d\mathrm{vol}(y)\,dv$. This proves part (1).

For part (2), on patches of small commuting configurations, the vanishing of the classical actions is proved in Lemma 33.7. On a general patch at a side with $2\pi/n < r_{\mathrm{flat}}$, it is the conclusion of Lemma 14.9 for all flat configurations: every averaging step has output side $m \geq n$, and $2\pi/m \leq 2\pi/n < r_{\mathrm{flat}}$ verifies the condition on the side at each step. By gauge invariance, these zeros transfer to the smooth based representatives used here. Since $E_d \geq 0$, its first derivative vanishes on the flat manifold. Since $E_d - \kappa E_0 \geq 0$ by (P1) and vanishes there, the Hessian of $E_d - \kappa E_0$ is positive semidefinite on real normal vectors. The lower bound of part (1) then implies $H_d = D_v^2(nE_d)(y,0) \geq c_n I$. The uniform derivative bounds of (P2) on the common larger chart give the upper bound and a common cubic Taylor error. If a quotient chart is not itself a representative with small links, we fix a gauge transformation taking its center into B_r and shrink the neighborhood inside the fixed larger classical chart. By compactness, finitely many such fixed gauge transformations suffice. Their derivatives and the bounds of Theorem 10.11 give the same bound by the chain rule, and no gauge transformation depending on the point is needed. We choose the radius of the tube so that the cubic error is at most one quarter of the lower bound for the Hessian times $|v|^2$. This proves the lower bound for nE_d on the whole smaller tube. All these choices depend only on the listed data. The normal rank is the dimension $6n^3+3$ of the based quotient minus five. □

Theorem 33.10. *The following statements hold.*

1. *For every integer $n \geq 4$ and every $\kappa > 0$ there exists $C_{n,\kappa} < \infty$ such that for $0 < g \leq 1$*

$$\int_{\mathcal{U}_n} e^{-\kappa E_0(V)/g^2}\, dH_n(V) \leq C_{n,\kappa} g^{6n^3-2}, \qquad E_0(V) = 4 \sum_{p \in \mathcal{P}_n} q(V_p).$$

   This is an integral over the whole configuration space, including neighborhoods of all eight flat configurations with central cycle holonomies. Divisibility of n by four is not needed, and $C_{n,\kappa}$ depends only on n and κ.

2. *Consider the stopped measures of Section 33.2. There exist $g_0(n) > 0$ and $0 < c_n \leq C_n < \infty$, with the dependence described in Theorem 33.8, such that for all depths $d = kJ$ and all $0 < \gamma \leq \gamma_0$ with $g = \sqrt{\gamma/n} \leq g_0(n)$,*

$$c_n g^{d_n+4} \leq \widehat{Z}_{n,d,\gamma} \leq C_n g^{d_n+4}, \qquad d_n = 6n^3 - 6.$$

Equivalently, $\widehat{Z}_{n,d,\gamma}$ is comparable to γ^{p_n}, $p_n = 3n^3 - 1$, uniformly in d and γ in this range, at the fixed side n. Here $\widehat{Z}_{n,d,\gamma}$ is the partition function of (33.1)*, with the centered effective interaction. If Z^{raw} is defined with $R_{d,\gamma}$ in place of $\overline{R}_{d,\gamma}$, then $\widehat{Z}_{n,d,\gamma} = e^{R_{d,\gamma}(I)} Z^{\mathrm{raw}}$ exactly.*

3. *For every $\rho > 0$ and $c > 0$ there exists $C_{\rho,c}$ such that for $0 < g \le 1$*

$$\int_{|X|<\rho} e^{-cQ(X)/g^2}\, dX \le C_{\rho,c} g^4.$$

Here ρ is an arbitrary radius, not the analytic radius. More precisely, for $g \le \min(1, \rho^2)$ the ball $|X| \le \sqrt{g}$ contributes $O(g^{9/2})$, and each annulus $\varrho/2 < |X| < \varrho$ with $\sqrt{g} \le \varrho \le \rho$ contributes $O(g^4 \varrho)$.

The lower bound in (2) comes from a fixed annulus of regular constant commuting configurations in the chart of Theorem 33.8, and it uses only the bound on the values of the centered effective interaction.

Proof. We prove the upper bound in (1) by covering the based quotient by neighborhoods of the eight central flat configurations, normal tubes over the remaining compact regular part of the flat set, and a compact set without flat configurations. Near the central configurations, we integrate the nonconstant directions with the gap of Theorem 33.8, and the constant directions with the estimate in (3). We then deduce (2) from (1), (P1), and (P3).

Step 1: constant configurations. We need an exact lower bound for the Wilson action on constant configurations. We write $U = aI + 2v^a\tau_a$ and $W = bI + 2w^a\tau_a$ with $a^2 + |v|^2 = b^2 + |w|^2 = 1$. The multiplication rule

$$(a, v)(b, w) = (ab - v \cdot w,\ aw + bv + v \times w)$$

follows directly from the products of the matrices τ_a. Conjugation by (a, v) sends w to $(a^2 - |v|^2)w + 2(v \cdot w)v + 2a(v \times w)$. Thus the scalar part of $UWU^{-1}W^{-1}$ is

$$b^2 + \left[(a^2 - |v|^2)w + 2(v \cdot w)v + 2a(v \times w)\right] \cdot w = 1 - 2|v \times w|^2,$$

which implies $q(UWU^{-1}W^{-1}) = 2|v \times w|^2$ exactly. For $U_i = e^{x_i/n}$ we have $v_i = \sin(|x_i|/(2n))\widehat{x}_i$, and summing over the n^3 plaquettes in each of the three planes gives, continuously also when some x_i vanish,

$$\begin{aligned} E_0(e^{X/n}) &= 8n^3 \sum_{i<j} \sin^2(|x_i|/(2n)) \sin^2(|x_j|/(2n)) |\widehat{x}_i \times \widehat{x}_j|^2 \\ &= \frac{1}{2n} \sum_{i<j} |x_i \times x_j|^2 \operatorname{sinc}^2(|x_i|/(2n)) \operatorname{sinc}^2(|x_j|/(2n)). \end{aligned} \tag{33.13}$$

Since the factors sinc^2 have positive lower and upper bounds on a fixed small ball, $E_0(e^{X/n})$ is comparable to $Q(X)/n$ there. This is a relative bound, valid also in almost commuting directions.

Step 2: the neighborhood of the identity. Applying the proof of Theorem 33.8 to the Wilson action alone, we obtain, on a fixed neighborhood of the identity in the based quotient,

$$E_0(e^{X/n+s}) \geq E_0(e^{X/n}) + c_n|s|^2 \geq c_n'(Q(X) + |s|^2), \tag{33.14}$$

where the second inequality is (33.13). This uses only the translation invariance of E_0, the gap at side n, and the smoothness of E_0, all verified explicitly in Steps 3 and 4 of that proof. It does not use the stopped density or the divisibility of n by four, and it holds at every integer $n \geq 4$.

Step 3: the nine-dimensional estimate. We prove (3). The ball $|X| \leq \sqrt{g}$ has volume $C_9 g^{9/2}$, which bounds its contribution. We now consider an annulus $\varrho/2 < |X| < \varrho$ with $\varrho \geq \sqrt{g}$, and set $X = \varrho Y$ and $\epsilon = g/\varrho^2 \leq 1$. Since Q is homogeneous of degree four, the integral over the annulus is

$$\varrho^9 \int_{1/2<|Y|<1} e^{-cQ(Y)/\epsilon^2}\, dY.$$

On the fixed closed annulus $1/2 \leq |Y| \leq 1$, the zero set of Q is a compact piece of the nonzero cone $\mathcal{M}$. In a fixed small normal tube around it the radius of the base point is bounded below, and by Lemma 33.2 we have $Q(y+b) \geq c'|b|^2$ and a bounded Jacobian. The tangential volume is finite by the volume formula of Lemma 33.2. Integrating in the four normal directions, we see that the tube contributes at most $C\epsilon^4$. Off the tube, Q has a positive minimum q_* on the annulus: a sequence with $Q \to 0$ would have a limit point in the zero set, hence in the tube. Since $\sup_{u>0} u^2 e^{-cq_* u} < \infty$, the integrand off the tube is at most $C\epsilon^4$. The annulus therefore contributes at most

$$C\varrho^9\epsilon^4 = Cg^4\varrho. \tag{33.15}$$

We take the radii $\rho, \rho/2, \rho/4, \ldots$ until the last annulus reaches $\sqrt{g}$. The sum of these radii is at most 2ρ, and the remaining ball has radius at most $2\sqrt{g}$ and contributes $O(g^{9/2})$. This proves the bound $C_{\rho,c}g^4$ for $g \leq \min(1, \rho^2)$. If $\rho^2 \leq g \leq 1$, the volume of the ball, $C\rho^9$, is at most $C\rho g^4$. The statements about the ball and the annuli follow from the same estimates.

Step 4: the whole configuration space. Integrating (33.14) against the bounded density of the chart, first in s and then in X, we find that the neighborhood of the identity contributes at most

$$C_{n,\kappa} g^{d_n} \int_{|X|<\rho_n} e^{-c_{n,\kappa} Q(X)/g^2}\, dX \leq C_{n,\kappa} g^{d_n+4},$$

by Step 3. To cover the other seven central points, we multiply, for each of the three directions, the links crossing one wrapping coordinate plane in that direction by either

I or $-I$, and call the resulting array of central link variables z. Since each plaquette contains either no such factor or two canceling ones, $z_p = I$ for every plaquette. The three cycle signs of z are arbitrary, and they give the eight central triples. The map $V \mapsto zV$ preserves every plaquette variable and the product Haar measure, and it commutes with based gauge transformations because z is central. It maps the identity point of the flat set in the based quotient to the corresponding central flat point. Transporting the chart just used, we obtain the same bound near every central point, without dividing by the volume of a stabilizer.

We choose smaller open neighborhoods inside these eight charts; the flat set outside them is a compact regular patch. By Lemma 33.9(1), it is covered by finitely many normal coordinate charts with bounded Haar density. By Taylor's formula as in the proof of part (2) of that lemma, with E_0 in place of E_d, we have $E_0 \geq c_n|v|^2$ on these tubes after shrinking them. Each such tube contributes at most Cg^{6n^3-2}, since its normal rank is $6n^3 - 2$. The complement of the union of these tubes and of the central neighborhoods is compact and contains no flat configuration. Since $E_0 \geq 0$ and its zero set consists exactly of the flat configurations, E_0 has a positive minimum e_n on this complement. The complement therefore contributes at most $e^{-\kappa e_n/g^2} \leq C_{n,\kappa} g^{6n^3-2}$ for $0 < g \leq 1$. Summing over the finite cover, and recalling that the based gauge transformations have mass one, we obtain (1).

Step 5: the stopped measure. For the upper bound in (2), we use (P1), which holds at every integer $d \geq 0$, and the bound $|\overline{R}_{d,\gamma}| \leq C_n$ of (P3) at the depths $d = kJ$. Enlarging the domain of integration from D_r to $\mathcal{U}_n$ and applying (1), we obtain

$$\widehat{Z}_{n,d,\gamma} \leq e^{C_n} \int_{\mathcal{U}_n} e^{-\kappa E_0/g^2}\, dH_n \leq C_n g^{6n^3-2}.$$

Only an upper integral has been enlarged, and the partition function is that of the centered density (33.1).

For the lower bound, we choose a small fixed annulus of constant commuting configurations $X = (\vartheta_i u)_i$, with $|\boldsymbol{\vartheta}|$ between two fixed positive radii, strictly inside the chart of Theorem 33.8, with positive tangential volume and with $\max_i |X_i|/n < \epsilon_{\mathrm{loc}}/2$. Such an annulus exists at every fixed side, since its radii can be taken arbitrarily small. Its commuting refinements and their representatives in the block axial gauge satisfy the domain conditions with the margins of Lemma 33.7, which are independent of the depth; no condition on the side is needed for this annulus. We shrink its fixed normal tube so that it stays inside B_r. On this compact annulus, Lemma 33.9 implies that $E_d \leq C_n|v|^2$ and that the Haar density has positive upper and lower bounds. The lower bound for the density times e^{-C_n} bounds the amplitude $e^{-\overline{R}_{d,\gamma}J}$ from below. We integrate only over $|v| \leq g$ and over a fixed smaller tangential subpatch of positive volume. For g below the

fixed radius of the tube, we obtain

$$\widehat{Z}_{n,d,\gamma} \geq c_n \int_{|v|\leq g} e^{-C_n|v|^2/g^2}\, dv \geq c'_n g^{6n^3-2}.$$

All the sets used here are subsets of D_r. Neither bound requires derivative bounds for the centered effective interaction or any convergence of its restriction to the flat directions as $\gamma \to 0$.

Since $d_n + 4 = 6n^3 - 2 = 2(3n^3 - 1)$ and $g^2 = \gamma/n$, the two bounds have the asserted form γ^{p_n} at the fixed side n. Finally,

$$e^{-E_d/g^2-(R_{d,\gamma}-R_{d,\gamma}(I))} = e^{R_{d,\gamma}(I)} e^{-E_d/g^2-R_{d,\gamma}}$$

on the same domain, which proves the relation between the two normalizations. All constants in the lower and upper bounds for $\widehat{Z}_{n,d,\gamma}$ are uniform in d and γ; their dependence on the side has not been bounded. □

33.7 Linearized flowed cycle logarithms

We now compute the covariance Σ_θ of (4.12), which appears in Theorem 2.10. It is the covariance, divided by γ, of the linear response of the flowed holonomy logarithms at a regular flat connection, under the Gaussian measure defined by the quadratic part of the Yang–Mills action. The computation has three ingredients: the covariance of the transverse Gaussian field at the flat background; the derivative of the flowed cycle logarithms, including the differential of the logarithm; and the projection onto the normal space $\mathcal{N}_y$, which removes the longitudinal part. We carry out the computation in the continuum and on the lattice, and compare the two. The lattice flow is the Wilson flow of Lüscher [128], with the normalization of Section 4.

Theorem 33.11. *Fix $L > 0$, $\theta > 0$, and a compact regular patch of commuting triples $y = (\vartheta_i u)_{i=1}^3$ with $u \in S^2$ and $0 < r_0 \leq |\vartheta| \leq r_1 < \pi$. Work in the variables of the unit torus, $\widetilde{A}(x) = LA(Lx)$, in which the flat background is $\widetilde{A}^0_i = \vartheta_i u$ and the time $t = \theta L^2$ becomes θ. Let $D_i = \partial_i + \vartheta_i \operatorname{ad}_u$ be the covariant derivative of the background, acting on $\mathfrak{su}(2)$-valued one-forms $a = (a_1, a_2, a_3)$ on $\mathbb{T}^3_1$, and consider the quadratic form*

$$\frac{1}{2\gamma} \int_{\mathbb{T}^3_1} \sum_{i<j} |D_i a_j - D_j a_i|^2\, dx.$$

Its kernel $\mathcal{K}$ consists of the covariant gradients $D\phi$ and the constant one-forms with values in $\mathbb{R}u$. The form is positive definite on the quotient by $\mathcal{K}$. Let a be the centered Gaussian field with distributional values on this quotient, realized on the L^2-orthogonal complement of $\mathcal{K}$, whose covariance is γ times the inverse of the positive operator associated with $\int_{\mathbb{T}^3_1} \sum_{i<j} |D_i a_j - D_j a_i|^2\, dx$

on this complement; it is constructed from its Fourier coefficients in Step 2 of the proof. Let $\mathcal{L}$ be the derivative at $\widetilde{A}^0$ of the map that sends a connection to the logarithms of the holonomies of its Yang–Mills heat flow at time θ around the three coordinate cycles based at 0, followed by the orthogonal projection onto $\mathcal{N}_y$. Then $\mathcal{L}$ vanishes on $\mathcal{K}$, and the covariance of $\mathcal{L}(a)$ is $\gamma\Sigma_\theta(y)$, where $\Pi_{\boldsymbol{\vartheta}} = I - \boldsymbol{\vartheta}\boldsymbol{\vartheta}^{\mathsf{T}}/|\boldsymbol{\vartheta}|^2$ and

$$k_m = 2\pi m + \boldsymbol{\vartheta}, \qquad \lambda_m = |k_m|^2, \qquad R_i(m,\boldsymbol{\vartheta}) = \begin{cases} 1, & m_i = 0, \\ \vartheta_i/(2\pi m_i + \vartheta_i), & m_i \neq 0, \end{cases}$$

$$d_i = \sum_{m\in\mathbb{Z}^3} \frac{e^{-2\theta\lambda_m}}{\lambda_m} R_i(m,\boldsymbol{\vartheta})^2, \qquad D = \operatorname{diag}(d_1,d_2,d_3), \qquad \Sigma_\theta(y) = (\Pi_{\boldsymbol{\vartheta}} D \Pi_{\boldsymbol{\vartheta}})\big|_{\boldsymbol{\vartheta}^\perp} \otimes I_{u^\perp}.$$

Here $\mathcal{N}_y$ is identified with $\boldsymbol{\vartheta}^\perp \otimes u^\perp$, and these formulas include the cases in which some coordinates of $\boldsymbol{\vartheta}$ vanish. Moreover, the following hold.

1. *On the patch, $cI_4 \le \Sigma_\theta \le CI_4$, and Σ_θ and its inverse are smooth, covariant under color rotations, and invariant under $(\boldsymbol{\vartheta}, u) \mapsto (-\boldsymbol{\vartheta}, -u)$. The inverse is*

$$\Big[D^{-1} - \frac{D^{-1}\boldsymbol{\vartheta}\boldsymbol{\vartheta}^{\mathsf{T}}D^{-1}}{\boldsymbol{\vartheta}^{\mathsf{T}}D^{-1}\boldsymbol{\vartheta}}\Big]\Big|_{\boldsymbol{\vartheta}^\perp} \otimes I_{u^\perp}.$$

   The constant charged mode $m = 0$ alone contributes $e^{-2\theta|\boldsymbol{\vartheta}|^2}|\boldsymbol{\vartheta}|^{-2} I_4$.

2. *Before the flow is applied, the derivative of the cycle logarithms is*

$$T_i a = J_i^{-1} \int_0^1 e^{v\vartheta_i \operatorname{ad}_u} a_i(ve_i)\, dv, \qquad J_i = \int_0^1 e^{v\vartheta_i \operatorname{ad}_u}\, dv,$$

   where J_i^{-1} is the differential of the logarithm. Its normal projection annihilates covariant gradients and the neutral color $\mathbb{R}u$, and the linearized flow multiplies the charged transverse Fourier mode m by $e^{-\theta\lambda_m}$.

3. *For $N \ge 4$ let $\mathcal{B}_N$ be the set of centered representatives of $\mathbb{Z}^3/N\mathbb{Z}^3$, and set*

$$\delta_i^N = N\big(e^{i(2\pi m_i + \vartheta_i)/N} - 1\big), \qquad \lambda_m^N = \sum_i |\delta_i^N|^2, \qquad R_i^N = i\vartheta_i/\delta_i^N,$$

   with $R_i^N = 1$ if $m_i = \vartheta_i = 0$ and $R_i^N = 0$ if $\vartheta_i = 0 \neq m_i$. On the lattice Λ_N of mesh $1/N$ in $\mathbb{T}^3_1$, consider the background links $e^{\vartheta_i u/N}$, the Gaussian measure defined by the quadratic part of the Wilson exponent $(4N/\gamma)\sum_p q(U_p)$ on the quotient by its kernel, and the derivative of the cycle logarithms after the Wilson flow at lattice time $4\theta N^2$, projected onto $\mathcal{N}_y$. The covariance of this derivative, divided by γ, is exactly

$$\Sigma_\theta^N(y) = \Big(\Pi_{\boldsymbol{\vartheta}} \operatorname{diag}\Big(\sum_{m\in\mathcal{B}_N} \frac{e^{-2\theta\lambda_m^N}}{\lambda_m^N} |R_i^N|^2\Big)\Pi_{\boldsymbol{\vartheta}}\Big)\Big|_{\boldsymbol{\vartheta}^\perp} \otimes I_{u^\perp},$$

   and $\sup_y \|\Sigma_\theta^N(y) - \Sigma_\theta(y)\| \le CN^{-2}$.

4. *As* $\varrho = |\boldsymbol{\vartheta}| \downarrow 0$, *with* $\varrho < r_1 < \pi$,

$$\Sigma_\theta(y) = \varrho^{-2} I_{\mathcal{N}_y} + O_\theta(1), \qquad \varrho^2 \Sigma_\theta(y) \to I_{\mathcal{N}_y},$$

uniformly in the directions of $\boldsymbol{\vartheta}$ *and* u.

The constants, and the bounds for any fixed number of derivatives on the patch, depend on r_0, r_1, θ, *the order of the derivatives, and the margins of the charts, but not on* N, *on* γ, *or on any depth. The bounds on the patch are not uniform as* $|\boldsymbol{\vartheta}| \to 0$.

The positive time is needed: for $\theta = 0$ the series defining d_i diverges logarithmically, since $R_i = 1$ on the plane $m_i = 0$. Part (4) is a statement about the explicit matrix Σ_θ; it is used in Section 36 only for a comparison measure.

Proof. The proof follows the three ingredients described above: Steps 1 and 2 construct the Gaussian field, Steps 3–5 compute the response, and Step 6 performs the projection. Steps 7–10 prove the bounds, the lattice formula, the comparison with the continuum, and the central asymptotics.

Step 1: normalization. The map $\widetilde{A}(x) = LA(Lx)$ sends the flat connection in physical units to $\widetilde{A}_i^0 = \vartheta_i u$ and the time $t = \theta L^2$ to θ. Since the curvature is multiplied by L^2, the volume by L^{-3}, and $g_3^2 L = \gamma$, the quadratic part of the exponent $E_L/(2g_3^2)$ becomes exactly the form in the statement.

Step 2: the Gaussian field. We fix an oriented orthonormal basis of $u^\perp$ in which $v \mapsto u \times v$ is multiplication by i, and regard the two real charged colors as one complex color. On the Fourier mode $e^{2\pi i m \cdot x}$, the operator D_i acts on charged fields as multiplication by $ik_{m,i}$, and the quadratic form on that mode is

$$\sum_{i<j} |k_{m,i} a_j - k_{m,j} a_i|^2 = \lambda_m |a|^2 - |k_m^{\mathsf{T}} a|^2. \tag{33.16}$$

Since $|\boldsymbol{\vartheta}| \geq r_0$ and $r_1 < \pi$,

$$|k_0| \geq r_0, \qquad |k_m| \geq 2\pi |m| - r_1 \quad (m \neq 0),$$

so $k_m \neq 0$ for every m. By (33.16) the charged kernel consists of the multiples of k_m, which are the charged covariant gradients. In neutral color the form at mode m is $|2\pi m|^2 |a|^2 - |2\pi m \cdot a|^2$, whose kernel consists of gradients for $m \neq 0$ and of all constants for $m = 0$. This proves the description of $\mathcal{K}$. The form is positive definite on the quotient by $\mathcal{K}$. We realize the quotient on the L^2-orthogonal complement of $\mathcal{K}$, namely the covariantly transverse one-forms, $\sum_j D_j a_j = 0$, that are orthogonal to the constant neutral one-forms. We show in Step 4 that $\mathcal{L}$ vanishes on $\mathcal{K}$. Since the form vanishes on $\mathcal{K}$ as well, the projection along $\mathcal{K}$ identifies any two complements isometrically for

the form and does not change $\mathcal{L}$. In particular, the law of $\mathcal{L}(a)$ does not depend on the choice of the complement. On the chosen complement we have $k_m^{\mathsf{T}} a = 0$ at each charged mode, and the covariance divided by γ is

$$\lambda_m^{-1} P(k_m), \qquad P(k) = I - kk^{\mathsf{T}}/|k|^2. \tag{33.17}$$

This follows by diagonalizing the finite-dimensional form (33.16) and using $\int e^{-x^2/(2\sigma^2)} e^{i\tau x}\, dx = e^{-\sigma^2\tau^2/2} \int e^{-x^2/(2\sigma^2)}\, dx$. We construct all the Fourier Gaussians in this way and take their sum as a distribution: for every $s > 1/2$ the expected squared norm in the Sobolev space H^{-s} is finite, since $\sum_{m\neq 0} |m|^{-2-2s} < \infty$. Since $\theta > 0$, every functional considered below is an absolutely summable Gaussian series.

The complex notation does not double the covariance. We regard the complex Hilbert space of charged fields as a real Hilbert space with inner product $\operatorname{Re} \int a^* b$. For each orthonormal complex Fourier vector e, the pair e, ie is real orthonormal, and a precision eigenvalue λ assigns the variance γ/λ to each of the two real coefficients. The realification of a Hermitian covariance C is therefore

$$\begin{pmatrix} \operatorname{Re} C & -\operatorname{Im} C \\ \operatorname{Im} C & \operatorname{Re} C \end{pmatrix},$$

with no extra scalar factor. When C is real, this is $C \otimes I_{u^\perp}$ in spatial and color notation.

Step 3: the derivative of the cycle logarithms. Let $Y_i = \vartheta_i u$. With the convention $H'(v) = H(v) A(\ell(v)) \dot{\ell}(v)$ of Definition 4.10, the transport along the ith cycle at the background is e^{vY_i} at the parameter v. Differentiating the transport equation, we find the right-trivialized derivative

$$\delta H_i \, H_i^{-1} = \int_0^1 e^{v\vartheta_i \operatorname{ad}_u} a_i(ve_i)\, dv.$$

For the exponential map the corresponding derivative is $\delta(e^{Y_i}) e^{-Y_i} = J_i \, \delta Y_i$ with $J_i = \int_0^1 e^{v\vartheta_i \operatorname{ad}_u}\, dv$. In neutral color $J_i = 1$, and in charged color $J_i = (e^{i\vartheta_i} - 1)/(i\vartheta_i)$, with value one at $\vartheta_i = 0$. It is invertible on the whole patch because $|\vartheta_i| < \pi$. The differential of the logarithm is therefore J_i^{-1}, which proves the formula for T_i in part (2). On the charged Fourier mode m this derivative is the scalar

$$\frac{\int_0^1 e^{i(2\pi m_i + \vartheta_i)v}\, dv}{\int_0^1 e^{i\vartheta_i v}\, dv}.$$

For $\vartheta_i \neq 0$, canceling $e^{i\vartheta_i} - 1$ gives $\vartheta_i/(2\pi m_i + \vartheta_i)$. If $m_i = 0$, the two integrals are equal, also when $\vartheta_i = 0$. If $\vartheta_i = 0$ and $m_i \neq 0$, the numerator vanishes and the denominator is one. These are exactly the cases in the definition of R_i.

Step 4: the normal projection. Let ϕ be a smooth periodic gauge parameter. Integrating the derivative of $v \mapsto e^{v\vartheta_i \operatorname{ad}_u}\phi(ve_i)$ over $[0,1]$ and using periodicity, we find

$$T_i(D\phi) = \vartheta_i \operatorname{ad}_u \phi(0).$$

As a triple indexed by i, this is $\boldsymbol{\vartheta}$ tensored with a vector of $u^\perp$, an infinitesimal simultaneous conjugation at the root, and the normal projection $\Pi_{\boldsymbol{\vartheta}} \otimes (I - uu^{\mathsf{T}})$ annihilates it. Every response in neutral color is parallel to u and is annihilated as well. Hence the constant neutral one-forms and all other flat tangent directions contribute zero, $\mathcal{L}$ vanishes on $\mathcal{K}$, and the normal response is well defined on the quotient, independently of the representative used to compute it.

Step 5: the linearized flow. At a flat background $[D_i, D_j] = 0$, and the linearization of the Yang–Mills heat flow $\partial_t A_i = \sum_j D_j F_{ji}$ is

$$\partial_\theta a_i = \sum_j D_j(D_j a_i - D_i a_j).$$

Covariant gradients are stationary for this equation. On covariantly transverse fields, $\sum_j D_j a_j = 0$, it reads $\partial_\theta a = \sum_j D_j^2 a$. The Fourier multiplier on charged modes is $-\lambda_m$, and the linearized flow multiplies the mode m by $e^{-\theta\lambda_m}$. A linearized gauge damping term can only change a covariant gradient, whose normal logarithmic response vanishes by Step 4. This derives the response of the Yang–Mills heat flow itself on the quotient, rather than replacing it by the scalar heat flow at a charged background.

Step 6: the covariance. Let $R_m = \operatorname{diag}(R_i(m, \boldsymbol{\vartheta}))$. Applying the response of Steps 3–5 to (33.17), we find the spatial covariance

$$\sum_m \frac{e^{-2\theta\lambda_m}}{\lambda_m} \big(\Pi_{\boldsymbol{\vartheta}} R_m P(k_m) R_m \Pi_{\boldsymbol{\vartheta}}\big)\big|_{\boldsymbol{\vartheta}^\perp}.$$

For each i, including every case in which a coordinate vanishes, $R_i k_{m,i} = \vartheta_i$. Then $R_m k_m = \boldsymbol{\vartheta}$, and the longitudinal term $R_m k_m k_m^{\mathsf{T}} R_m / \lambda_m$ is annihilated exactly by $\Pi_{\boldsymbol{\vartheta}}$. What remains is $\Pi_{\boldsymbol{\vartheta}} D \Pi_{\boldsymbol{\vartheta}}$ restricted to $\boldsymbol{\vartheta}^\perp$. Since this matrix is real, the realification of Step 2 gives the factor $I_{u^\perp}$. This proves the formula for Σ_θ.

Step 7: bounds, inverse, and invariance. Every R_i is bounded on the patch. For any fixed number of derivatives in $\boldsymbol{\vartheta}$, the terms of the series are bounded by $C(1+|m|)^q e^{-c\theta|m|^2}$, with constants depending on the order, on r_0 and r_1, and on θ. The sum of these bounds is finite, as one sees by separating the three coordinates and comparing $\sum_{j\in\mathbb{Z}}(1+|j|)^q e^{-c\theta j^2}$ with a finite initial segment and a convergent integral. Termwise differentiation is therefore valid. The term $m = 0$ has $R_i = 1$ and contributes

$$e^{-2\theta|\boldsymbol{\vartheta}|^2}\big|\boldsymbol{\vartheta}\big|^{-2} I_4.$$

This term gives a positive lower bound on the compact patch, and the summable series gives an upper bound; in particular, all d_i are positive. To invert the form, let $b, v \perp \boldsymbol{\vartheta}$ with $\Pi_{\boldsymbol{\vartheta}} D v = b$. Then $Dv = b + \alpha\boldsymbol{\vartheta}$ for a scalar α, and the condition $\boldsymbol{\vartheta}^{\mathsf{T}} v = 0$ gives

$$\alpha = -\frac{\boldsymbol{\vartheta}^{\mathsf{T}} D^{-1} b}{\boldsymbol{\vartheta}^{\mathsf{T}} D^{-1} \boldsymbol{\vartheta}}.$$

This proves the formula for the inverse. Its denominator is positive, and the bounds just proved give smoothness and the two-sided bound. Color rotations act by the corresponding orthogonal maps of $u^{\perp}$. The reversal $(\boldsymbol{\vartheta}, u) \mapsto (-\boldsymbol{\vartheta}, -u)$ is implemented in the series by $m \mapsto -m$ and complex conjugation of the charged color, since $R_i(m, -\boldsymbol{\vartheta}) = R_i(-m, \boldsymbol{\vartheta})$ and $\lambda_m(-\boldsymbol{\vartheta}) = \lambda_{-m}(\boldsymbol{\vartheta})$. Thus the covariance and its inverse have the asserted invariance. This proves part (1).

Step 8: the lattice covariance. We compute the lattice covariance directly, without using the continuum. At the background links $U_i^0 = e^{\vartheta_i u/N}$, we write a perturbation as $e^{a_i(x)/N} U_i^0$, where x is now an integer lattice coordinate. Differentiating the four factors of the plaquette variable, we find, in charged color,

$$\delta \operatorname{Log} U_{p_{ij}(x)} = N^{-1}\big\{ e^{i\vartheta_i/N} a_j(x + e_i) - a_j(x) - e^{i\vartheta_j/N} a_i(x + e_j) + a_i(x) \big\}.$$

On the Fourier mode m this is $N^{-2}(\delta_i^N a_j - \delta_j^N a_i)$. The coefficient $4N/\gamma$ of the Wilson exponent and $q(e^v) = |v|^2/8 + O(|v|^4)$ give the quadratic exponent

$$\frac{1}{2\gamma N^3} \sum_x \sum_{i<j} |\delta_i^N a_j - \delta_j^N a_i|^2. \tag{33.18}$$

Fourier orthonormality uses the normalized volume $N^{-3}\sum_x$. With $\delta = (\delta_i^N)_i$, the corresponding transverse projection is $P_\delta = I - \delta\delta^*/\lambda_m^N$, and the covariance divided by γ is $(\lambda_m^N)^{-1} P_\delta$. We treat the quotient by the kernel and its independence of the complement as in Step 2, using the description of the kernel in the proof of Lemma 33.9.

We check the flow factor in the same coordinates. In the Lie-algebra coordinates $b = a/N$ of the links, the quadratic part of $\sum_p q(U_p)$ is $\|d_U b\|^2/8$, and its Hessian is $d_U^* d_U/4$. Since the left group coordinates are orthonormal for the group metric at the critical flat configuration, the linearized negative gradient equation is $\partial_s b = -d_U^* d_U b/4$. On the transverse mode m its eigenvalue is $-\lambda_m^N/(4N^2)$, and at the lattice time $s = 4\theta N^2$ the multiplier is exactly $e^{-\theta\lambda_m^N}$.

The derivative of the cycle product, including the differential of its final logarithm, is

$$J_i^{-1} \frac{1}{N} \sum_{l=0}^{N-1} e^{i(2\pi m_i + \vartheta_i) l/N}.$$

For $\vartheta_i \neq 0$, the formula for a geometric sum and the formula for J_i reduce this to

$$\frac{i\vartheta_i}{N\big(e^{i(2\pi m_i+\vartheta_i)/N}-1\big)} = R_i^N.$$

For $\vartheta_i = 0$ the sum is one if $m_i = 0$ and zero otherwise, which are the prescribed values. We conclude that, with $R_m^N = \operatorname{diag}(R_i^N)$,

$$R_m^N \delta = i\boldsymbol{\vartheta}, \qquad \Pi_{\boldsymbol{\vartheta}} R_m^N P_\delta (R_m^N)^* \Pi_{\boldsymbol{\vartheta}} = \Pi_{\boldsymbol{\vartheta}} \operatorname{diag}(|R_i^N|^2) \Pi_{\boldsymbol{\vartheta}}.$$

This equality uses the complex phases of R_i^N before the longitudinal part cancels; the phases can be discarded only afterwards. Summing over the modes in the real covariance, as in Step 2, we obtain the formula for Σ_θ^N.

Step 9: comparison with the continuum. For centered representatives and $N \geq 4$ we have $|k_{m,i}/(2N)| \leq \pi/2 + r_1/8 < 5\pi/8$. On this interval the function $\sin x/x$ has a positive minimum, and Taylor's formula gives $|4\sin^2(x/2) - x^2| \leq C|x|^4$. Since $\lambda_m^N = \sum_i 4N^2 \sin^2(k_{m,i}/(2N))$, we obtain

$$c|k_m|^2 \leq \lambda_m^N \leq |k_m|^2, \qquad |\lambda_m^N - |k_m|^2| \leq CN^{-2}|k_m|^4. \tag{33.19}$$

Also

$$|R_i^N|^2 = R_i^2 \Big(\frac{k_{m,i}/(2N)}{\sin(k_{m,i}/(2N))}\Big)^2, \qquad \big||R_i^N|^2 - R_i^2\big| \leq CN^{-2} R_i^2 k_{m,i}^2 \leq CN^{-2},$$

where the continuous extensions at the vanishing cases are understood. In particular $R_i^2 k_{m,i}^2 = \vartheta_i^2$, also when $m_i = 0$, and all these multipliers are bounded. For $F(x) = e^{-2\theta x}/x$ we have $|F'(x)| = e^{-2\theta x}(2\theta/x + x^{-2})$. By the mean value theorem and (33.19), the difference of corresponding summands is at most

$$CN^{-2} e^{-c\theta|k_m|^2} \big(1 + |k_m|^2 + |k_m|^{-2}\big),$$

which is summable uniformly on the patch. The continuum modes not in $\mathcal{B}_N$ satisfy $|m_i| \geq N/2$ for some i, and their Gaussian tail is at most $Ce^{-c'\theta N^2} \leq C_\theta N^{-2}$. Summing, we obtain the uniform bound CN^{-2} in part (3). Fixed derivatives in the parameters obey the same bound. Indeed, differentiating the Taylor remainders in the sine expressions leaves a factor N^{-2} times a fixed polynomial in $|k_m|$. All inverse powers of λ_m^N and λ_m are bounded by the gap on the patch, and the differentiated exponentials add only polynomial factors. The same summable majorant applies, with constants depending also on the order, and smooth local normal frames introduce only constants depending on the margins of the patch.

Step 10: the central asymptotics. Let $\varrho = |\boldsymbol{\vartheta}| \downarrow 0$ with $\varrho < r_1 < \pi$. The nonzero modes still satisfy $|k_m| \geq 2\pi|m| - r_1$, and their multipliers R_i are bounded uniformly in all directions, since $|2\pi m_i + \vartheta_i| \geq \pi$ for $m_i \neq 0$. Their total contribution is $O_\theta(1)$. The zero mode contributes

$$e^{-2\theta\varrho^2}\varrho^{-2} I_4 = \varrho^{-2} I_4 + O_\theta(1).$$

Since the projection onto the normal space has norm one, this proves both assertions of part (4), uniformly in the directions. It also shows why the bounds on the regular patch cannot be extended uniformly to the central point. □

33.8 The stopped measure near regular flat configurations

We now combine the preceding results. The first part of the next proposition is the Laplace approximation of the stopped measure transverse to a compact patch of regular flat configurations. The second part is an exact decomposition of the covariance Σ_θ^N of Theorem 33.11 at the flat reconstruction, obtained by completion of squares for Gaussian measures in the constrained coordinates of Theorem 12.13. In Section 35 this decomposition identifies the covariance of the Gaussian approximation obtained at finitely many scales with Σ_θ.

Proposition 33.12. *Consider the stopped measures of Section 33.2 at the side n, a compact regular patch, and a fixed normal tube over a larger compact regular patch whose closure lies in D_r. Assume that $2\pi/n < r_{\mathrm{flat}}$, where r_{flat} is the radius of Lemma 14.9, which lies below the fixed margins of all classical, constraint, Haar disintegration, and gauge domains. For a patch of small commuting configurations as in Lemma 33.7, the margins of that lemma may be used instead of this condition.*

1. *There is a finite atlas of normal coordinates $V(y,v)$ over the patch, of normal rank $\mathfrak{d}_n = 6n^3 - 2 = d_n + 4$, in which the image of H_n has a smooth positive density $J(y,v)$, and for every integer $d \geq 0$*

$$nE_d(V(y,v)) = \tfrac{1}{2} v^{\mathsf{T}} H_d(y) v + O_n(|v|^3),$$
$$c_n I \leq H_d(y) \leq C_n I, \qquad nE_d(V(y,v)) \geq c_n |v|^2.$$

Let χ be a fixed normal cutoff equal to one near $v = 0$, let f be a bounded measurable function of y with compact support in the patch, and let P_y be a family of polynomials of a fixed degree with bounded measurable coefficients. Put

$$z_0 = H_d(y)^{1/2} v/\sqrt{\gamma}, \qquad a_{d,\gamma}(y,v) = e^{-\overline{R}_{d,\gamma}(V(y,v))} J(y,v).$$

Then for $d = kJ$ and $0 < \gamma \le \gamma_0$, with the partition of unity of the atlas understood and the insertion extended by zero outside the charts,

$$\widehat{Z}_{n,d,\gamma}\mathbb{E}_{\widehat{\nu}_{n,d,\gamma}}[f(y)\chi(v)P_y(z_0)] = (2\pi\gamma)^{\mathfrak{d}_n/2}\Big[\int f(y)\frac{a_{d,\gamma}(y,0)}{\sqrt{\det H_d(y)}}\mathbb{E}P_y(G_{\mathfrak{d}_n})\,d\mathrm{vol}(y) + O_{n,f,P}(\sqrt{\gamma})\Big].$$

The error is uniform in d and γ. Given y, the moments of z_0 under the normal conditional law, normalized by its own normal integral, differ from those of $G_{\mathfrak{d}_n}$ by $O_n(\sqrt{\gamma})$, and all fixed moments of z_0 are bounded. The tangential density may vary with γ within its bounds, without converging. Here $\widehat{Z}_{n,d,\gamma}$ is the partition function of Theorem 33.10. For every nonnegative f as above with $\int f\,d\mathrm{vol} > 0$ there exists $c_{n,f} > 0$ such that $\mathbb{E}_{\widehat{\nu}_{n,d,\gamma}}[f(y)\chi(v)] \ge c_{n,f}$ for all depths $d = kJ$ and all sufficiently small γ.

2. *Suppose in addition that the cycle holonomies of the patch have logarithms $y = (\vartheta_i u)_i$ with $0 < r_0 \le |\boldsymbol{\vartheta}| \le r_1 < \pi$, and fix $\theta > 0$. Let $K \ge 0$, $N = nB^K$, $n_j = nB^j$, $d = JK$, and $H_K^{\mathrm{act}}(y) = D_v^2(nE_{JK})(y,0)$. Consider the reconstruction of a configuration on Λ_N from the stopping field V on Λ_n and the normalized fluctuation variables $w_j = (w_{j,l})_{0\le l<J}$ of the RG steps $j = 1,\dots,K$, given by the triangular coordinates*

$$z_{j,l} = z_{j,l}^{*} + g_{j,l}K_{j,l}^{-1/2}w_{j,l}$$

of Theorem 12.13, computed in smooth local charts in which the expressions in different gauges agree, and satisfying $T_M^{JK}U = V$. At the flat reconstruction of the flat stopping field $V(y,0)$, where all w_j vanish, differentiate the composition of this reconstruction with the map that sends a configuration on Λ_N to the logarithms of the cycle holonomies, based at the root, of its Wilson flow at physical time θL^2, followed by the orthogonal projection onto $\mathcal{N}_y$. Normalize the normal variable of the stopping field by $v = \sqrt{\gamma}(H_K^{\mathrm{act}})^{-1/2}z_0$. After division by $\sqrt{\gamma}$, denote the resulting linear maps by $A_{0,K}(y) : \mathbb{R}^{\mathfrak{d}_n} \to \mathcal{N}_y$ and $A_{j,K}(y) : \mathbb{R}^{D_j} \to \mathcal{N}_y$, $1 \le j \le K$, where $D_j = 6(n_j^3 - n_{j-1}^3)$ is the number of real normalized fluctuation variables of the jth RG step. Then for every finite K,

$$A_{0,K}A_{0,K}^{\mathsf{T}} + \sum_{j=1}^{K} A_{j,K}A_{j,K}^{\mathsf{T}} = \Sigma_\theta^N(y), \qquad \|A_{0,K}\|_{\mathrm{HS}}^2 + \sum_{j=1}^{K}\|A_{j,K}\|_{\mathrm{HS}}^2 \le C.$$

Each $A_{j,K}$ includes the factors $g_{j,l}/\sqrt{\gamma}$, the inverse square roots of the constrained Hessians at the flat background, and the derivative of the composition with all finer reconstruction steps. If T_K denotes the response of the normal variable of the stopping field before normalization and $H_K^E = D_v^2E_{JK}(y,0)$ in the same normal coordinates, then

$$H_K^{\mathrm{act}} = nH_K^E, \qquad A_{0,K}A_{0,K}^{\mathsf{T}} = n^{-1}T_K(H_K^E)^{-1}T_K^{\mathsf{T}}.$$

The same identities hold for the reconstruction maps $\widehat{\mathscr{R}}$ of Theorem 15.12.

The constants depend on n, L, θ, M, J, Θ, the patch, the larger tube, the bounds for the polynomials, and the fixed analytic domains, with the dependence described in item (6) of Definition 4.14. They are independent of K, of the depth, and of $\gamma \in (0, \gamma_0]$.

The identities in part (2) concern the Gaussian quadratic model at the flat reconstruction; they do not assert that the normalized fluctuation variables are independent under the interacting measure. The normal responses of the stopping field, including those of the constant charged modes, are part of the identity: for $K = 0$ the block $A_{0,0}$ gives the whole covariance.

Proof of part (1) of Proposition 33.12. We first check that the flat configurations and their refinements lie in the domains of the construction, separately from the normal integral. Then we apply Lemma 33.3 in the normal coordinates of Lemma 33.9.

Step 1: flat refinements. First suppose that $2\pi/n < r_{\mathrm{flat}}$. Fix the side n before the coupling, and let

$$\delta_{\mathrm{flat}} = r_{\mathrm{flat}} - 2\pi/n > 0. \tag{33.20}$$

The radius r_{flat} lies below all the classical, constraint, Haar disintegration, and gauge margins of one RG step, with the strict margin required in Lemma 14.9. These margins include the fixed conversions for the words of the block axial gauge. A flat triple of cycle holonomies has commuting logarithms H_i with $|H_i| \le 2\pi$. At every averaging step with output side $m \ge n$, its constant representative and its refinement at the next finer side have link logarithms H_i/m and $H_i/(Mm)$, and

$$\max_i |H_i|/m \le 2\pi/n = r_{\mathrm{flat}} - \delta_{\mathrm{flat}}.$$

By the computation for commuting products leading to (33.11), the representative in the block axial gauge is $U_0(c)$, and the free logarithmic coordinates and the logarithms on the eliminated edges vanish. The conclusion of Lemma 14.9 for all flat configurations, with smallest side n, verifies every intermediate classical, constraint, based gauge, and small-field condition, for every K. The classical action of the free coordinates, which is nonnegative, vanishes at this point. By the uniqueness of the conditional constrained minimizer in the same conclusion, the point is $z_i^*(c) = 0$, and each normalized fluctuation variable vanishes. This verifies the hypothesis of part (2) at all the depths involved. The margins and the radii of the fluctuation cutoff domains are fixed by the parameters. No neighborhood of the flat set depending on the cutoffs of the small-field event is used as a normal tube. Under the alternative local hypothesis, we apply Lemma 33.7 on a slightly larger compact patch satisfying its strict inequality. It gives the same conclusions at every side $m \ge n$ and every depth, and its positive domain margins replace δ_{flat} below.

Step 2: phase and amplitude. The finite atlas and the estimates for the phase are those of Lemma 33.9, applied on the larger patch and then shrunk. The normal rank is $\mathfrak{d}_n = 6n^3 + 3 - 5 = 6n^3 - 2 = d_n + 4$. The vanishing of E_d on the flat set, the lower bound (P1), and the uniform bounds on third derivatives were verified there. The centered effective interaction of Theorem 14.8 is bounded on D_r by (P3). For its derivatives, we take the normal atlas on the larger tangential patch with a larger normal radius, and finitely many relatively compact parameter subcharts $W_l \Subset W_l^+$ covering the working tube. The maps $\Psi_l(y, v) = V(y, v)$ and their based lifts are smooth on W_l^+, as constructed in Lemma 33.9, and extend past $\overline{W}_l$. Let $\mathcal{K}$ be the compact union of the images of the closures in the larger tube; it lies in D_r by hypothesis and does not depend on d or γ. On these compact subcharts we apply (33.10). Finitely many fixed based gauge transformations map neighborhoods of $\mathcal{K}$ into B_{r_1}, with $r < r_1 < \rho$ and the fixed margin η. We refine the subcharts so that each closure lies in one of the larger neighborhoods in the proof of Lemma 33.6. Each gauge transformation acts smoothly on all of $\mathcal{U}_n$. The chart composed with it extends to a neighborhood of the closure of the subchart, and its derivatives of every fixed order are bounded on these finitely many compact closures, independently of d and γ. These are the conditions on subcharts in Theorem 14.8, at each chart of the atlas. The chain rule then gives $|D_{y,v}\overline{R}_{d,\gamma}(V(y, v))| \le C_n E_*$ on each compact parameter closure, uniformly in the depth and the coupling. The amplitude

$$a_{d,\gamma}(y, v) = e^{-\overline{R}_{d,\gamma}(V(y,v))} J(y, v)$$

therefore has fixed positive upper and lower bounds and a fixed Lipschitz bound in v; it includes the Haar density of the based quotient. Since all insertions in the charts are supported in D_r, the indicator of D_r equals one where these coordinates are used. On each normal fiber, with $B_n = \sup_{D_r} |\overline{R}_{d,\gamma}|$, the mean value theorem gives

$$|a_{d,\gamma}(y, v) - a_{d,\gamma}(y, 0)| \le e^{B_n} \big(\|J\|_\infty C_n E_* + \|D_v J\|_\infty \big) |v|.$$

This is the Lipschitz bound in the normal direction required by Lemma 33.3; a bound on the values of the effective interaction alone would not imply it.

Step 3: the Laplace approximation. We apply Lemma 33.3 with $\delta = \gamma$, the phase nE_d, the Hessian $L = H_d$, and the weight h given by f times the partition of unity of the atlas; the formula for general f follows by splitting f into its positive and negative parts. The phase, the amplitude, and the Hessian are smooth in each real normal trivialization, hence jointly Borel, and we choose the normal cutoff smooth as well. The tests and the polynomial coefficients are measurable, as required in that lemma. We decrease the constant c_0 of that lemma and increase C_0 to include the bounds for the normal Hessian,

the lower bound for the phase, the bounds for the amplitude, and the Lipschitz constant just verified. No matrix L_∞ is substituted in this application. We obtain

$$(2\pi\gamma)^{\mathfrak{d}_n/2}\Big[\int f(y)\frac{a_{d,\gamma}(y,0)}{\sqrt{\det H_d(y)}}\mathbb{E}P_y(G_{\mathfrak{d}_n})\,d\mathrm{vol}(y)+O_{n,f,P}(\sqrt{\gamma})\Big].$$

Since the exponent of (33.1) is $E_d/g^2 = nE_d/\gamma$, the left side of (33.3) is exactly the integral of the insertion extended by zero against the unnormalized stopped density, namely $\widehat{Z}_{n,d,\gamma}\mathbb{E}_{\widehat{v}_{n,d,\gamma}}[f(y)\chi(v)P_y(z_0)]$. This proves the displayed identity, with the partition function of Theorem 33.10. The statements about conditional moments and bounded moments are part (1) of Lemma 33.3. If the conditional law is taken on the whole tube instead of with the cutoff, the additional part lies outside a fixed smaller normal ball. By Corollary 33.4 and the bounds on the whole tube verified below, it is exponentially small, and the conditional statements are unchanged.

Step 4: lower bounds for tangential tests. Let $f \geq 0$ with $\int f\,d\mathrm{vol} > 0$. By the case $P = 1$ of the formula, with the error $C\sqrt{\gamma}\int f$, the numerator is at least $c_{n,f}\gamma^{\mathfrak{d}_n/2}$ for all sufficiently small γ. The upper bound of Theorem 33.10 is $\widehat{Z}_{n,d,\gamma} \leq C_n g^{\mathfrak{d}_n} = C_n n^{-\mathfrak{d}_n/2}\gamma^{\mathfrak{d}_n/2}$, with n fixed. Dividing, we obtain the uniform positive lower bound for the expectation. For an event expressed by a bounded insertion, dividing this expectation by the supremum of the insertion gives a lower bound for the probability as well. The tangential amplitude may depend on γ arbitrarily within its uniform bounds. □

Proof of the last assertion of Corollary 33.4. We verify the additional hypotheses on the whole tube in the setting of part (1) of Proposition 33.12, with $d = JK$. On the fixed working tube, Step 2 and Lemma 33.9 give $nE_{JK}(V(y,v)) \geq c_n|v|^2$, the quadratic expansion, and the bounds for the spectrum of H_K^{act}. The amplitude $a_{JK,\gamma}(y,v) = e^{-\overline{R}_{JK,\gamma}(V(y,v))}J(y,v)$ has uniform positive upper and lower bounds there: the centered effective interaction is bounded on D_r, and the Haar density of the based quotient is smooth and positive on the fixed compact subcharts. These bounds are used before the partition of unity of the atlas is absorbed into the tangential weight. Then the normal integral over the whole tube is at least $c_n\gamma^{\mathfrak{d}_n/2}$, uniformly in K and y, and the statements of Corollary 33.4 on the whole tube apply with $\delta = \gamma$, $L = H_K^{\mathrm{act}}$, and rank $\mathfrak{d}_n = 6n^3 - 2$, with constants independent of K. □

Proof of part (2) of Proposition 33.12. We first count the variables. Then we expand the classical action to second order along the flat reconstruction, which gives an identity $S_K^{\mathsf{T}}\mathcal{H}_N S_K = I$ for the differential S_K of the reconstruction. Finally, we apply the derivative of the observable and Theorem 33.11.

Step 5: the count of variables. By Theorem 12.13, one averaging step from side Mm to side m has $6((Mm)^3 - m^3)$ real free coordinates. Summing over the J averaging steps of the jth RG step, from side n_j to side n_{j-1}, we find

$$D_j = 6(n_j^3 - n_{j-1}^3), \qquad \mathfrak{d}_n + \sum_{j=1}^{K} D_j = 6N^3 - 2. \tag{33.21}$$

These are counts on based quotients. The five flat tangent directions belong to the stopping field, and they are held fixed in the quadratic computation. The right side $6N^3 - 2$ is the dimension of the based tangent space at side N, $6N^3 + 3$, minus the five-dimensional kernel of the Hessian of the Wilson action at a regular flat configuration (Lemma 33.9).

Step 6: the flat reconstruction. At a flat stopping field, Step 1 gives the flat refinement with vanishing normalized fluctuation variables at every averaging step, with the same based cycle holonomies and zero classical action. This uses Lemma 14.9 or, under the alternative local hypothesis, Lemma 33.7. The conditional constrained minimizers are these flat refinements. In particular, the flat zero-fluctuation reconstruction is critical for each classical action, and it is stationary for the Wilson flow on the finest lattice. The fixed domain conditions give smooth constraint coordinates and Haar disintegration densities near this reconstruction. By Theorem 15.12, the reconstruction maps $\widehat{\mathscr{R}}$ preserve the coarse field, the orbit of the minimizer, the free coordinates, the square roots of the constrained Hessians, and the density in these coordinates. Their gauge transformations are smooth on these local charts and equal to the identity at the coarse vertices. No gauge transformation chosen measurably as a function of the configuration is differentiated. At each RG step we use the nested domains $\mathscr{D}_{\mathrm{in}} \Subset \mathscr{D}_{\mathrm{mid}} \Subset \mathscr{D}_{\mathrm{out}}$ of Theorem 15.12. The flat coarse field lies below its margin by the domain margins verified in Step 1, and every free coordinate vanishes. Hence a joint neighborhood of the flat reconstruction lies in $\mathscr{D}_{\mathrm{in}}$ before the outer domain of holomorphy is used. The fluctuation cutoff domains satisfy (33.2), and the reconstruction maps keep these domains, their kernels, and their identities at the coarse vertices. These checks use only the fixed parameters and the integer sides mM^i, $m \geq n \geq 4$, and no domain depending on the depth.

Step 7: completion of squares. We consider one averaging step with coarse field c and free coordinate z, and set

$$F(c,z) = E_{\mathrm{old}}(b(c,z)), \qquad z = z^*(c) + g_{\mathrm{old}} K(c)^{-1/2} w, \qquad K(c) = D_z^2 F(c, z^*(c)),$$

where E_{old} and g_{old} are the effective classical action and the coupling on the finer side. The minimizer satisfies $D_z F(c, z^*(c)) = 0$. By Taylor's formula and the definition of $K(c)$, we have

$$\frac{F(c,z)}{g_{\mathrm{old}}^2} = \frac{F(c,z^*(c))}{g_{\mathrm{old}}^2} + \tfrac{1}{2}|w|^2 + U^{\mathrm{cl}}(c,w), \qquad D_w^\alpha U^{\mathrm{cl}}(c,0) = 0 \quad (|\alpha| \leq 2).$$

The exact identity for the classical actions in Theorem 12.13 identifies the first term with $E_{\mathrm{new}}(c)/g_{\mathrm{new}}^2$, and these identities compose over the averaging steps. Since the displayed derivatives vanish for every coarse field c in the domain, U^{cl} has no joint Taylor terms of total degree at most two in the variation of the coarse field and the normalized fluctuation variables at the flat reconstruction. Hence, at the flat reconstruction, the quadratic part of the exponent is exactly

$$\frac{1}{2\gamma}\langle v, H_K^{\mathrm{act}} v\rangle + \frac{1}{2}\sum_{j=1}^{K}|w_j|^2, \qquad H_K^{\mathrm{act}} = D_v^2(nE_{JK})(y,0), \tag{33.22}$$

where we used that the exponent at the stopping side is $E_{JK}/g_n^2 = nE_{JK}/\gamma$. Second derivatives of the changes of coordinates do not affect this conclusion. In the second derivative of a composed scalar function, they are multiplied by the first derivative of the function, which vanishes at a flat configuration. Since the dependence of the positive square roots on the background is included in the differential of the coordinates, it creates no missing quadratic cross term. The Haar disintegration factors and the effective interaction remain in the amplitude and are not part of this identity for the classical quadratic form.

Step 8: Gaussian linear algebra. Let $\mathcal{H}_N$ be the Hessian of NE_0 at the finest flat configuration, on the based tangent space modulo its five-dimensional kernel; it is positive definite there by Lemma 33.9. By the count in the proof of that lemma, this quotient is the quotient of the full space of link variations by the kernel of the Hessian, which consists of all covariant gradients and the three constant neutral directions. Thus it is the space on which the lattice covariance of Theorem 33.11(3) is computed, and the exponent NE_0/γ is the Wilson exponent $(4N/\gamma)\sum_p q(U_p)$ used there. As in the statement, $v = \sqrt{\gamma}(H_K^{\mathrm{act}})^{-1/2} z_0$. The normalized fluctuation variable $w_{j,l}$ of each averaging step enters through the differential $g_{j,l}K_{j,l}^{-1/2}w_{j,l}$ of the free coordinate. Composing with all finer reconstruction steps, we obtain the differential of the configuration on the finest lattice. After extracting $\sqrt{\gamma}$, we denote by S_K this linear map from $(z_0, w_1, \dots, w_K)$ to the quotient on the finest lattice. It does not depend on γ: the remaining coupling factors are $g_{j,l}/\sqrt{\gamma}$, and the classical maps and Hessians do not depend on the coupling. Since the quadratic part of NE_0/γ at the finest flat configuration, composed with the reconstruction, is (33.22), we have

$$S_K^{\mathsf{T}} \mathcal{H}_N S_K = I. \tag{33.23}$$

This makes S_K injective. Since its domain and codomain have the same dimension by (33.21), S_K is invertible, and

$$S_K S_K^{\mathsf{T}} = \mathcal{H}_N^{-1}.$$

Equivalently, consider independent standard real Gaussian variables in the normal coordinates of the stopping field and in all normalized fluctuation variables. In the auxiliary quadratic model, the differential of the reconstruction sends them to the Gaussian field on the finest lattice with covariance $\gamma \mathcal{H}_N^{-1}$.

Step 9: the observable. Let ℓ_N be the derivative of the flowed based cycle logarithms on the finest lattice, followed by the projection onto $\mathcal{N}_y$. By the computations for gauge directions and flat tangent directions in the proof of Theorem 33.11, ℓ_N vanishes on the kernel of the quotient. Applied to the columns of S_K, it gives exactly the response maps of the statement:

$$\ell_N S_K = (A_{0,K}, A_{1,K}, \dots, A_{K,K}).$$

The finest flat reconstruction has the same based cycle holonomies as the constant links $e^{\vartheta_i u/N}$. To justify the use of this Fourier representative, we fix a spanning tree and compare the flat transports of the reconstruction with those of the constant links. Their transports along the tree determine a periodic vertex gauge transformation, equal to the identity at the root, because the three cycle holonomies agree. This gauge transformation identifies the two flat configurations. The Wilson action and the Wilson flow commute with it, and the based holonomies are the same before and after it. If such a gauge transformation depends on parameters, its derivative contributes a covariant gradient, whose normal logarithmic response vanishes by the same computation. The covariance of ℓ_N is therefore exactly the one computed in Theorem 33.11(3), and

$$\sum_{j=0}^{K} A_{j,K} A_{j,K}^{\mathsf{T}} = \ell_N S_K S_K^{\mathsf{T}} \ell_N^{\mathsf{T}} = \ell_N \mathcal{H}_N^{-1} \ell_N^{\mathsf{T}} = \Sigma_\theta^N(y).$$

Taking traces and using the uniform upper bound for Σ_θ^N on the patch, which follows from Theorem 33.11(1) and (3), we obtain $\sum_{j=0}^{K} \|A_{j,K}\|_{\mathrm{HS}}^2 \le 4C$.

Step 10: the block of the stopping field. If T_K is the response of the normal variable of the stopping field before normalization, then

$$H_K^{\mathrm{act}} = n H_K^E, \qquad A_{0,K} = T_K (H_K^{\mathrm{act}})^{-1/2} = n^{-1/2} T_K (H_K^E)^{-1/2}.$$

Multiplying by the transpose, we obtain the last identity of the statement. For $K = 0$ this block gives the whole covariance; in particular, it cannot be omitted. Since the gauge transformations of the reconstruction maps $\widehat{\mathscr{R}}$ are equal to the identity at the coarse vertices and contribute only gauge variations, which are annihilated, the proof applies to these maps without a new choice of representatives. No growth in the number of scales enters the trace bound or the error of the Laplace approximation. □

Remark 33.13. The convergence of the effective classical actions as the depth tends to infinity (Theorem 11.2) does not allow one to replace the phase at finite depth in an

exponent divided by g^2, uniformly as $\gamma \to 0$. None of the proofs above makes such a replacement. The Gaussian covariance computed here is the covariance of the quadratic model at a flat background; transferring its moments to the flowed observables under the interacting measures requires the additional estimates of Sections 34 and 35. The identification of the limiting observables uses Theorem 29.25, and Lemma 5.6 identifies the continuous functions of the cycle holonomies that are invariant under simultaneous conjugation as functions of the seven traces; neither identification replaces a comparison of normal moments.

33.9 An Abelian comparison measure

For later comparison with the measures λ_γ we record one explicit comparison measure in which all cycle holonomies commute: the Abelian Maxwell measure with Haar cycle holonomies of Definition 4.13. It is used, together with the other comparison measures, in Sections 35 and 36.

Lemma 33.14. *Embed the subgroup $\{e^{v\tau_3} : v \in \mathbb{R}\}$ of $\mathrm{SU}(2)$. Take a centered transverse Gaussian Maxwell field with one real color on $\mathbb{T}^3_L$, with covariance $g_3^2(-\Delta)^+P_{\mathrm{tr}}$, where $(-\Delta)^+$ is the inverse of $-\Delta$ on the nonconstant Fourier modes and P_{tr} the projection onto transverse fields, and three independent phases, uniformly distributed in $(\mathbb{R}/4\pi\mathbb{Z})^3$ and independent of the field. Smooth the field by the scalar heat flow at a fixed positive time, add the flat connection with these cycle phases, and form the three cycle holonomies in the embedded subgroup. Then the following hold.*

1. *The smoothed field is almost surely smooth, so the holonomies are defined. Conditionally on the Maxwell field, the three cycle angles are distributed according to the Haar probability measure on $(\mathbb{R}/4\pi\mathbb{Z})^3$; hence their joint law is exactly Haar. The three holonomies commute, and an independent common random conjugation does not change the value of any function invariant under simultaneous conjugation.*
2. *Let R_{ab} be the Euclidean norm of the three logarithms of the cycle holonomies, taken in the principal chart. For every nonnegative $\varphi \in C_c^\infty((1,2))$ and every δ with $0 < 4\delta < 2\pi$,*

$$\mathbb{E}_{\mathrm{ab}}\varphi(R_{\mathrm{ab}}/\delta) = (4\pi)^{-3}\,4\pi\delta^3\int_1^2 \varphi(v)v^2\,dv.$$

This lemma specifies a comparison probability measure and makes no assertion about the Wilson measure.

Proof. In the Fourier modes $k = 2\pi m/L$, $m \neq 0$, we use the transverse multiplier $g_3^2|k|^{-2}(I - kk^{\mathsf{T}}/|k|^2)$ in one real color, with real sine and cosine bases orthonormal in $L^2(\mathbb{T}^3_L, dx)$. Independent real Gaussian coefficients in a transverse orthonormal basis define this field. For every $s > 1/2$, the expected sum of the squared coefficients with

the weight $(1+|k|^2)^{-s}$ is finite, since $\sum_{m\neq 0}|m|^{-2-2s}<\infty$. The weighted sum of squared coefficients is then a nonnegative random variable with finite expectation, and the Fourier series converges almost surely in this weighted Hilbert norm. This constructs the field as a distribution. After any positive heat time, the expected sum of the absolute values of the differentiated Fourier coefficients is finite at every order of differentiation, because of the factor $e^{-t|k|^2}$. The smoothed field is therefore almost surely smooth, and the three cycle integrals are defined.

We add the independent flat connection whose three cycle integrals are the independent uniform phases $\alpha_i \in \mathbb{R}/4\pi\mathbb{Z}$. In the embedded Abelian subgroup, each smoothed cycle angle is $\alpha_i + l_i$ modulo 4π, where l_i is a function of the Maxwell field. Since a translation of a uniform variable on the circle preserves its law, the three angles are distributed, conditionally on the Maxwell field, according to the Haar probability measure. If $\beta_i \in [-2\pi, 2\pi)$ are their representatives, the distance of $e^{\beta_i \tau_3}$ from the identity is $|\beta_i|$, and $R_{\mathrm{ab}} = |\beta|$. Since the support of the insertion lies in the Euclidean ball of radius $2\delta < 2\pi$, polar coordinates in $\mathbb{R}^3$ give

$$(4\pi)^{-3}\int_{\mathbb{R}^3}\varphi(|\beta|/\delta)\,d\beta = (4\pi)^{-3}\,4\pi\delta^3\int_1^2 \varphi(v)v^2\,dv.$$

All group elements here belong to the same Abelian subgroup. An independent common conjugation therefore preserves the values of all functions invariant under simultaneous conjugation, and it preserves commutativity. This completes the proof. □

SECTION 34

Uniform fluctuation bounds and comparison of holonomies

In this section, we prove estimates for the conditional refinement of the coarse field to the fine field that are uniform as the dimensionless coupling $\gamma = g_3^2 L$ tends to zero, and we transfer them to the holonomy matrices of the Wilson flow at a positive time. The main application is Theorem 34.13, which is Theorem 2.9: every subsequential limit of the continuum measures λ_γ as $\gamma \to 0$ is supported on stationary flat trajectories. The holonomy estimates are also the inputs for the normal fluctuations near regular commuting triples in Section 35 and for the quartic asymptotics near the central triples in Section 36.

The basic comparison is the following. We fix the coarse field and the normalized fluctuation variables of the first m renormalization group steps from the coarse side, and we set the normalized fluctuation variables w_j of all later steps equal to zero. Applying the same reconstruction maps gives a configuration on the finest lattice, which we evolve by the same Wilson flow as the reconstructed field. We then compare the holonomies of the two flowed configurations around fixed loops, as matrices in one common initial gauge frame. The comparison configuration is neither the interpolation of the field on the m-th lattice nor a conditional mean: setting $w_j = 0$ is different from setting the centered variable $w_j - \mathbb{E}(w_j \mid \mathcal{F}_{j-1})$ to zero.

We use three probability settings, summarized in Table 34.1.

Two estimates explain the exponent conditions used throughout. First, under the conditioned measure the reconstructed field at mesh ℓ_j has supremum norm at most of order $r\varrho^j + g_3\sqrt{\ell_j}\, p_j$, where $\varrho < B^{-1/2}$ is the contraction factor of the zero-fluctuation reconstruction maps and p_j is the logarithmic cutoff on the fluctuation variables. The signed difference between the linearized reconstruction and the interpolation of the coarser field costs a factor $\ell_j^{\alpha-1}$ in the norm of the linear heat evolution. Its random part therefore has size $g_3 \ell_j^{\alpha-1/2}$, which is summable over the geometric sequence of meshes because $\alpha > 1/2$. A classical quadratic term has size ϱ^{2j}/ℓ_j, which is summable because $B\varrho^2 < 1$. The second point concerns maxima. The supremum over the finest lattice of a linear function of the fluctuation variables would cost a factor $\sqrt{\log(L/a)}$, which grows as the finest mesh $a \to 0$. Instead, we cover the coefficient arrays at the mesh ℓ_j of their inputs, in metrics of bounded diameter, and chain in these metrics. The loss is then

Setting	What is fixed	Random variables	Conclusion
Conditioned Wilson measure (Theorems 34.9 and 34.10)	The parameters; the coarse field is random	Fluctuation variables with their conditional fluctuation kernels	Holonomy differences have moments of order $\gamma^{p/2}$, and the leading term decays in m
Prescribed coarse field (Theorem 34.11)	Every initial field $v = e^{\theta_0}$ with $\|\theta_0\|_\infty \le r$	The same kernels, iterated from v	Moments of order $\gamma^{p/2}$ of the supremum over a time interval, uniformly in v
Prescribed flat field (Lemma 34.12)	A regular flat coarse field y	Independent standard Gaussian vectors inserted into derivatives of the reconstruction	The omitted Gaussian covariance decays geometrically in m

Table 34.1. The three probability settings of this section.

$\sqrt{\log(2 + L/\ell_j)}$, which is summable against the positive powers of ℓ_j. Combined with dimension-free concentration for the conditional fluctuation kernels, this gives moment bounds of order $\sqrt{\gamma}$ without a factor $|\log \gamma|$ in the leading term.

The proofs use the following inputs. The concentration estimates for the conditional fluctuation kernels are those of Theorem 5.4, which adapt the methods of Brascamp and Lieb [33] and Bakry and Émery [8] to products of balls with reflecting boundary. The quadratic estimate there is of Hanson–Wright type [108], in the setting of dependent coordinates exemplified by Adamczak [1]. Neither independence nor Gaussianity of the fluctuation variables is used. The maximal estimates use increment chaining in the tradition of Dudley [79] and Dirksen [74, Theorems 3.2 and 3.5], in the elementary form of Lemma 16.4. The reconstruction maps, their coefficient bounds, and the conditional kernels come from Section 15; the zero-fluctuation maps are built from constrained minimizers in the tradition of Bałaban's background fields [10, 11, 13, 16]. The parameters are those of Theorem 23.2. The coefficient bounds for the four parts of a reconstruction increment and for their ordered quadratic products are those of Sections 26 to 28. The decomposition of a rough initial datum into its linear heat evolution, its quadratic Picard term, and a smoother remainder follows Da Prato and Debussche [63] and Cao and Chatterjee [42]; the lattice flow theory is in Sections 24 and 25, and the flow is Lüscher's Wilson flow [128]. The final theorem uses the continuum measures and the energy compactness of Section 29, which rest on the state space of Cao and Chatterjee [43] and on Uhlenbeck's compactness theorem [151], and the stopped measures on the coarse lattice of Section 33.

Sections 34.1 and 34.2 fix the notation and collect the deterministic inputs: heat estimates, covering estimates for the coefficient arrays, the zero-fluctuation continuation, and two elementary probability facts. Sections 34.3 to 34.6 prove conditional bounds uniform in γ, recall the stability of based holonomy matrices, and compare the two reconstructions, first through their flow data and then through their holonomies, under the conditioned measure and for every prescribed coarse field. Sections 34.7 and 34.8 contain the applications: the Gaussian estimate at a prescribed flat field and the flat support of the weak-coupling limits.

34.1 Setting and notation

Throughout this section we fix $L > 0$, $\theta > 0$, a finite horizon $T \geq \theta L^2$, an odd integer $M \geq 3$, an integer $J \geq 1$, $B = M^J$, and a coupling ceiling $0 < \gamma_0 \leq 1$. All parameters of the small-field event, the analytic domains, and the coefficient bounds of the reconstruction are fixed as in Theorem 23.2, before $\gamma \in (0, \gamma_0]$ is chosen. We fix an integer $n \in 4\mathbb{N}$ in the lattice refinement sequence under consideration, at least the minimum coarse side of Theorem 23.2, and such that every flat coarse field has a representative well inside the small-field domain. Precisely, we fix $r_{\mathrm{flat}} < r$ with $2\pi/n < r_{\mathrm{flat}}/4$, so that Lemma 14.9 applies; here r is the radius of the small-link domain B_r. We use the exponents

$$\tfrac{1}{2} < \alpha = \alpha_{\mathrm{fl}} < \tfrac{2}{3}, \qquad \beta = \alpha - \tfrac{1}{2}, \qquad \kappa_{\mathrm{fl}} = 1 - \tfrac{3\alpha}{2}, \qquad 0 < \sigma = \sigma_{\mathrm{sm}} < 1 - \alpha,$$

and the weighted norms X^a_α, Y^a_α, H^a_σ, and V^a_σ of Definition 4.8 on the time interval $[0, T]$. These norms include every component, every physical first difference, and every shift of the Wilson stencil required there. For a random norm such as $\mathsf{X}^a_\alpha(f)$, we write $\|\mathsf{X}^a_\alpha(f)\|_p$ for the L^p norm of this scalar random variable, and similarly for conditional L^p norms. The moment order p is unrelated to the cutoff radii p_j defined below.

Definition 34.1. Fix an integer $K \geq 0$ and set $N = nB^K$. For $0 \leq j \leq K$ put

$$\ell_j = \frac{L}{n} B^{-j}, \quad a = \ell_K, \quad \mathfrak{g}_j^2 = \frac{\gamma}{nB^j} = g_3^2 \ell_j, \quad t_j = M^{(J-1)/2} \mathfrak{g}_j, \quad p_j = A_{\mathrm{w}} \log(1/t_j).$$

1. *Conditional refinement.* Let $\nu = \nu_{N,n,\gamma}$ be the conditioned Wilson measure. Let $\widehat{\theta}_0$ be the link logarithm of the coarse field on Λ_n in the gauge of the reconstruction maps, and for $1 \leq j \leq K$ let
$$\widehat{\theta}_j = \widehat{\Phi}_j\big(\widehat{\theta}_{j-1}, (g_{j,r} w_{j,r})_r\big),$$
where $\widehat{\Phi}_j$ is the reconstruction map of Theorem 15.12 for the j-th renormalization group step counted from the coarse side, from mesh ℓ_{j-1} to mesh ℓ_j. Here $w_j = (w_{j,r})_r$ are the normalized fluctuation variables of this step, r runs over its J intermediate scales, and $g_{j,r}$ are the couplings of these scales; their ratios to t_j

lie between $M^{-(J-1)/2}$ and 1. Let $\mathcal{F}_j = \sigma(\widehat{\theta}_0, w_1, \dots, w_j)$ be the backward filtration. Conditionally on $\mathcal{F}_{j-1}$, the vector w_j has the law $k_j(\widehat{\theta}_{j-1}, dw_j)$ of the conditional fluctuation kernel (4.8) of this step, on its fluctuation cutoff domain and at prior depth $J(K-j)$ (Lemma 15.10 and Theorem 15.9).

2. *Zero-fluctuation maps.* Let $P_j(v) = \widehat{\Phi}_j(v, 0)$ and $L_j = DP_j(0)$. There exists a convex working ball, given by Lemma 15.15, which contains all the fields $\widehat{\theta}_j$ and all the zero-fluctuation continuations below, and on which

$$\sup_j \|DP_j\| \le a_{\mathrm{map}}, \qquad a_{\mathrm{map}}\sqrt{B} \le \tfrac{32}{49}, \qquad \mathfrak{q} = Ba_{\mathrm{map}}^2 < 1, \qquad \kappa = -\frac{\log a_{\mathrm{map}}}{\log B} > \tfrac{1}{2}.$$

We write $\varrho = a_{\mathrm{map}}$. The absolute coefficient bounds of the reconstruction maps (on rows and on volume-normalized columns), their bounds in the weighted heat norms with first differences, the bounds on the three ordered quadratic forms of Theorem 27.5, the bounds on the conditional means, and the bounds on the derivatives of the normalized conditional log-densities with respect to the incoming field, $\partial \log k = -\partial V + \mathbb{E}_k \partial V$ (with the parameters and bounds of Theorems 13.10 and 15.9), are fixed on a larger domain before the working ball is chosen. Since $q_{\mathrm{anc}} \le \mathfrak{q}$, the ratio $\mathfrak{q}$ may be used in place of q_{anc} in all the estimates of Section 27.

3. *Zero-fluctuation continuation.* For $0 \le m \le K$ let $\widehat{\theta}_j^0 = \widehat{\theta}_j$ for $j \le m$, and $\widehat{\theta}_j^0 = P_j \cdots P_{m+1}\widehat{\theta}_m$ for $m < j \le K$.

4. *Flow data.* Let $I_{\ell_j \to a}$ be the cardinal interpolation of Lemma 16.3 from mesh ℓ_j to mesh a, with $I_{a\to a}$ the identity, and let P_t^a be the lattice heat semigroup. On the finest lattice define

$$x_j = P_\cdot^a I_{\ell_j\to a}(\widehat{\theta}_j/\ell_j), \qquad y_j = \mathcal{Q}_a(x_j, x_j),$$
$$x_j^0 = P_\cdot^a I_{\ell_j\to a}(\widehat{\theta}_j^0/\ell_j), \qquad y_j^0 = \mathcal{Q}_a(x_j^0, x_j^0),$$

where $\mathcal{Q}_a$ is the bilinear Duhamel term of the Wilson flow with gauge damping, in the order displayed in Section 4; it is not symmetric.

5. *Increments.* Let $A_j = \widehat{\theta}_j/\ell_j$, $H = \ell_{j-1}$, and $\zeta_j = w_j - \mathbb{E}(w_j \mid \mathcal{F}_{j-1})$. Then $d_j = x_j - x_{j-1}$ satisfies $d_j = s_j + z_j + r_j + u_j$, where

$$\begin{aligned} s_j &= \frac{\mathfrak{g}_j}{\ell_j} P_\cdot^a I_{\ell_j\to a} E_{\widehat{\theta}_{j-1}} \zeta_j, \qquad z_j = P_\cdot^a I_{\ell_j\to a}\big(A_j - \mathbb{E}(A_j \mid \mathcal{F}_{j-1})\big) - s_j, \\ r_j &= P_\cdot^a \Big(I_{\ell_j\to a}\frac{L_j\widehat{\theta}_{j-1}}{\ell_j} - I_{H\to a}\frac{\widehat{\theta}_{j-1}}{H}\Big), \\ u_j &= P_\cdot^a I_{\ell_j\to a} U_j^0, \qquad U_j^0 = \mathbb{E}(A_j \mid \mathcal{F}_{j-1}) - \frac{L_j\widehat{\theta}_{j-1}}{\ell_j}. \end{aligned} \tag{34.1}$$

Here E_θ is the normalized first Taylor coefficient of the reconstruction at the conditional mean, in the centered fluctuation variables, as in Lemma 26.2. Thus s_j is the

centered linear fluctuation term, z_j the centered nonlinear heat term, r_j the signed interpolation defect, and u_j the predictable term. For $j > m$ the continuation has increment $d_j^0 = x_j^0 - x_{j-1}^0 = r_j^0 + u_j^{\mathrm{cl},0}$, where r_j^0 is r_j with $\widehat{\theta}_{j-1}$ replaced by $\widehat{\theta}_{j-1}^0$, and $u_j^{\mathrm{cl},0} = P_\cdot^a I_{\ell_j \to a} U_j^{\mathrm{cl}}(\widehat{\theta}_{j-1}^0)$ with $U_j^{\mathrm{cl}}(v) = \ell_j^{-1}(P_j(v) - L_j v)$.

6. *Holonomies.* Let $\mathcal{H}^K = (\mathcal{H}_i^K)_{i=1}^3$ be the based holonomies around the three coordinate cycles of $\mathbb{T}_L^3$ of the configuration $\Psi_{\theta L^2}^{(N)}(\exp \widehat{\theta}_K)$, that is, of $\exp \widehat{\theta}_K$ after the Wilson flow for the lattice flow time $4\theta L^2/a^2$. Let $\Xi_m^K = (\Xi_{m,i}^K)_{i=1}^3$ be the same triple for $\exp \widehat{\theta}_K^0$. Both triples are computed in the common initial frame of the reconstruction maps.

The two configurations on the finest lattice compared in this section are

$$U_K = \exp \widehat{\theta}_K, \qquad U_{K,m}^0 = \exp\bigl(P_K \cdots P_{m+1} \widehat{\theta}_m\bigr).$$

Above level m, the first is refined with the random fluctuation variables and the second with zero fluctuation variables:

$$\begin{aligned}
&\widehat{\theta}_0 \ \to \ \cdots \ \to \ \widehat{\theta}_m \ \xrightarrow{\widehat{\Phi}_{m+1}(\cdot, g w_{m+1})} \ \widehat{\theta}_{m+1} \ \to \cdots \to \ \widehat{\theta}_K, \\
&\widehat{\theta}_0 \ \to \ \cdots \ \to \ \widehat{\theta}_m \ \xrightarrow{\qquad P_{m+1} \qquad} \ \widehat{\theta}_{m+1}^0 \ \to \cdots \to \ \widehat{\theta}_K^0.
\end{aligned}$$

We have $U_j^0 = U_j^{\mathrm{cl}}(\widehat{\theta}_{j-1}) + m_j^{\mathrm{ph}}(\widehat{\theta}_{j-1})$, where the conditional mean correction $m_j^{\mathrm{ph}}(v) = \mathbb{E}(A_j \mid \mathcal{F}_{j-1}) - \ell_j^{-1} P_j(v)$, at $\widehat{\theta}_{j-1} = v$, is the difference between the conditional mean and the zero-fluctuation value. It enters $d_j - d_j^0$ and is estimated separately, never as part of a centered term.

We call $\mathcal{H}^K$ the flowed holonomy triple and Ξ_m^K the zero-fluctuation continuation triple. With $a_j = \ell_j$, $g_j = \mathfrak{g}_j$, the common mesh $\delta = a$, and the depth $\mathfrak{d}_j = J(K-j)$, the four terms in (34.1) are those of Lemma 26.2. There the logarithmic reconstruction map is $\mathscr{R}_j(\theta, w_j) = \widehat{\Phi}_j(\theta, (g_{j,r} w_{j,r})_r)$; for an incoming link logarithm v, the zero-fluctuation reconstructed lattice potential is $C_j(v) = \ell_j^{-1} P_j(v)$; and the linearization on lattice potentials is $\mathsf{P}_j = B L_j$, so that $\ell_j^{-1} L_j v = H^{-1} \mathsf{P}_j v$. The expansion is taken at the conditional mean, not at zero (see Remark 26.3). In particular, the centered nonlinear heat term is $z_j = P_\cdot^a I_{\ell_j \to a} Z_j$, the heat evolution of the conditionally centered nonlinear reconstruction residual Z_j of that lemma.

Constants. Unless stated otherwise, constants $C, c, \dots$ have the dependence described in item (6) of Definition 4.14, and may in addition depend on T, α, σ, the lengths of the loops considered, the margins of the reference neighborhoods of the flow, the fixed coefficient bounds of the reconstruction, and the fixed bounds on the conditional fluctuation kernels, their conditional means, and the derivatives of their log-densities. These data are fixed before the coupling is varied. The constants are independent of γ, K, N, the prior depths,

the indices m, j, i, and the finest mesh, unless an index is displayed. A subscript p allows dependence on a fixed moment order. All estimates concern the torus itself; no block region or frozen coordinate is varied. Recall that $g_3^2 = \gamma/L$, that $\mathfrak{g}_j = g_3\sqrt{\ell_j}$ is the coupling at mesh ℓ_j, that t_j is the largest coupling of the intermediate scales of the j-th step, and that p_j is the cutoff radius of its fluctuation variables.

Quadratic forms pulled back to earlier levels. The quadratic Picard term of the signed defect and of the predictable term is controlled through quadratic forms in the fields of earlier levels, as in Section 27. For $0 \le i \le j-1$ let $L_{j-1,i} = L_{j-1} \circ \cdots \circ L_{i+1}$, with $L_{j-1,j-1}$ the identity, and for an array v at level i we define

$$\mathsf{U}_{j,i}v = P_\cdot^a I_{\ell_j \to a} \frac{L_j L_{j-1,i} v}{\ell_j}, \qquad \mathsf{V}_{j,i}v = P_\cdot^a \Big(I_{\ell_j \to a} \frac{L_j L_{j-1,i} v}{\ell_j} - I_{\ell_{j-1} \to a} \frac{L_{j-1,i} v}{\ell_{j-1}} \Big).$$

The three ordered quadratic forms are

$$T_{j,i}^{\mathsf{UV}}(v,v) = \mathcal{Q}_a(\mathsf{U}_{j,i}v, \mathsf{V}_{j,i}v), \qquad T_{j,i}^{\mathsf{VU}}(v,v) = \mathcal{Q}_a(\mathsf{V}_{j,i}v, \mathsf{U}_{j,i}v),$$
$$T_{j,i}^{\mathsf{VV}}(v,v) = \mathcal{Q}_a(\mathsf{V}_{j,i}v, \mathsf{V}_{j,i}v),$$

and we write $\omega \in \{\mathsf{UV}, \mathsf{VU}, \mathsf{VV}\}$ for the label. Since $\mathsf{V}_{j,j-1}\widehat{\theta}_{j-1} = r_j$ and $\mathsf{U}_{j,j-1}\widehat{\theta}_{j-1} - \mathsf{V}_{j,j-1}\widehat{\theta}_{j-1} = x_{j-1}$, we have, at $(\widehat{\theta}_{j-1}, \widehat{\theta}_{j-1})$,

$$\mathcal{Q}_a(r_j, r_j) = T_{j,j-1}^{\mathsf{VV}}, \qquad \mathcal{Q}_a(x_{j-1}, r_j) = T_{j,j-1}^{\mathsf{UV}} - T_{j,j-1}^{\mathsf{VV}}, \qquad \mathcal{Q}_a(r_j, x_{j-1}) = T_{j,j-1}^{\mathsf{VU}} - T_{j,j-1}^{\mathsf{VV}}. \tag{34.2}$$

The same identities hold for the continuation, with r_j^0, x_{j-1}^0, and $\widehat{\theta}_{j-1}^0$. Let $S_{j,j-1}(v,v)$ be the quadratic part of $I_{\ell_j \to a} U_j^{\mathrm{cl}}(v)$, and $S_{j,i}(v,v) = S_{j,j-1}(L_{j-1,i}v, L_{j-1,i}v)$; we call $S_{j,i}$ the quadratic initial forms, and we call H_σ^a the initial-array norm. By construction both kinds of forms are pulled back exactly by the linearized maps:

$$T_{j,i-1}^{\omega}(v,v) = T_{j,i}^{\omega}(L_i v, L_i v), \qquad S_{j,i-1}(v,v) = S_{j,i}(L_i v, L_i v). \tag{34.3}$$

By Theorem 27.5, the coefficient norm of $T_{j,i}^{\omega}$ with output in the norm Y_α^a is at most $C(1+j)^c \mathfrak{q}^{j-1-i}/\ell_i$, and by Theorem 27.7 the coefficient norm of $S_{j,i}$ with output in H_σ^a is at most $C\mathfrak{q}^{j-1-i}/\ell_i$. We write $K_{ji} = \mathfrak{q}^{j-1-i}/\ell_i$.

The identities (34.3) give a cancellation that we use repeatedly. For a bilinear form A and $P = L + E$ with L linear and $E(v)$ of order $|v|^2$, we have

$$A(Pv, Pv) - A(Lv, Lv) = A(Lv, Ev) + A(Ev, Lv) + A(Ev, Ev). \tag{34.4}$$

The right side has degree at least three in v. Its difference at two points v, v' is bounded by $(|v| + |v'|)^2 |v - v'|$ times the coefficient norm of A, and two undifferentiated factors remain. With $A = T_{j,i}^{\omega}$ or $S_{j,i}$ and $P = P_i$, $L = L_i$, this identity reduces the comparison of quadratic forms along the two reconstructions to centered fluctuation terms, classical terms of degree at least three, and conditional means.

The bilinear expansion of the quadratic Picard term. Since $\mathcal{Q}_a$ is bilinear, we have

$$y_l - y_m = \sum_{j=m+1}^{l} \big\{ \mathcal{Q}_a(x_{j-1}, d_j) + \mathcal{Q}_a(d_j, x_{j-1}) + \mathcal{Q}_a(d_j, d_j) \big\}. \tag{34.5}$$

Inserting $d_j = s_j + z_j + r_j + u_j$ produces, for each j, the sixteen ordered products $\mathcal{Q}_a(v_j, w_j)$ with $v, w \in \{s, z, r, u\}$, and the eight cross terms $\mathcal{Q}_a(x_{j-1}, v_j)$ and $\mathcal{Q}_a(v_j, x_{j-1})$ with the preceding field. We never estimate a product of two rough heat paths in the norm X^a_α directly. Instead, each term is handled by one of four tools: the estimates for the quadratic expression in the centered linear term in Theorem 26.12; the mixed linear rows of Theorem 26.10, for a product of s_j with a predictable heat path; the forms (34.2); and the ordered product inequality of Lemma 28.5, which states that for two heat paths v and $w = P^a_\cdot w_0$,

$$\mathsf{Y}^a_\alpha\big(\mathcal{Q}_a(v, w)\big) + \mathsf{Y}^a_\alpha\big(\mathcal{Q}_a(w, v)\big) \le C\, \mathsf{X}^a_\alpha(v)\, \mathsf{H}^a_\sigma(w_0), \tag{34.6}$$

separately for the two orders, with a constant independent of the coupling, the coarse side, and the depth. For differences between the two reconstructions we use the identity

$$\mathcal{Q}_a(v, u) - \mathcal{Q}_a(v^0, u^{\mathrm{cl},0}) = \mathcal{Q}_a(v, u - u^{\mathrm{cl},0}) + \mathcal{Q}_a(v - v^0, u^{\mathrm{cl},0}), \tag{34.7}$$

where $v \in \{s, z, r, u\}$ and $v^0 = 0, 0, r^0, u^{\mathrm{cl},0}$ respectively, together with the identity in which both arguments are interchanged; for the cross terms the same identity holds with $(v, v^0) = (x_{j-1}, x^0_{j-1})$. Table 34.2 lists the tool used for each term in the three proofs where the expansion appears.

34.2 Heat estimates on a common mesh and fluctuation tails

We first record the elementary calculations needed to apply the coefficient bounds of Sections 15 and 26 to 28 uniformly in the coupling, and we specify which part of each earlier estimate at fixed coupling is used.

All uses below satisfy the following domain conditions. Each renormalization group step consists of J averaging steps; the lattice at level j has side nB^j, and the prior depth at level j is $J(K - j)$. Since $t_1^2 = \gamma/(Mn)$ and $t_j = t_1 B^{-(j-1)/2}$, the minimum-side condition of Theorem 23.2 puts every t_j below the upper bound on the couplings in the conditional kernel theorem. The inputs $g_{j,r} w_{j,r}$ of the reconstruction maps have size at most $t_j p_j$, and the larger coefficient domain and the working ball are those of Lemma 15.15, fixed before the coupling. In particular the deterministic amplitude bound of that lemma applies to these inputs, and the bounds with the factor a_{map} used below require no stochastic estimate uniform in the mesh. The heat horizon is always T. Every refinement ratio $\ell_i/a = B^{K-i}$ is an integer, and every order of spatial differences used below is an integer. The side n satisfies $2\pi/n < r_{\mathrm{flat}}/4$, hence the condition on flat fields in Lemma 14.9.

These conditions let us evaluate the coefficients at zero fluctuation for a fixed incoming field, including a flat one; they do not identify a stopped measure with a marginal of the conditioned Wilson measure.

The linearized maps have the geometric contraction ratio $q_{\mathrm{anc}} = C_{\mathrm{CP}}^2/B$ of Lemma 15.15, and by the choice in Definition 34.1 we have $q_{\mathrm{anc}} \le \mathfrak{q} < 1$. All geometric losses below are taken from the positive gap $-\log \mathfrak{q}/\log B$ and the other positive exponents displayed in this section. The two ratios remain distinct in the normalization of differentiated coefficient rows; see (34.21).

In every use of the weighted coefficients of Theorem 27.5, the constants may depend on the coarse mesh $H_0 = L/n$. Indeed, for $H = \ell_{j-1} = H_0 B^{-(j-1)}$ and $j \ge 1$ we have

$$\begin{aligned} 1 + \log(1 + T/H^2) &\le 1 + \log(1 + T/H_0^2) + 2(j-1)\log B \\ &\le C_{T,H_0,B}(1+j), \end{aligned} \tag{34.8}$$

where in the first inequality we used $1 + B^{2(j-1)}T/H_0^2 \le B^{2(j-1)}(1 + T/H_0^2)$. This constant is independent of the coupling, of all level indices, of the prior depth, and of the finest mesh. The coefficient rows without time weights keep the dependence stated in Theorem 27.5.

Lemma 34.2. *Put $H_0 = L/n$ and $\lambda = -\log \mathfrak{q}/\log B = 2\kappa - 1 > 0$. The following bounds hold.*

1. *For cardinal interpolation from any input mesh $H \ge a$ compatible with the common lattice, that is, with H/a an integer, and every fixed integer $q \ge 0$,*

$$\|D_a^q P_t^a I_{H\to a} v\|_\infty \le C_q (t + H^2)^{-q/2} \|v\|_\infty. \tag{34.9}$$

2. *Let E be a coefficient array of a reconstruction map with respect to normalized fluctuation variables at input mesh H, whose output-fixed absolute coefficient row sums and volume-normalized input-fixed column sums satisfy the bounds of Lemma 15.15. Then*

$$\sup_x \|D_a^q P_t^a I_{H\to a} E(x,\cdot)\|_{\ell^2(w)} \le C_q H^{3/2} (t + H^2)^{-3/4 - q/2}, \tag{34.10}$$

   where $\ell^2(w)$ is the counting ℓ^2 norm in the fluctuation variables, and the operator norm of $D_a^q P_t^a I_{H\to a} E$ from $\ell^2(w)$ to the physical space L_a^2, with measure a^3 times counting measure, is at most $C_q H^{3/2}(t + H^2)^{-q/2}$. The constants may depend on the fixed ratios of the reference volumes of the coordinate types within one renormalization group step.

3. *Let $H = \ell_{j-1}$, and let $\mathscr{D}_j v = I_{\ell_j \to a}(L_j v/\ell_j) - I_{H\to a}(v/H)$ be the initial value of the signed defect r_j when the incoming field is v. Then*

$$\mathsf{X}_\alpha^a(P_\cdot^a \mathscr{D}_j v) \le C H^{\alpha - 1} \|v\|_\infty. \tag{34.11}$$

4. *Let $V_j(v)$ be the part of degree at least three of the initial value $I_{\ell_j\to a}U_j^{\mathrm{cl}}(v)$ (this V_j is unrelated to the coarse configuration V of Section 34.8), so that $I_{\ell_j\to a}U_j^{\mathrm{cl}}(v) = S_{j,j-1}(v,v) + V_j(v)$. On the working ball,*

$$\|V_j(v) - V_j(v')\|_\infty \le \frac{C}{H}(\|v\|_\infty + \|v'\|_\infty)^2\|v - v'\|_\infty. \tag{34.12}$$

5. *The conditional mean correction satisfies*

$$\|m_j^{\mathrm{ph}}(v)\|_\infty \le Cg_3^2\|v\|_\infty, \qquad U_j^0 = U_j^{\mathrm{cl}}(\widehat{\theta}_{j-1}) + m_j^{\mathrm{ph}}(\widehat{\theta}_{j-1}). \tag{34.13}$$

Every bound on the supremum norm of an initial array in items (4) and (5) implies the corresponding bound in the full norm H_σ^a, with a fixed factor.

6. *If $x = P_\cdot^a I_{H\to a}(v/H)$ and $h = H/B$, then*

$$\sup_{t\le T}\big\{(t+h^2)^{\alpha/2}\|x(t)\|_\infty + (t+h^2)^{(\alpha+1)/2}\|D_a x(t)\|_\infty\big\} \le C\big\{\mathsf{X}_\alpha^a(x) + \|v\|_\infty H^{\alpha-1}\big\}. \tag{34.14}$$

Each fixed higher difference $D_a^q x$ satisfies the corresponding bound with the weight $(t+h^2)^{(\alpha+q)/2}$.

7. *For $b \ge 0$, $e > 0$, and $0 < s < \min(e,\lambda)$,*

$$\sum_{i>m}(1+i)^b B^{-ei} \le C_{b,e}(1+m)^b B^{-em}, \tag{34.15}$$

$$\sum_{j>m}\sum_{i=m+1}^{j-1}(1+j)^b \mathfrak{q}^{j-1-i}B^{-ei} \le C_{b,e,s}(1+m)^b B^{-sm}. \tag{34.16}$$

In (34.16) *an initial term $(1+j)^b\mathfrak{q}^j$ satisfies the same bound. These constants depend on b, e, s and not on m.*

Proof. We begin with the cardinal interpolation. It has tensor-product basis functions $\psi((y-x)/H)$, where $\psi = \phi^{\otimes 3}$ and $\phi(u) = b_0(u)/\sum_{k\in\mathbb{Z}} b_0(u-k)$ for the fixed even smooth bump b_0 of Section 16.2, which is supported in $[-1,1]$, positive inside, and flat at its endpoints; in the notation there, $b_0 = b$, $\phi = \zeta$, and $\psi = \zeta_3$. Its translates sum to one. Grouping the fine vertices according to their offset in a coarse cell, we find

$$a^3\sum_{y\in\Lambda_N}\psi((y-x)/H) = H^3, \qquad a^3\sum_y \mathrm{dist}(y,x)|\psi((y-x)/H)| \le CH^4.$$

Taking q differences of the smooth basis costs $C_q H^{-q}$, independently of a/H. In particular these statements also hold for $H = a$, where the interpolation is the identity on arrays.

The scalar heat estimates follow from the symbol

$$\omega_a(k) = 4a^{-2}\sum_{i=1}^3 \sin^2(\pi a k_i/L), \qquad k\in\mathbb{Z}^3,\ |k_i| \le L/(2a).$$

On this frequency cube $\omega_a(k) \geq c|k|^2/L^2$, and the symbol of D_a^q is at most $C_q(|k|/L)^q$. By Parseval's identity and comparison of each unit frequency cube with the corresponding Gaussian integral, we have

$$\|D_a^q P_t^a(x,\cdot)\|_{L_a^2} \leq C_{q,L,T}(t+a^2)^{-3/4-q/2},$$

where the kernel is taken with respect to the physical measure. The corresponding L^1 bound is $C_{q,L,T}(t+a^2)^{-q/2}$. To prove it without discarding the constant mode, we periodize the heat kernel p_t of the infinite lattice. By the Cauchy–Schwarz inequality with the weight $(1+|x|^2/(t+a^2))^2$ and Parseval's identity, the L^1 norm of $D_a^q p_t$ is at most

$$C(t+a^2)^{3/4}\big\|(1+|x|^2/(t+a^2))D_a^q p_t(x)\big\|_{L_a^2} \leq C_q(t+a^2)^{-q/2}.$$

In the last inequality, we used that multiplication by x_i corresponds to differentiation of the Fourier multiplier. Differentiating $e^{-t\omega_a}$ once or twice produces $t\partial_i\omega_a$ or $t\partial_i^2\omega_a + t^2(\partial_i\omega_a)^2$, and differentiating a difference symbol lowers its frequency power by the number of derivatives. The bounds $|\partial_i\omega_a| \leq C\sqrt{\omega_a}$ and $|\partial_i^2\omega_a| \leq C$, together with the Gaussian integrals above, give the displayed powers. For $t \leq a^2$, the difference stencil and the facts that P_t^a is positive and has mass one (which follow from the Poisson series of the nearest-neighbor walk) give the bound $C_q a^{-q}$ instead. Periodization does not increase the L^1 norm, and the contribution of the constant mode to the L^2 norm is bounded on the horizon T by a constant depending on L and T. Splitting at $t = H^2$ now proves (34.9): for $t \leq H^2$ we put the differences on the cardinal basis and use that P_t^a has mass one, and for $t \geq H^2$ we use the L^1 bound and $t + a^2 \geq (t+H^2)/2$.

Next, we prove item (2). By Lemma 15.15, the array E has bounded output-fixed absolute coefficient row sums and bounded volume-normalized input-fixed column sums, and it is exponentially localized in units of the input mesh. Let $\mathcal{J} = I_{H\to a}E$. Its absolute row sums are at most C, and each of its columns has physical mass at most CH^3. For an input ξ in counting ℓ^2, by the weighted Cauchy–Schwarz inequality we have

$$a^3\sum_y\Big|\sum_\lambda \mathcal{J}_{y\lambda}\xi_\lambda\Big|^2 \leq a^3\sum_{y,\lambda}|\mathcal{J}_{y\lambda}||\xi_\lambda|^2\sum_\mu|\mathcal{J}_{y\mu}| \leq CH^3\sum_\lambda|\xi_\lambda|^2.$$

For $t \leq H^2$, the absolute row of the differenced cardinal interpolation bounds the ℓ^2 row in (34.10) by CH^{-q}, and its volume-normalized column sum gives the same Schur bound for the operator norm with the extra factor H^{-q}. For $t \geq H^2$, we compose $\mathcal{J}\colon \ell^2(w) \to L_a^2$ with the physical L_a^2 row of $D_a^q P_t^a$ computed above. The two norms multiply to $CH^{3/2}t^{-3/4-q/2}$, which proves (34.10). Composition with the operator $D_a^q P_t^a$ on L_a^2, whose norm is at most $Ct^{-q/2}$, gives $CH^{3/2}t^{-q/2}$ and proves the operator bound. Conversion to the counting output norm would introduce a factor $a^{-3/2}$, which is canceled by the conversion of the physical heat-kernel coefficient row. Coordinate types at the other $J-1$ meshes of the step change these factors only by fixed powers of M.

For item (3), we use the signed mass identity of Lemma 15.15. The column of the linearized refinement and the column of the parent cardinal interpolation have equal physical mass, separately for every input orientation and color, and their difference has first absolute moment at most CH^4 about the input location. In a heat convolution we subtract the kernel value at the input location before summing such a column. Using the first difference of the kernel and this moment, we obtain, for every fixed integer $q \geq 0$,

$$\|D_a^q P_t^a \mathscr{D}_j v\|_\infty \leq \frac{C_q \|v\|_\infty}{H} (t + H^2)^{-q/2} \frac{H}{\sqrt{t + H^2}}.$$

For $t \leq H^2$ the same estimate follows from the unsigned cardinal rows. For $t \geq H^2$ the row bound requires a sampling estimate. On a cube of side H, repeated one-dimensional telescoping and averaging bounds the supremum of a sampled scalar function f by $CH^{-3} \sum_{|\eta| \leq 3} H^{|\eta|} \|D_a^\eta f\|_{L^1_a}$ on the enlarged cube, with at most one difference in each coordinate. In one dimension, we choose a vertex where $|f|$ is at most its average and telescope from that vertex; this is the discrete form of $|f(x)| \leq H^{-1} \int |f| + \int |Df|$. We apply it successively in the three coordinates. Applied to a differenced heat-kernel coefficient row, it shows that the sum over the cubes of H^3 times the local supremum is at most the L^1 bounds of its differences through three further orders. When $t \geq H^2$, these are at most $C(t + H^2)^{-(q+1)/2}$, since $H/\sqrt{t + H^2} \leq 1$. The first moment of the column gives the remaining factor H. For columns outside a fixed enlarged cube we apply this estimate on successive shells, whose polynomial volumes are summable against the exponential decay of the coefficients. This proves the row bound without counting output sites. Multiplying by the two weights of X_α^a and using $a \leq H$ proves (34.11); the weighted maxima are at most $CH^{\alpha - 1}$ since $\alpha < 1$.

For item (4), we expand $P_j = L_j + P_{j,2} + P_{j,\geq 3}$ on the larger domain, where $P_{j,2}$ is quadratic and $P_{j,\geq 3}$ has degree at least three. The coefficientwise majorant series of Lemma 15.15 bounds the difference of the part of degree at least three by $C(\|v\| + \|v'\|)^2 \|v - v'\|$ on the working ball. Division by $\ell_j = H/B$ and interpolation prove (34.12), with B fixed.

For item (5), the bound on m_j^{ph} and the decomposition of U_j^0 are the conditional-mean assertions of Theorem 27.7 and Lemma 28.5, together with Lemma 26.2. For a fixed incoming field v, the amplitude bound in those statements may be taken equal to $\|v\|_\infty$. This proves (34.13). Since the heat semigroup contracts the supremum norm, the value part of $\mathsf{H}_\sigma^a(f)$ for an initial array f is at most $C_{T,\sigma} \|f\|_\infty$; the bound $\|D_a P_t^a f\|_\infty \leq C(t + a^2)^{-1/2} \|f\|_\infty$ proved above gives the same bound for its first-difference part.

For (34.14), when $t \geq H^2$ we have $t + h^2 \leq 2(t + a^2)$, and the weights are bounded by those of X_α^a. When $t \leq H^2$, we use (34.9): for instance $(t + h^2)^{\alpha/2} \|x(t)\|_\infty \leq C(2H^2)^{\alpha/2} H^{-1} \|v\|_\infty$. For a higher difference, above H^2 we put the additional differences on a half heat step, and below H^2 we put them on the cardinal basis. This proves the assertion about higher differences.

To prove (34.15), we write $i = m + k$ and use $1 + m + k \le (1 + m)(1 + k)$; the remaining series is $\sum_{k \ge 1} (1 + k)^b B^{-ek} < \infty$. For (34.16), we set $j = i + 1 + k$ and sum first in k. The factor $(1 + j)^b$ is at most $(2 + i)^b (1 + k)^b$, and $\sum_{k \ge 0} (1 + k)^b \mathfrak{q}^k < \infty$. This proves the bound with exponent e for the restricted double sum in (34.16). If an earlier level $i \le m$ is included, its convolution with $j > m$ is bounded by the same calculation after factoring out B^{-sm}; the two remaining geometric ratios are $B^{-(e-s)}$ and $B^{-(\lambda - s)}$, since $\mathfrak{q} = B^{-\lambda}$. This also proves the assertion for the initial term. □

The next lemma prepares the chaining arguments. Each component of a reconstruction increment is a random field indexed by time, position, and finitely many labels, and it is a linear, quadratic, or nonlinear function of the normalized fluctuation variables of one step, with deterministic coefficients. We divide each coefficient by the scale at which it is expected to be bounded, and we measure the distance between two indices by the distance between their normalized coefficients. In the lemma, we show that these coefficient metrics have bounded diameter and covering numbers polynomial in L/h_*, where h_* is the input mesh of the coefficients and not the finest mesh a. This is why the maximal estimates below contain $\log(2 + L/\ell_j)$ rather than $\log(L/a)$.

Lemma 34.3. *Fix the cutoff radii, an incoming field in the reconstruction domain, and a common mesh a no coarser than all input meshes in use. Each process below is indexed by the time $t \in [0, T]$, the position on the lattice of mesh a, and the finitely many labels (components, shifts, and the choice between value and first difference) required by its norm. Write $h = \ell_j$, $H = \ell_{j-1}$, and for $1 \le i \le j - 1$ put $G = \ell_i = B^k H$ with $k = j - 1 - i$, and*

$$b_i(v) = C_J \big(a_{\mathrm{map}} \|v\|_\infty + \mathfrak{g}_i p_i \big).$$

The quantity $b_i(v)$ bounds $\|\widehat{\theta}_i\|_\infty$ on the whole conditional fiber over the incoming field $v = \widehat{\theta}_{i-1}$. We consider the following families.

1. *The coefficient of $w_j - \mathbb{E}(w_j \mid \mathcal{F}_{j-1})$ in s_j, in the norm X^a_α, with scale A_s.*
2. *The quadratic part of the initial value of z_j, in the norm H^a_σ, with scale $A_{z,\sigma}$, and of the heat path z_j, in the norm X^a_α, with scale $A_{z,\alpha}$.*
3. *The quadratic part of $\mathcal{Q}_a(s_j, s_j)$, in the norm Y^a_α, with scale A_{ss}.*
4. *The two ordered terms $\mathcal{Q}_a(b, s_j)$ and $\mathcal{Q}_a(s_j, b)$, in the norm Y^a_α, where b is a predictable heat path with $\|D^q_a b(t)\|_\infty \le C_q \mathcal{R} (t + \ell_j^2)^{-(\alpha+q)/2}$ for $0 \le q \le 4$; the scale is $C g_3 \mathcal{R} h^{\alpha - 1/2}$.*
5. *For each ω separately, the gradient in w_i of $T^\omega_{j,i}(\widehat{\theta}_i, \widehat{\theta}_i)$ on the whole conditional fiber, in the norm Y^a_α, with scale $C(1 + j)^c K_{ji} \mathfrak{g}_i b_i(v) G^{2\alpha - 1}$.*
6. *The gradient in w_i of $S_{j,i}(\widehat{\theta}_i, \widehat{\theta}_i)$ on the whole conditional fiber, in the weighted value norm V^a_σ, with scale $C K_{ji} \mathfrak{g}_i b_i(v) G^\sigma$.*

In items (1)–(3) the coefficients are real vectors or real symmetric matrices in the centered vector $w_j - \mathbb{E}(w_j \mid \mathcal{F}_{j-1})$*, before subtraction of any quadratic mean, and*

$$\begin{aligned} A_s &= C\mathfrak{g}_j h^{\alpha-1}, \qquad A_{z,\sigma} = C g_3^2 h^{\sigma}, \\ A_{z,\alpha} &= C g_3^2 h^{\alpha}, \qquad A_{ss} = C g_3^2 h^{2\alpha-1}. \end{aligned} \tag{34.17}$$

In items (5)–(6) the gradients are taken before subtraction of the conditional mean. Put $h_* = H$ *in item (5) and* $h_* = h$ *otherwise. Let* S *be the applicable scale, and after division by* S *let* d_* *be the counting* ℓ^2 *distance of coefficient rows for a linear family, the maximum of the Hilbert–Schmidt and operator distances for a quadratic family, and* $\sup_w \|\nabla_w F_z - \nabla_w F_{z'}\|_2$ *for a gradient family. If* $S = 0$*, the corresponding evaluations vanish and are omitted. If the fixed factor in* S *is large enough, then there exist a fixed dimensionless space-time distance* d_0*, which separates the finitely many labels, and fixed* $P_0 < \infty$*,* $\zeta > 0$*, and* $P, Q_1 < \infty$ *such that*

$$\begin{aligned} d_*(z,z') &\le C h_*^{-P_0} d_0(z,z')^{\zeta}, \\ \operatorname{diam}(d_*) \le 2, \qquad N(v, d_*) &\le C(1 + L/h_*)^P v^{-Q_1} \quad (0 < v \le 1). \end{aligned} \tag{34.18}$$

At every fixed cutoff, the normalized coefficient or gradient images have continuous compact completions. The constants may depend also on the constants C_q *of the background in item (4); they are independent of the coupling, the cutoff, the separation* $j - i$*, the incoming field, and the finer common mesh.*

Proof. All assertions concern deterministic functions on a fixed conditional fiber, that is, for a fixed incoming field.

We begin with the scales. For the centered linear family, by (34.10) and the operator bound of Lemma 34.2, the rows have size

$$C(\mathfrak{g}_j/h) h^{3/2} (t + h^2)^{-3/4-\iota/2}, \qquad \iota = 0, 1,$$

for the value and the first difference. Multiplication by $(t + a^2)^{(\alpha+\iota)/2}$ gives at most $C\mathfrak{g}_j h^{\alpha-1}$: for $t \le h^2$ we use $t + a^2 \le 2h^2$, and for $t \ge h^2$ the remaining power $t^{\alpha/2-3/4}$ is decreasing. The quadratic coefficient rows of Theorem 26.11 have size $C g_3^2 h^{3/2}(t + h^2)^{-3/4-\iota/2}$; the same two-range calculation, with norm exponent σ or α, gives the two scales of the centered nonlinear heat term. The Hilbert–Schmidt and operator rows of the Duhamel term in Theorem 26.12 contain the factor $t/(t + h^2)$, which vanishes at microscopic times, and give the scale A_{ss} in the norm Y_α^a. None of these steps uses a maximal estimate from those results.

Next we consider the covers. Every input of a coefficient lies on the input lattice of mesh h, which carries at most $C_J(L/h)^3$ scalar coordinates. The derivative bounds of the cardinal interpolation in Lemma 16.3 cost $h^{-\iota}$ at each fixed spatial order ι. We apply the exact shifted product rule of Lemma 24.2 to the source of a quadratic coefficient. Time

derivatives are two physical differences of the smooth input, and the time derivative of a Duhamel term is its source plus its Laplacian, which we commute onto the source. Absolute coefficient rows bound the nuclear norm, hence the Hilbert–Schmidt and operator norms, of these differentiated matrices. In these crude estimates we may even sum over all inputs, since their number is a fixed power of h^{-1}. Thus the derivative bounds cost fixed powers of h^{-1}, keep the coupling prefactor, and contain no inverse volume of the finest mesh. Division by the scale cancels the prefactor. For a weight exponent $0 < \eta \le 1$ we have

$$|(t + a^2)^\eta - (s + a^2)^\eta| \le |t - s|^\eta.$$

Together with the differentiated rows, this gives for each normalized coefficient a modulus $Ch^{-P_0}(\operatorname{dist}(x, y) + |t - s|^\zeta)$ with fixed P_0 and $\zeta > 0$, including at $t = 0$. Different scalar labels are covered by a finite union. Each normalized coefficient has norm at most one, which proves that the diameter is at most two, independently of the modulus.

For the mixed terms of item (4), the deterministic part of Theorem 26.10 and Lemma 26.7 applies with input mesh h and the four differences assumed for the background. It gives the scale $g_3 \mathcal{R} h^{\alpha - 1/2}$, the normalized cover, and the diameter bound. Its two output row bounds are

$$C g_3 \mathcal{R} h \int_0^t (s + h^2)^{-(\alpha+1)/2} (t - s + h^2)^{-\mathfrak{e}}\, ds, \qquad \mathfrak{e} \in \{3/4, 5/4\}. \tag{34.19}$$

These are the deterministic ordered rows of that theorem, in its version for a predictable heat background with four differences. Splitting the integral at h^2 and at $t/2$, we find that the two weights of the norm give the stated scale. In later applications, the background is the signed defect or the field of the preceding level. The signed defect has the required four differences by the bound on $D_a^q P_t^a \mathscr{D}_j$ in the proof of Lemma 34.2, and the inequality

$$(t + H^2)^{\alpha/2} H (t + H^2)^{-1/2} \le H^\alpha \qquad (\alpha < 1)$$

gives the background bound $\mathcal{R} \le C \|\widehat{\theta}_{j-1}\|_\infty H^{\alpha - 1}$ on its two input lattices. The heat equation gives its time increments.

Integrating the bounds on the rows of the reconstruction maps with respect to the fluctuation inputs in Lemma 15.15 along the segment of fluctuation inputs, we obtain $\|\widehat{\theta}_i\|_\infty \le \varrho \|\widehat{\theta}_{i-1}\|_\infty + C \mathfrak{g}_i p_i$. Thus $b_i(v)$ bounds $\|\widehat{\theta}_i\|_\infty$ on the whole conditional fiber. Iterating, and using $p_l \le p_i$ for $l \le i$ and $\varrho \sqrt{B} < 1$, we obtain

$$\|\widehat{\theta}_i\|_\infty \le r \varrho^i + C \sum_{l=1}^{i} \varrho^{i-l} \mathfrak{g}_l p_l \le C \{ r \varrho^i + g_3 \sqrt{\ell_i}\, p_i \}. \tag{34.20}$$

In the last inequality we used $\mathfrak{g}_l = \mathfrak{g}_i B^{(i-l)/2}$, so that the sum is at most $\mathfrak{g}_i p_i \sum_{k \ge 0} (\varrho \sqrt{B})^k$.

For the gradients of item (5) we use the gradient rows and the differentiated gradient rows of Theorem 27.5, without time weights. Their weighted size is the scale of item (5).

The crude differentiated rows there have the prefactor $B_* = C_{\mathrm{CP}}^{2k}\mathfrak{g}_i b_i(v)G^{-2}$ and cost fixed powers of H^{-1}. Since $C_{\mathrm{CP}}^2 = Bq_{\mathrm{anc}}$ and $G = B^k H$, both the coupling and the fiber bound cancel:

$$\frac{B_*}{S} \le C\Big(\frac{q_{\mathrm{anc}}}{\mathfrak{q}}\Big)^k H^{-1}G^{1-2\alpha} \le CH^{-2\alpha}. \tag{34.21}$$

In the last inequality we used $q_{\mathrm{anc}} \le \mathfrak{q}$ and $G^{1-2\alpha} \le H^{1-2\alpha}$, which holds since $G \ge H$ and $\alpha > 1/2$. The factor $(1+j)^c$ in S only decreases this ratio. The supremum over the fiber of the gradient differences therefore has the same polynomial modulus. Each normalized gradient has norm at most one on the whole fiber, and the diameter is at most two. This verifies the increment condition in the gradient metric directly, rather than deducing it from pointwise concentration.

For the gradients of item (6), the deterministic rows without time weights in Theorem 27.7 give the stated scale. Their crude derivatives have the prefactor $CK_{ji}\mathfrak{g}_i b_i(v)$ and cost fixed powers of ℓ_j^{-1}. After division by S their cost is at most $C\ell_j^{-P_0-\sigma}$, since $G \ge \ell_j$. The weight, with exponent $\sigma/2 > 0$, is continuous at time zero. This proves the modulus and the diameter bound for the weighted value process. The norm with first differences is obtained afterwards from the deterministic heat-splitting inequality of Theorem 27.7, and no additional cover is needed.

Finally, a modulus $Ch_*^{-P_0}(\mathrm{dist}(x,y) + |t-s|^{\zeta})$ is covered at radius v by the spatial step $cvh_*^{P_0}$ and the time step $(cvh_*^{P_0})^{1/\zeta}$. If the spatial step is smaller than a, we use every lattice point, whose number is then smaller than the proposed count. Otherwise we choose lattice representatives in spatial cubes; lattice paths between them give the same modulus. The resulting number of points is at most a fixed power of $1 + L/h_*$ times a fixed power of v^{-1}. All the coefficient maps are continuous in time and have finitely many spatial outputs. In the gradient case, since the fiber is compact, the supremum of the gradient norm keeps this continuity. The images therefore have compact completions with countable dense subsets. This proves every claimed cover with the stated dependence of the constants. □

The following lemma controls the zero-fluctuation continuation from any coarse field. It is used for the comparison configuration in the rest of this section, and in Sections 35 and 36, where its holomorphic version gives Cauchy estimates.

Lemma 34.4. *Let θ_0 be a link logarithm on the lattice of mesh $H_0 = L/n$ in the reconstruction domain with $\|\theta_0\|_\infty \le r$, and let $\theta_j = P_j\theta_{j-1}$ for $j \ge 1$. Let x_j and y_j be the flow data of θ_j as in Definition 34.1. For arbitrary compatible prior depths, every $l \ge m \ge 0$, and every compatible common mesh $a \le \ell_l$, the following hold; here compatibility means that the refinement ratios ℓ_i/a, $i \le l$, and the ratios of the intermediate meshes to a are integers.*

1. *We have*

$$\|\theta_j\|_\infty \le r\varrho^j, \qquad \sup_j\big\{\mathsf{X}_\alpha^a(x_j) + \mathsf{Y}_\alpha^a(y_j)\big\} \le R_{\mathrm{cl}}.$$

2. *We have*

$$\mathsf{X}^a_\alpha(x_l - x_m) + \mathsf{Y}^a_\alpha(y_l - y_m) \le C(1+m)^c \vartheta^m, \qquad \vartheta = \max\{\varrho B^{1-\alpha}, \mathfrak{q}\} < 1.$$

3. *There exist radii $r < r_1 < r_2$, fixed together with the working ball, such that the maps $\theta_0 \mapsto \theta_j, x_j, y_j$ extend holomorphically to the polydisc $\mathbb{D}_{r_2}$ of complex link logarithms θ_0 whose $D = 9n^3$ real coordinates are complexified with modulus less than r_2, and, with the norms applied to complex arrays,*

$$\sup_{\theta_0 \in \mathbb{D}_{r_2}} \left\{ \mathsf{X}^a_\alpha(x_j) + \mathsf{Y}^a_\alpha(y_j) \right\} \le C,$$
$$\sup_{\theta_0 \in \mathbb{D}_{r_2}} \left\{ \mathsf{X}^a_\alpha(x_l - x_m) + \mathsf{Y}^a_\alpha(y_l - y_m) \right\} \le C(1+m)^c \vartheta^m.$$

Write $x_j(\theta_0) = \sum_\mu f_{j,\mu} \theta_0^\mu$ and $y_j(\theta_0) = \sum_\mu h_{j,\mu} \theta_0^\mu$ for the Taylor expansions at zero in these D coordinates. Then

$$\sum_\mu r_1^{|\mu|} \left\{ \mathsf{X}^a_\alpha(f_{j,\mu}) + \mathsf{Y}^a_\alpha(h_{j,\mu}) \right\} \le C,$$
$$\sum_\mu r_1^{|\mu|} \left\{ \mathsf{X}^a_\alpha(f_{l,\mu} - f_{m,\mu}) + \mathsf{Y}^a_\alpha(h_{l,\mu} - h_{m,\mu}) \right\} \le C(1+m)^c \vartheta^m.$$

These bounds are uniform in the prior depths, the length of the continuation, and the compatible common mesh, and the constants may depend in addition on r_1 and r_2. If $\theta_0 = F(u)$ is the image of a parameter u under a fixed finite-scale reconstruction F, the same assertions hold on a complex neighborhood of the real parameters that may depend on F, but not on the length l of the continuation.

The constants R_{cl}, C, c depend on H_0, r, and the data of item (6) of Definition 4.14, and are independent of the coupling and of the length of the sequence.

Proof. We begin with item (1) and the first component in item (2). Since $P_j(0) = 0$, integrating DP_j along the segment from 0 to v, we obtain $\|P_j v\|_\infty \le \varrho \|v\|_\infty$. Thus $b_j = r\varrho^j$ bounds the sequence. Its increments split as $d_j^0 = r_j^0 + u_j^{\mathrm{cl},0}$, with no conditional mean, and

$$\mathsf{X}^a_\alpha(r_j^0) \le C b_{j-1} \ell_{j-1}^{\alpha-1}, \qquad \mathsf{H}^a_\sigma(u_j^{\mathrm{cl},0}(0)) \le C b_{j-1}^2 / \ell_{j-1}. \tag{34.22}$$

The first inequality is (34.11). The second follows from the series of P_j in degrees at least two and from item (5) of Lemma 34.2. The two geometric ratios are $\varrho B^{1-\alpha} < 1$ and $B\varrho^2 = \mathfrak{q} < 1$. The initial field x_0 has bounded norm $\mathsf{X}^a_\alpha(x_0)$ by (34.9). Summing these bounds, and using the inequality $\mathsf{X}^a_\alpha(P^a_\cdot f) \le C \mathsf{H}^a_\sigma(f)$ (which holds since $\sigma < \alpha$ and T is finite) for the terms $u_j^{\mathrm{cl},0}$, we find the uniform bound on $\mathsf{X}^a_\alpha(x_j)$ and the tail $\mathsf{X}^a_\alpha(x_l - x_m) \le C\vartheta^m$.

We now turn to the quadratic component. We fix one of the three ordered forms and denote it by $T_{j,i}$. Its coefficient norm with output in Y^a_α is at most $C(1+j)^c K_{ji}$. By the pullback identity (34.3), we have the finite identity

$$\begin{aligned} T_{j,j-1}(\theta_{j-1},\theta_{j-1}) &= T_{j,0}(\theta_0,\theta_0) \\ &\quad + \sum_{i=1}^{j-1} \big\{ T_{j,i}(P_i\theta_{i-1}, P_i\theta_{i-1}) - T_{j,i}(L_i\theta_{i-1}, L_i\theta_{i-1}) \big\}. \end{aligned} \tag{34.23}$$

Here $P_i - L_i$ starts at degree two. The coefficientwise majorant series gives $\|P_i v - L_i v\| \le C\varrho\|v\|^2$ and $\|P_i v\| + \|L_i v\| \le C\varrho\|v\|$ on the working ball. By (34.4) and the coefficient bound, we have

$$\mathsf{Y}^a_\alpha\big(T_{j,j-1}(\theta_{j-1},\theta_{j-1})\big) \le C(1+j)^c \Big\{ \frac{r^2 \mathfrak{q}^{j-1}}{H_0} + \sum_{i=1}^{j-1} \frac{\mathfrak{q}^{j-1-i}}{\ell_i} b_{i-1}^3 \Big\}. \tag{34.24}$$

The sum is at most $Cr^3 H_0^{-1}\mathfrak{q}^{j-1}$. Indeed, since $\ell_i^{-1} = H_0^{-1}B^i$ and $\mathfrak{q} = B\varrho^2$, its i-th term divided by $\mathfrak{q}^{j-1}$ is $H_0^{-1} r^3 \varrho^{i-3}$; the factor ϱ^{-3} is fixed and $\sum_{i\ge 1}\varrho^i$ is finite.

By (34.2) for the continuation, $\mathcal{Q}_a(r_j^0, r_j^0)$, $\mathcal{Q}_a(x_{j-1}, r_j^0)$, and $\mathcal{Q}_a(r_j^0, x_{j-1})$ are T^{VV}, $T^{\mathsf{UV}} - T^{\mathsf{VV}}$, and $T^{\mathsf{VU}} - T^{\mathsf{VV}}$ at $(\theta_{j-1},\theta_{j-1})$. Applying (34.24) to each order gives summable bounds for these three terms. Every remaining term of

$$y_l - y_m = \sum_{j=m+1}^{l} \big\{ \mathcal{Q}_a(x_{j-1}, d_j^0) + \mathcal{Q}_a(d_j^0, x_{j-1}) + \mathcal{Q}_a(d_j^0, d_j^0) \big\}$$

contains $u_j^{\mathrm{cl},0}$ as one argument. We apply the two ordered inequalities (34.6), using the bounded norms $\mathsf{X}^a_\alpha(x_j)$ just proved and (34.22). Their total tail is $C(1+m)^c\mathfrak{q}^m$ by (34.15), and the three forms above contribute at most $C(1+m)^c\mathfrak{q}^m$ as well. The initial term y_0 also has a fixed bound: its smooth cardinal input has bounded values and first two differences. Heat contraction and the stencil of the quadratic term, which contains a single difference, then bound its Duhamel value and its first difference on $[0,T]$. This proves the bound R_{cl} and both tails.

For item (3), we note that the argument above uses only absolute values of coefficients. The coefficientwise majorant series of Lemma 15.15, evaluated on a slightly larger polydisc of complex inputs still inside the working domain, gives the same bounds for complex inputs. Indeed, by the strict choice of the working radius, its derivative series is bounded by ϱ there. No positivity of a real field was used in (34.23). The quadratic coefficient bounds include the volume-normalized columns and all output differences, and every absolute sum above remains valid. Since r is smaller than a fixed fraction of the working radius, we may choose $r < r_1 < r_2$ such that $\mathbb{D}_{r_2}$ lies inside that larger polydisc, independently of the subsequent number of steps. This proves the two bounds

on $\mathbb{D}_{r_2}$, with r replaced by a multiple of r_2 in the constants. For the Taylor coefficients we apply the Cauchy estimates in each of the D coordinates on $\mathbb{D}_{r_2}$: for a holomorphic map g with values in a normed space and $\sup_{\theta_0\in\mathbb{D}_{r_2}}\|g(\theta_0)\|\le A$, its Taylor coefficients satisfy $\|g_\mu\|\le Ar_2^{-|\mu|}$. Summing, we find

$$\sum_{\mu} r_1^{|\mu|}\|g_\mu\| \le A\sum_{\mu}(r_1/r_2)^{|\mu|} = A(1-r_1/r_2)^{-D}.$$

Applied to x_j, y_j, and the differences x_l-x_m, y_l-y_m in the norms X^a_α and Y^a_α, this gives the coefficient bounds, with the fixed factor $(1-r_1/r_2)^{-D}$. For a fixed finite-scale input, we first take a complex neighborhood whose image under the fixed finite reconstruction has positive distance from the boundary of the working domain, and then apply this argument to the composed map. This proves item (3). □

The chaining estimate we use is the following specialization of Lemma 16.4.

Lemma 34.5. *Let $(F_z)_{z\in\mathcal{T}}$ be a centered real process indexed by a compact pseudometric space $(\mathcal{T},d_*)$, continuous in d_* at each fixed cutoff. Let $z_0\in\mathcal{T}$, $A>0$, and $c_0>0$, and suppose that one of the following two sets of conditions holds for every $u>0$ and $z,z'\in\mathcal{T}$:*

1. *$\mathbb{P}(|F_z-F_{z'}|>Ad_*(z,z')u)\le 2e^{-u^2/c_0}$ and $\mathbb{P}(|F_{z_0}|>Au)\le 2e^{-u^2/c_0}$;*
2. *$\mathbb{P}(|F_z-F_{z'}|>Ad_*(z,z')(\sqrt{u}+u))\le 2e^{-u/c_0}$ and $\mathbb{P}(|F_{z_0}|>A(\sqrt{u}+u))\le 2e^{-u/c_0}$.*

Assume that for some $H>0$

$$\operatorname{diam}(\mathcal{T},d_*)\le C_0,\qquad N(v,d_*)\le C(1+L/H)^P v^{-Q_0}\quad(0<v\le 1).$$

Then for every $1\le p<\infty$,

$$\Big\|\sup_z|F_z|\Big\|_{L^p}\le C_pA\sqrt{1+\log(2+L/H)}$$

under the conditions (1), and

$$\Big\|\sup_z|F_z|\Big\|_{L^p}\le C_pA\big[1+\log(2+L/H)\big]$$

under the conditions (2). Here C_p depends only on p,c_0,C_0,C,P,Q_0. The same holds under a conditional probability kernel when the hypotheses hold for each fixed value of the conditioning variables.

By Lemma 34.3, the normalized coefficient metrics for linear rows, for quadratic rows (with the maximum of the Hilbert–Schmidt and operator distances), and for gradients have diameter at most two and covering numbers of this form at their input mesh.

Proof. We apply Lemma 16.4 with the metric d_*, the diameter bound C_0, the cover prefactor $C(1+L/H)^P$, and the exponent Q_0. Under the conditions (1) we take $s = A\sqrt{c_0}$ and $b = 0$ in that lemma, and under the conditions (2) we take $s = A\sqrt{c_0}$ and $b = Ac_0$. These choices correspond to the substitutions $u = \sqrt{c_0 v}$ and $u = c_0 v$ in the two tails, which turn them into the form $\mathbb{P}\{|F_z - F_{z'}| > d_*(z,z')(s\sqrt{v} + bv)\} \le 2e^{-v}$ required there. The conditions at the reference point z_0 take the same form. Since

$$\log\bigl(2C(1+L/H)^P\bigr) + Q_0 \le C'\bigl[1 + \log(2 + L/H)\bigr],$$

the moment bound of Lemma 16.4 implies the two stated bounds, with the stated dependence of the constants. The conditional version is the corresponding clause of that lemma. □

Lemma 34.6. *We have $p_j \le C(1 + j + |\log\gamma|)$. Further, for every $\varepsilon > 0$ and $d \ge 0$,*

$$\sup_{0<\gamma\le\gamma_0} \gamma^{\varepsilon} p_j^d \le C_{\varepsilon,d}(1+j)^d,$$

where $C_{\varepsilon,d}$ depends in addition on ε and d.

In every later application a logarithm of the coupling is absorbed in this way only together with a positive power of γ.

Proof. By the definition of t_j, we have

$$p_j = \frac{A_{\mathrm{w}}}{2}\bigl\{\log(n/\gamma) + j\log B - (J-1)\log M\bigr\},$$

which proves the first bound. Since $\gamma \le 1$, we may write $v = |\log\gamma|$. For any $d \ge 0$ we have $(1+j+v)^d \le (1+j)^d(1+v)^d$, and $\sup_{v\ge0} e^{-\varepsilon v}(1+v)^d < \infty$, as one sees from the logarithmic derivative $-\varepsilon + d/(1+v)$ of the last function. This proves the second bound. □

34.3 Conditional bounds uniform in the coupling

We now bound the four parts of a reconstruction increment, conditionally on the preceding levels and with constants independent of γ. The leading terms carry no factor $|\log\gamma|$: the logarithm of the coupling enters only through the cutoff radii p_j, in terms of higher order in g_3. The theorem also bounds the quadratic forms pulled back to earlier levels and the conditional means in the predictable term. For $1 \le i \le j-1$ we write

$$Z^{\omega}_{j,i} = T^{\omega}_{j,i}(\widehat{\theta}_i, \widehat{\theta}_i) - \mathbb{E}\bigl[T^{\omega}_{j,i}(\widehat{\theta}_i, \widehat{\theta}_i) \mid \mathcal{F}_{i-1}\bigr], \qquad F_{j,i} = S_{j,i}(\widehat{\theta}_i, \widehat{\theta}_i) - \mathbb{E}\bigl[S_{j,i}(\widehat{\theta}_i, \widehat{\theta}_i) \mid \mathcal{F}_{i-1}\bigr]$$

for the centered pulled-back forms, and

$$e^{\omega}_{j,i} = \mathbb{E}\bigl[T^{\omega}_{j,i}(\widehat{\theta}_i, \widehat{\theta}_i) \mid \mathcal{F}_{i-1}\bigr] - T^{\omega}_{j,i-1}(\widehat{\theta}_{i-1}, \widehat{\theta}_{i-1})$$

for the conditional drifts, with the analogous drift $e^{S}_{j,i}$ for the quadratic initial forms. By (34.3), the drift $e^{\omega}_{j,i}$ is the sum of the classical part $T^{\omega}_{j,i}(P_i v, P_i v) - T^{\omega}_{j,i}(L_i v, L_i v)$ at $v = \widehat{\theta}_{i-1}$ and of the conditional-mean part $\mathbb{E}[T^{\omega}_{j,i}(\widehat{\theta}_i, \widehat{\theta}_i) \mid \mathcal{F}_{i-1}] - T^{\omega}_{j,i}(P_i v, P_i v)$.

Theorem 34.7. *Assume the setting of Definition 34.1. For every fixed $1 \le p < \infty$, all $K \ge j \ge 1$, every incoming field $\widehat{\theta}_{j-1}$ in the reconstruction domain, and every finer common mesh $a \le \ell_j$, the following conditional estimates hold. Let $h = \ell_j$ and let $\mathcal{Z}_j$ be the initial value of z_j. Then*

$$\big\|\mathsf{X}^a_\alpha(s_j)\big\|_{L^p(\cdot|\mathcal{F}_{j-1})} \le C\mathfrak{g}_j h^{\alpha-1}\big[\sqrt{\log(2+L/h)} + \sqrt{p}\big],$$

$$\big\|\mathsf{H}^a_\sigma(\mathcal{Z}_j)\big\|_{L^p(\cdot|\mathcal{F}_{j-1})} \le C_p\big\{g_3^2 h^{\sigma}(1+j) + g_3^3 h^{1/2} p_j^3\big\},$$

$$\big\|\mathsf{X}^a_\alpha(z_j)\big\|_{L^p(\cdot|\mathcal{F}_{j-1})} \le C_p\big\{g_3^2 h^{\alpha}(1+j) + g_3^3 h^{1/2} p_j^3\big\}.$$

The centered part of $\mathcal{Q}_a(s_j, s_j)$ has conditional $L^p(\mathsf{Y}^a_\alpha)$ norm at most $C_p g_3^2 h^{2\alpha-1}(1+j)$, and its conditional mean has norm Y^a_α at most $C_p g_3^2 \|\widehat{\theta}_{j-1}\|_\infty$. Fix constants $C_0, \dots, C_4 < \infty$, independently of the coupling, the level indices, and the common mesh. Let b be an $\mathcal{F}_{j-1}$-measurable heat path on the lattice of mesh a such that, for $0 \le q \le 4$ and $0 \le t \le T$,

$$\|D_a^q b(t)\|_\infty \le C_q \mathcal{R}(t + \ell_j^2)^{-(\alpha+q)/2}.$$

Then each of the two ordered terms $\mathcal{Q}_a(b, s_j)$ and $\mathcal{Q}_a(s_j, b)$ has conditional $L^p(\mathsf{Y}^a_\alpha)$ norm at most $C_p g_3 h^{\alpha-1/2}(1+j)^c \mathcal{R}$. The constant in this mixed estimate may also depend on $C_0, \dots, C_4$.

For each ω separately, each $1 \le i \le j-1$, and the incoming field $v = \widehat{\theta}_{i-1}$, put $b_i(v) = C_J(a_{\mathrm{map}}\|v\|_\infty + \mathfrak{g}_i p_i)$. Then

$$\big\|\mathsf{Y}^a_\alpha(Z^{\omega}_{j,i})\big\|_{L^p(\cdot|\mathcal{F}_{i-1})} \le C_p(1+j)^c \mathfrak{q}^{j-1-i} \mathfrak{g}_i b_i(v) \ell_i^{2\alpha-2},$$

$$\big\|\mathsf{H}^a_\sigma(F_{j,i})\big\|_{L^p(\cdot|\mathcal{F}_{i-1})} \le C_p(1+j)^c \frac{\mathfrak{q}^{j-1-i}}{\ell_i} \mathfrak{g}_i b_i(v) \ell_i^{\sigma}.$$

The deterministic bound $b_i \le C\{r a^i_{\mathrm{map}} + g_3\sqrt{\ell_i}\, p_i\}$ holds. The conditional drifts satisfy

$$\mathsf{Y}^a_\alpha(e^{\omega}_{j,i}) + \mathsf{H}^a_\sigma(e^{S}_{j,i}) \le C(1+j)^c \frac{\mathfrak{q}^{j-1-i}}{\ell_i}\big\{a_{\mathrm{map}}^2 b_{i-1}^3 + \mathfrak{g}_i^2 b_{i-1} + \mathfrak{g}_i^3 p_i^3\big\},$$

and their conditional-mean parts are bounded by the last two terms alone. All norms include every required first difference and Wilson shift. Further, there exist $c, \epsilon > 0$ such that for every $z > 0$,

$$\sup_{0<\gamma\le\gamma_0} \sup_{K\ge m} \nu\big\{\mathsf{X}^a_\alpha(x_K - x_m) + \mathsf{Y}^a_\alpha(y_K - y_m) > z\big\} \le C_z(1+m)^c B^{-\epsilon m}.$$

In particular this tail tends to zero in the order $K \to \infty$, then $\gamma \to 0$, then $m \to \infty$.

Here C_p depends in addition on p, and C_z on z; no factor $\log(1/t_j)$ is hidden in the leading constants.

Proof. The proof has six steps. We first check that the concentration estimates of Theorem 5.4 apply to the conditional kernels. We combine them with the covers of Lemma 34.3 to bound the centered linear and quadratic terms, and we treat the remainder of higher degree and the conditional means separately. Finally, we sum over levels with explicit powers of ℓ_i and estimate the products in the bilinear expansion (34.5).

Step 1: concentration. All coefficient estimates are evaluated on the larger fixed domain, and only then restricted to a fixed incoming field. The conditional potential of the fluctuation variables is C^2 on a neighborhood of its convex product of balls. The Hessian condition of Theorem 23.2 implies that its Hessian is bounded below there by a fixed $m_* > 0$: the perturbation of the identity Hessian of the normalized variables is at most $8/27$. Then Theorem 5.4 applies with one constant m_*, independently of the radii of the balls, of the dimension, and of the prior depth.

Step 2: coefficient metrics and conditional maxima. We use Lemma 34.3 with $h = \ell_j$ and with its parameters for the pulled-back forms, followed by Theorem 5.4. Note that a difference of coefficient rows is linear in the centered vector ζ_j, and a difference of coefficient matrices is quadratic in it. By the Lipschitz concentration and the quadratic estimate of Theorem 5.4, their increments satisfy the tail conditions (1) and (2) of Lemma 34.5, respectively, with $A = CS$, where S is the scale. For the gradients of a nonlinear function of the fluctuation variables we have

$$\operatorname{Lip}_w(F_z - F_{z'}) \le S d_*(z, z'), \qquad (F_z - \mathbb{E}F_z) - (F_{z'} - \mathbb{E}F_{z'}) = (F_z - F_{z'}) - \mathbb{E}(F_z - F_{z'}).$$

The Lipschitz concentration bound therefore applies to this difference, and also at the reference point of the chaining, with scale CS. This proves the increment conditions under the conditional fluctuation kernel. The continuity required in the gradient metric also follows directly: for $g = F_z - F_{z'}$ on the convex finite fiber Ω with conditional law μ, we have

$$|g(w) - \mathbb{E}g| \le \int_\Omega |g(w) - g(v')|\, d\mu(v') \le \operatorname{diam}(\Omega)\, S d_*(z, z').$$

The diameter of Ω is used only for continuity at a fixed cutoff, never in the constant of a maximal bound. The linear and quadratic coefficient images have the same continuity by the Cauchy–Schwarz inequality in finite dimension, applied to their centered evaluations. This verifies the countable separable realization required for chaining. Lemma 16.4, applied as in the proof of Lemma 34.5 but keeping track of the moment order, gives the losses

$$C\big[\sqrt{\log(2 + L/h_*)} + \sqrt{p}\big] \qquad \text{and} \qquad C\big[\log(2 + L/h_*) + p\big]$$

for linear and quadratic rows, respectively. Since $\log(2 + L/\ell_j) \le C(1+j)$, these losses imply the first bound of the theorem, the quadratic parts of the bounds on $\mathcal{Z}_j$ and z_j, the bound on the centered part of $\mathcal{Q}_a(s_j, s_j)$, the bound on the mixed terms with the background condition of item (4) of Lemma 34.3, and the bounds on $Z^{\omega}_{j,i}$ and $F_{j,i}$. For the last two, the scales of items (5) and (6) of that lemma are $C(1+j)^c \mathfrak{q}^{j-1-i} \mathfrak{g}_i b_i(v) \ell_i^{2\alpha-2}$ and $C\mathfrak{q}^{j-1-i}\ell_i^{-1}\mathfrak{g}_i b_i(v)\ell_i^{\sigma}$, since $K_{ji} = \mathfrak{q}^{j-1-i}/\ell_i$ and $G = \ell_i$.

Step 3: higher-degree remainder, conditional means, and first differences. The centered remainder of degree at least three in the fluctuation variables has supremum norm at most $C g_3^3 h^{1/2} p_j^3$ by Theorem 26.11, and the heat-splitting inequality of Theorem 27.7 bounds its first difference. The conditional mean of $\mathcal{Q}_a(s_j, s_j)$ is the mean in Theorem 26.12, which is at most $C g_3^2 \|\widehat{\theta}_{j-1}\|_\infty$ in the norm Y^a_α.

To verify that the bound on $\mathcal{Z}_j$ holds in the norm H^a_σ, which includes first differences, let f be an initial array. If $t \ge a^2$, we have

$$\|D_a P^a_t f\|_\infty \le C t^{-1/2} \|P^a_{t/2} f\|_\infty \le C t^{-(\sigma+1)/2} \mathsf{V}^a_\sigma(f).$$

If $t \le a^2$, we use $\|f\|_\infty \le a^{-\sigma}\mathsf{V}^a_\sigma(f)$ and $\|D_a P^a_t\|_{\infty\to\infty} \le C/a$. Multiplication by $(t + a^2)^{(\sigma+1)/2}$ cancels these factors. This proves $\mathsf{H}^a_\sigma(f) \le C\mathsf{V}^a_\sigma(f)$, uniformly in the finer mesh, and we apply it to the centered initial field.

Step 4: the conditional drifts. The splitting of the conditional drift into its classical part and its conditional-mean part is given in Theorem 27.5 for the ordered forms and in Theorem 27.7 for the quadratic initial forms. Its three bounds are

$$C(1+j)^c K_{ji}\big(\varrho^2 b_{i-1}^3 + \mathfrak{g}_i^2 b_{i-1} + \mathfrak{g}_i^3 p_i^3\big).$$

The first term bounds the classical part, which is the error of the zero-fluctuation pullback. The last two terms bound the conditional-mean part, which contains the conditional mean of the fluctuation variables and the covariance correction.

Step 5: summation over levels. We record the powers of the mesh needed to check summability. Fixed powers of H_0 are included in C. Using (34.20), $\varrho^i = (\ell_i/H_0)^\kappa$, and $\mathfrak{g}_i = g_3\sqrt{\ell_i}$, we find that the centered pulled-back bounds and the conditional drifts split before the convolution in $\mathfrak{q}$ as

$$\begin{aligned}
\mathfrak{g}_i b_i \ell_i^{2\alpha-2} &\le C\big\{g_3 r \ell_i^{\kappa+2\alpha-3/2} + g_3^2 \ell_i^{2\alpha-1} p_i\big\},\\
\mathfrak{g}_i b_i \ell_i^{\sigma-1} &\le C\big\{g_3 r \ell_i^{\kappa+\sigma-1/2} + g_3^2 \ell_i^{\sigma} p_i\big\},\\
\frac{\varrho^2 b_{i-1}^3 + \mathfrak{g}_i^2 b_{i-1} + \mathfrak{g}_i^3 p_i^3}{\ell_i} &\le C\big\{r^3 \ell_i^{3\kappa-1} + g_3^2 r \ell_i^{\kappa} + g_3^3 \ell_i^{1/2}(p_i+1)^3\big\}.
\end{aligned}$$

In the last line we used $(u+v)^3 \le 4(u^3+v^3)$. Every exponent of ℓ_i is positive.

The initial value of the predictable term decomposes as $u_j(0) = S_{j,j-1}(\widehat{\theta}_{j-1}, \widehat{\theta}_{j-1}) + V_j(\widehat{\theta}_{j-1}) + I_{\ell_j \to a} m_j^{\mathrm{ph}}(\widehat{\theta}_{j-1})$, and telescoping the first term by (34.3), we obtain

$$S_{j,j-1}(\widehat{\theta}_{j-1}, \widehat{\theta}_{j-1}) = S_{j,0}(\widehat{\theta}_0, \widehat{\theta}_0) + \sum_{i=1}^{j-1} (F_{j,i} + e_{j,i}^S).$$

The initial term is at most $Cr^2(1+j)^c \mathfrak{q}^{j-1}/H_0$. The other two terms of $u_j(0)$ are bounded by (34.12) and (34.13), and their bounds have the same powers as the third line above. Combining the chaining bounds of Step 2, the absorption of the logarithms of the coupling by Lemma 34.6, and the convolution bound (34.16), we obtain $\tau > 0$, a finite b, and constants independent of the coupling such that

$$\|\mathsf{H}_\sigma^a(u_j(0))\|_p + \|\mathsf{X}_\alpha^a(u_j)\|_p \le C_p (1+j)^b B^{-\tau j}. \tag{34.25}$$

For instance, we may take τ strictly below $\min(\sigma, 1/2, \lambda, \kappa + \sigma - 1/2)$ and reduce it for the finitely many other positive exponents listed above. The bound on $\mathsf{X}_\alpha^a(u_j)$ follows from the one on $\mathsf{H}_\sigma^a(u_j(0))$, since $\mathsf{X}_\alpha^a(P_\cdot^a f) \le C\mathsf{H}_\sigma^a(f)$. All fixed moments follow from the conditional bounds by the conditional Minkowski inequality and then the ordinary Minkowski inequality under ν.

Combining the bounds on s_j and z_j with (34.11), (34.20), and (34.25), we find

$$\sup_{K,j} \|\mathsf{X}_\alpha^a(x_j)\|_p \le C_p, \qquad \Big\| \mathsf{X}_\alpha^a\Big(\sum_{j>m} d_j \Big) \Big\|_p \le C_p (1+m)^b B^{-\tau_1 m} \tag{34.26}$$

for some $\tau_1 > 0$. Here the bound on s_j is of order $g_3 \ell_j^{\alpha - 1/2} \sqrt{1+j}$, the bound on r_j is $CH^{\alpha-1}\|\widehat{\theta}_{j-1}\|_\infty$ with $H = \ell_{j-1}$, and the initial field costs only $C_{H_0} r$. The correction in (34.14) also has bounded fixed moments: by (34.20) its powers of ℓ_{j-1} are $\kappa + \alpha - 1 > 0$ and $\alpha - 1/2 > 0$, with positive powers of the coupling on every remaining factor p_{j-1}.

Step 6: products and the probability tail. We now bound $y_K - y_m$ through (34.5), following the second column of Table 34.2. We write S_j for the bound on $\mathsf{X}_\alpha^a(s_j)$, Z_j^- and Z_j^+ for the bounds on $\mathsf{H}_\sigma^a(\mathcal{Z}_j)$ and $\mathsf{X}_\alpha^a(z_j)$, R_j for the bound on $\mathsf{X}_\alpha^a(r_j)$ given by (34.11), and U_j for the bound in (34.25), always using moments of order $2p$ in a product. Up to a fixed factor, the sixteen ordered products $\mathcal{Q}_a(v_j, w_j)$, with v indexing rows and w indexing columns, are bounded in $L^p(\mathsf{Y}_\alpha^a)$ by the entries of

	s	z	r	u
s	F_j	$S_j Z_j^-$	$S_j R_j$	$S_j U_j$
z	$S_j Z_j^-$	$Z_j^+ Z_j^-$	$R_j Z_j^-$	$U_j Z_j^-$
r	$R_j S_j$	$R_j Z_j^-$	W_j	$R_j U_j$
u	$U_j S_j$	$U_j Z_j^-$	$R_j U_j$	U_j^2

Here $F_j = C_p g_3^2[\ell_j^{2\alpha-1}(1+j)+b_{j-1}]$ includes the conditional mean of $\mathcal{Q}_a(s_j,s_j)$, and W_j is the bound on $\mathsf{Y}_\alpha^a(T^{\mathsf{VV}}_{j,j-1}(\widehat\theta_{j-1},\widehat\theta_{j-1}))$ obtained by telescoping as above: the initial term, the centered terms $Z^{\mathsf{VV}}_{j,i}$, and both the classical and the conditional-mean parts of the conditional drifts $e^{\mathsf{VV}}_{j,i}$. The entries with z or u use (34.6) and Hölder's inequality under ν. The entries (s,r) and (r,s) use (34.19), conditionally on $\mathcal{F}_{j-1}$, with the predictable background r_j, which has the four differences required there and $\mathcal{R}\le CR_j$. The entry (r,r) is the form T^{VV}, not a difference of uncontrolled forms. Thus every entry is justified in L^p. The slowest powers of ℓ_j that occur include $2\alpha-1$, $\kappa+2\alpha-3/2$, $\kappa+\alpha+\sigma-1$, and $\sigma+\alpha-1/2$; the entries with u also keep the decay $B^{-\tau j}$. All these exponents are positive. The parts of degree at least three in the fluctuation variables carry an additional factor $\ell_j^{1/2}$ and create no smaller exponent.

For the eight cross terms with x_{j-1}, we use (34.19) and the bounded norm (34.14) of x_{j-1} at its input mesh for s; (34.6) and Z_j^- for z; the forms $T^{\mathsf{UV}}-T^{\mathsf{VV}}$ and $T^{\mathsf{VU}}-T^{\mathsf{VV}}$ of (34.2) for r; and (34.6) with (34.25) and (34.26) for u. This covers both orders of all four arguments. By (34.15) and (34.16), the sums over $j>m$ of these bounds and of the sixteen products are at most $C_p(1+m)^b B^{-\epsilon m}$ for some smaller $\epsilon>0$. The expansion (34.5) then bounds $\|\mathsf{Y}_\alpha^a(y_K-y_m)\|_p$ by the same expression. By Markov's inequality and (34.26), we obtain the probability tail, after enlarging C_z to cover the finitely many small indices. □

34.4 The initial gauge frame along the flow

A based holonomy transforms by conjugation at its basepoint. Two configurations evolved with independent time-dependent gauge transformations can therefore have holonomies with equal traces but very different matrices. The Wilson flow is analyzed in a damped gauge, in which its linear part is the heat equation. The damping gauge transformations solve an ordinary differential equation started at the identity, and the difference of their generators is integrable in time uniformly in the mesh. Hence the holonomy matrices of two configurations that start in the same frame can be compared directly. We use the following form of Theorem 25.10.

Remark 34.8. Fix $R<\infty$, $0<t_-\le t_+\le T$, and finitely many based piecewise C^1 loops $\mathsf{c}_1,\dots,\mathsf{c}_k$ with lattice approximations $\mathsf{c}_{i,a}$ of uniformly bounded physical length. Let $U=e^{aA_0}$ and $U'=e^{aA_0'}$ be two configurations on the same lattice of mesh $a=L/N$, in the reconstruction domain and represented in the same initial vertex and basepoint frame, whose flow data (x,y) and (x',y') on $[0,T]$ have norms $\mathsf{X}_\alpha^a+\mathsf{Y}_\alpha^a$ at most R. Let $\mathcal{D}=\mathsf{X}_\alpha^a(x-x')+\mathsf{Y}_\alpha^a(y-y')$. By Theorem 25.10, applied with radius $\max(1,R)$ and input horizon T, there exists a flow stability constant $\Lambda_{R,t_-,T}<\infty$ such that

$$\sup_{t_-\le t\le t_+}\max_i\big\|\mathrm{Hol}_{\mathsf{c}_{i,a}}\Psi_t^{(N)}(U)-\mathrm{Hol}_{\mathsf{c}_{i,a}}\Psi_t^{(N)}(U')\big\|_{\mathrm{op}}\le\Lambda_{R,t_-,T}\,\mathcal{D},$$

where $\Psi_t^{(N)}$ is the Wilson flow run for the lattice flow time $4t/a^2$. The constant depends only on R, t_-, T, the loops, the fixed analytic domains, and the margins of the reference neighborhoods of the continuum flow in Theorem 24.10, with the dependence described in item (7) of Definition 4.14; it is independent of the mesh, the prior depth, and the coupling, and it covers the finitely many meshes that are too coarse for the small-mesh condition of the local theory. Let T_R and a_R be the constants of Theorem 24.5 for radius $\max(1, R)$, and put $h_R = \min(T_R, T)$. After decreasing a_R if necessary, for $a \le a_R$ and $0 \le s \le h_R$ the damped potentials A, A' and their damping gauge transformations k, k', with $k(0) = k'(0) = I$, satisfy the following estimates, where $v_a(s) = s + a^2$.

$$\|D_a(A - A')(s)\|_\infty \le C_R \mathcal{D}\{v_a(s)^{-(\alpha+1)/2} + v_a(s)^{-\alpha} + v_a(s)^{\kappa_{\mathrm{fl}}-1/2}\},$$

$$\|k(s, x_0) - k'(s, x_0)\|_{\mathrm{op}} \le C \int_0^s \|D_a(A - A')(u)\|_\infty \, du \le C_R \mathcal{D}.$$

The three powers of $v_a(s)$ are integrable at zero uniformly in the mesh, since $(\alpha+1)/2 < 1$, $\alpha < 1$, and $1/2 - \kappa_{\mathrm{fl}} < 1$. For $a \le a_*$ and $\mathcal{D} \le \delta$, with a_* and δ supplied by Lemma 25.9 with $T_0 = T$ and $\tau = t_-$, both flows can use a common reference solution and the same fixed restarts on the later intervals. For other pairs or meshes, the matrix inequality follows from the unitary diameter bound or the finite-dimensional Wilson flow, as in Theorem 25.10. All matrices are expressed in their initial frames; no conjugation of either matrix is optimized.

34.5 Comparison of linear and quadratic flow data

We now compare the flow data of the reconstruction with those of its zero-fluctuation continuation after level m. The comparison is exact on the finest lattice: both fields are interpolated by the identity there, and no interpolation error enters at level K. The two fields agree at level m.

Theorem 34.9. *Assume the setting of Definition 34.1. For every fixed $p \ge 1$ and all $K \ge j \ge m \ge 0$, under the conditioned Wilson measure ν,*

$$\big\| \|\widehat{\theta}_j - \widehat{\theta}_j^0\|_\infty \big\|_p \le C_p \mathfrak{g}_j (1+j)^{1/2}, \qquad \big\| \|\widehat{\theta}_j\|_\infty \big\|_p \le C_p \{ r a_{\mathrm{map}}^j + \mathfrak{g}_j (1+j)^{1/2} \}.$$

On the finest lattice, writing $\Delta x_j = x_j - x_j^0$, we have

$$\Delta x_K = \sum_{j=m+1}^{K} (d_j - d_j^0), \qquad y_K - y_K^0 = \sum_{j=m+1}^{K} \big(y_j - y_{j-1} - y_j^0 + y_{j-1}^0\big).$$

For each ordered form $T_{j,i}^\omega$ and each quadratic initial form $S_{j,i}$, the pullback (34.3) *is exact. In particular, with $L_i = DP_i(0)$, the function*

$$R_{j,i}^\omega(v) = T_{j,i}^\omega(P_i v, P_i v) - T_{j,i}^\omega(L_i v, L_i v)$$

has degree at least three and, on the working ball,

$$\mathsf{Y}^a_\alpha\big(R^\omega_{j,i}(v)-R^\omega_{j,i}(v')\big)\le C(1+j)^c\,\frac{\mathfrak{q}^{\,j-1-i}}{\ell_i}\big(\|v\|_\infty+\|v'\|_\infty\big)^2\|v-v'\|_\infty.$$

The corresponding estimate for the quadratic initial forms holds in the full initial-array norm H^a_σ. *There exist* $s>0$ *and* $c,d<\infty$, *independent of* K, m, *and* γ, *such that for every fixed* $p\ge 1$,

$$\begin{aligned}\sup_{m\le l\le K}\|\mathsf{X}^a_\alpha(\Delta x_l)\|_p+\sum_{j=m+1}^{K}\big\|\mathsf{H}^a_\sigma\big(u_j(0)-u_j^{\mathrm{cl},0}(0)\big)\big\|_p\\ \le C_p\big[\sqrt{\gamma}+\gamma(1+|\log\gamma|)^d\big](1+m)^cB^{-sm},\end{aligned}$$

$$\big\|\mathsf{X}^a_\alpha(x_K-x_K^0)+\mathsf{Y}^a_\alpha(y_K-y_K^0)\big\|_p\le C_p\sqrt{\gamma}(1+m)^cB^{-sm}+C_p\gamma(1+|\log\gamma|)^d.$$

Further, for each ω *let*

$$\mathcal{T}^\omega_{K,m}=\sum_{j=m+1}^{K}\big\{T^\omega_{j,j-1}(\widehat\theta_{j-1},\widehat\theta_{j-1})-T^\omega_{j,j-1}(\widehat\theta^0_{j-1},\widehat\theta^0_{j-1})\big\}.$$

Then $\|\mathsf{Y}^a_\alpha(\mathcal{T}^\omega_{K,m})\|_p\le C_p[\sqrt{\gamma}+\gamma(1+|\log\gamma|)^d](1+m)^cB^{-sm}$. *One may choose* s *strictly below each of the positive numbers*

$$\alpha-\tfrac12,\quad \sigma,\quad 2\alpha-1,\quad \kappa+\sigma-\tfrac12,\quad \kappa+2\alpha-\tfrac32,\quad 2\kappa-1,\quad \kappa+\alpha+\sigma-1,\quad -\frac{\log\mathfrak{q}}{\log B},$$

and below the fixed smaller exponents of the product estimates in Lemma 28.5.

Proof. We first bound the moments of the fields, before any product is formed. We then use (34.4) to write the difference of each pulled-back quadratic form along the two reconstructions as a sum of centered terms, classical terms of degree at least three, and conditional means. We record the size of each term, counting the classical part of degree at least three of the predictable term once. Summation over levels then gives the bounds on the predictable term, on the linear heat evolution, and on the three ordered forms. Finally, we bound both orders of every product in (34.5), following the third column of Table 34.2, with Hölder's inequality for higher moments under ν in place of independence. The only delicate product is that of Δx_{j-1} with the classical predictable term, whose sum over levels is not uniformly small in m before it is multiplied by the decaying factor. Throughout, we write $\varrho=a_{\mathrm{map}}$ and $\delta_j=\widehat\theta_j-\widehat\theta^0_j$, and all conditional expectations are for the conditional kernels of ν.

Step 1: moments of the fields. We define the innovation about the zero-fluctuation value by

$$\epsilon_j=\widehat\Phi_j(\widehat\theta_{j-1},g_{j,\cdot}w_j)-P_j(\widehat\theta_{j-1}).$$

By the coefficient bounds of the reconstruction maps, the Euclidean gradient of each scalar output with respect to the fluctuation variables is at most $C_J \mathfrak{g}_j$, and there are at most $C_J (nB^j)^3$ such outputs. Applying Theorem 5.4 for a fixed incoming field and taking a union bound over the outputs, we obtain

$$\mathbb{P}\big\{ \|\epsilon_j - \mathbb{E}_{j-1}\epsilon_j\|_\infty > C\mathfrak{g}_j(\sqrt{1+j} + \sqrt{u}) \;\big|\; \mathcal{F}_{j-1} \big\} \le Ce^{-u},$$

where $\mathbb{E}_{j-1} = \mathbb{E}(\cdot \mid \mathcal{F}_{j-1})$. Integrating the tail, we obtain the bound $C_p \mathfrak{g}_j \sqrt{1+j}$ in every fixed L^p, without a factor of the cutoff. Since $\mathbb{E}_{j-1}\epsilon_j = \ell_j m_j^{\mathrm{ph}}(\widehat{\theta}_{j-1})$, (34.13) implies that $\|\mathbb{E}_{j-1}\epsilon_j\|_\infty \le C\mathfrak{g}_j^2 \|\widehat{\theta}_{j-1}\|_\infty \le Cr\mathfrak{g}_j^2$, where in the last inequality we used that the working ball has a fixed radius. The exact recursion, with $\delta_m = 0$, is

$$\delta_j = P_j(\widehat{\theta}_{j-1}) - P_j(\widehat{\theta}^0_{j-1}) + \epsilon_j.$$

The segment between the two inputs lies in the convex working ball. By the Minkowski inequality and the bound on DP_j, we have

$$\big\| \|\delta_j\|_\infty \big\|_p \le C_p \sum_{i=m+1}^{j} \varrho^{j-i} \big[\mathfrak{g}_i \sqrt{1+i} + r\mathfrak{g}_i^2 \big].$$

Since $\mathfrak{g}_i = \mathfrak{g}_j B^{(j-i)/2}$, the first sum is at most $C_p \mathfrak{g}_j \sqrt{1+j}/(1-\varrho\sqrt{B})$. For the second sum, after division by $\mathfrak{g}_j$, we use $\mathfrak{g}_i \le \mathfrak{g}_{m+1}$ to bound it by $r\mathfrak{g}_{m+1}/(1-\varrho\sqrt{B})$, and $\mathfrak{g}_{m+1} \le \mathfrak{g}_1$ is bounded uniformly by the coupling ceiling. This proves the first estimate. The second follows by comparing the reconstruction with the zero-fluctuation continuation from the same coarse field (the case $m = 0$), whose norm is at most $r\varrho^j$ by Lemma 34.4. By the same argument, for every $i \ge m$ we have

$$\begin{aligned} \big\| \|\widehat{\theta}_i\|_\infty \big\|_p + \big\| \|\widehat{\theta}^0_i\|_\infty \big\|_p &\le C_p \big[r\varrho^i + \mathfrak{g}_i \sqrt{1+i} \big], \\ \big\| \|\delta_i\|_\infty \big\|_p &\le C_p \mathfrak{g}_i \sqrt{1+i}. \end{aligned} \tag{34.27}$$

For the continuation in the first line we apply $\|P_i \cdots P_{m+1} v\|_\infty \le \varrho^{i-m}\|v\|_\infty$ to the moment at level m just proved, and use $\varrho^{i-m}\mathfrak{g}_m \le \mathfrak{g}_i$.

Step 2: exact telescopes and the classical cubic difference. At level m the two fields and their interpolations coincide, and $I_{a\to a}$ is the identity at the finest level. Subtracting the two finite telescopes proves the two identities for Δx_K and $y_K - y_K^0$ in the statement, without an interpolation error at level m.

Let $A_{j,i}$ denote any one of $T^{\mathsf{UV}}_{j,i}$, $T^{\mathsf{VU}}_{j,i}$, $T^{\mathsf{VV}}_{j,i}$, or $S_{j,i}$. Its coefficient norm is at most $C(1+j)^c K_{ji}$, where the polynomial factor is needed only for the ordered forms, and the pullback (34.3) is exact by the construction in Theorems 27.5 and 27.7. Set $P_i = L_i + E_i$, where E_i starts at degree two. By (34.4), we have

$$C_{j,i}(v) = A_{j,i}(P_i v, P_i v) - A_{j,i}(L_i v, L_i v) = A_{j,i}(L_i v, E_i v) + A_{j,i}(E_i v, L_i v) + A_{j,i}(E_i v, E_i v).$$

By the coefficientwise majorant series of Lemma 15.15, we have $\|E_i v\| \le C\|v\|^2$, $\|DE_i(v)\| \le C\|v\|$, and $\|L_i\| \le \varrho$ on the working ball. Applying the product rule to the last identity, we obtain

$$\|DC_{j,i}(v)[w]\|_{\mathrm{out}} \le C(1+j)^c K_{ji}\|v\|_\infty^2\|w\|_\infty. \tag{34.28}$$

Here the output norm is Y^a_α, or, for a quadratic initial form, the initial-array norm H^a_σ after cardinal interpolation. In the latter case, the coefficient row bound of the quadratic initial form controls the supremum of the initial value, and item (5) of Lemma 34.2 then controls the first differences. Equivalently, in the expansion in homogeneous coefficients one distinguishes one argument, keeps the other two, and sums the remaining degrees inside the fixed radius; the differentiated series converges there, and the constant is therefore independent of the length of the sequence. Integrating (34.28) along the segment from v' to v proves the difference estimate in the statement, including first differences. It also proves that $R^\omega_{j,i} = C_{j,i}$ has no quadratic part.

Step 3: decomposition of the pulled-back forms. We define

$$\begin{aligned} Z_{j,i} &= A_{j,i}(\widehat\theta_i,\widehat\theta_i) - \mathbb{E}_{i-1}A_{j,i}(\widehat\theta_i,\widehat\theta_i),\\ M_{j,i}(v) &= \mathbb{E}\big[A_{j,i}\big(\widehat\Phi_i(v,g_{i,\cdot}w),\widehat\Phi_i(v,g_{i,\cdot}w)\big)\;\big|\;\widehat\theta_{i-1}=v\big] - A_{j,i}(P_iv,P_iv). \end{aligned}$$

By the splitting of the conditional means in Theorems 27.5 and 27.7, we have

$$\|M_{j,i}(v)\|_{\mathrm{out}} \le C(1+j)^c K_{ji}\big[\mathfrak{g}_i^2\|v\|_\infty + \mathfrak{g}_i^3 p_i^3\big]. \tag{34.29}$$

The classical part of degree three is contained in $C_{j,i}$ and does not appear again in (34.29). The pullback identity (34.3) implies that $A_{j,i}(\widehat\theta_i,\widehat\theta_i) - A_{j,i-1}(\widehat\theta_{i-1},\widehat\theta_{i-1}) = Z_{j,i} + C_{j,i}(\widehat\theta_{i-1}) + M_{j,i}(\widehat\theta_{i-1})$. For the continuation, the same difference equals $C_{j,i}(\widehat\theta^0_{i-1})$ when $i > m$. Summing over i, we obtain the identity

$$\begin{aligned} &A_{j,j-1}(\widehat\theta_{j-1},\widehat\theta_{j-1}) - A_{j,j-1}(\widehat\theta^0_{j-1},\widehat\theta^0_{j-1})\\ &\quad= \sum_{i=m+1}^{j-1}\big\{Z_{j,i} + C_{j,i}(\widehat\theta_{i-1}) - C_{j,i}(\widehat\theta^0_{i-1}) + M_{j,i}(\widehat\theta_{i-1})\big\}. \end{aligned} \tag{34.30}$$

The terms at level m cancel identically, since both arguments are $\widehat\theta_m$.

Step 4: sizes of the terms and summation. We give the quantitative bounds before suppressing positive powers of the mesh. In this proof we set $q_i = 1 + i + |\log\gamma|$; then $p_i \le Cq_i$ by Lemma 34.6. Conditionally on the incoming field, the fiber bound in

Theorem 34.7 is $C(\varrho\|\widehat{\theta}_{i-1}\|_\infty + \mathfrak{g}_i p_i)$. Taking its outer moments with (34.27), we obtain the following bounds, up to the factor $C_p(1+j)^c \mathfrak{q}^{j-1-i}$:

term	bound before the convolution in $\mathfrak{q}$
$Z_{j,i}$, quadratic initial form	$\sqrt{\gamma}\, r\ell_i^{\kappa+\sigma-1/2} + \gamma\ell_i^{\sigma} q_i$
$Z_{j,i}$, ordered form	$\sqrt{\gamma}\, r\ell_i^{\kappa+2\alpha-3/2} + \gamma\ell_i^{2\alpha-1} q_i$
$C_{j,i}(\widehat{\theta}_{i-1}) - C_{j,i}(\widehat{\theta}^0_{i-1})$	$\sqrt{\gamma}\, r^2\ell_i^{2\kappa-1/2}(1+i)^{1/2} + \gamma r\ell_i^{\kappa} q_i^2 + \gamma^{3/2}\ell_i^{1/2} q_i^3$
$M_{j,i}(\widehat{\theta}_{i-1})$	$\gamma r\ell_i^{\kappa} + \gamma^{3/2}\ell_i^{1/2} q_i^3$

(34.31)

Fixed factors depending on L, n, B, and r are allowed in these bounds. To verify the third line, we use (34.28) and Hölder's inequality with moments of order $3p$, which bound the difference by

$$\frac{C_p}{\ell_i}\big[r\varrho^{i-1} + \mathfrak{g}_{i-1}\sqrt{1+i}\big]^2 \mathfrak{g}_{i-1}\sqrt{1+i}.$$

Expanding the square and using $\varrho^i = H_0^{-\kappa}\ell_i^{\kappa}$ and $\mathfrak{g}_i^2 = \gamma\ell_i/L$ gives the listed powers. The first two lines follow by multiplying the conditional fiber bound by $\mathfrak{g}_i\ell_i^{\sigma-1}$ or by $\mathfrak{g}_i\ell_i^{2\alpha-2}$, respectively, as in Theorem 34.7. The last line follows from (34.29) and (34.27). Every power multiplying $\sqrt{\gamma}$ is free of $|\log\gamma|$, and every term that contains this logarithm has coupling order at least γ and a strictly positive power of the mesh.

We apply (34.30) to the quadratic initial term of $u_j(0) - u_j^{\mathrm{cl},0}(0)$. The remaining classical part of this difference is $V_j(\widehat{\theta}_{j-1}) - V_j(\widehat{\theta}^0_{j-1})$, whose bound by (34.12) is the third line of (34.31) without the factor $\mathfrak{q}^{j-1-i}$. The remaining mean is $I_{\ell_j\to a} m_j^{\mathrm{ph}}(\widehat{\theta}_{j-1})$, which by (34.13) and (34.27) is at most $C_p[\gamma r\ell_{j-1}^{\kappa} + \gamma^{3/2}\ell_{j-1}^{1/2}\sqrt{1+j}]$. All these bounds hold in the initial-array norm H^a_σ; for the centered quadratic initial terms, the first-difference part was proved by heat splitting in Theorem 34.7. By (34.15) and (34.16), we obtain, for some $s_0 > 0$,

$$\sum_{j=m+1}^{K} \big\|\mathsf{H}^a_\sigma\big(u_j(0) - u_j^{\mathrm{cl},0}(0)\big)\big\|_p \le C_p\big[\sqrt{\gamma} + \gamma(1+|\log\gamma|)^d\big](1+m)^c B^{-s_0 m}. \tag{34.32}$$

This bounds the predictable term in the norm of its initial value, which is stronger than a bound in X^a_α.

For the linear heat evolution, the difference of the increments splits exactly as

$$d_j - d_j^0 = s_j + z_j + (r_j - r_j^0) + (u_j - u_j^{\mathrm{cl},0}).$$

The bounds (34.11) and (34.27) imply that

$$\|\mathsf{X}^a_\alpha(r_j - r_j^0)\|_p \le C_p\sqrt{\gamma}(1+j)^{1/2}\ell_{j-1}^{\alpha-1/2}.$$

The centered linear term has the same leading power by Theorem 34.7, and the centered nonlinear heat term contributes $C_p[\gamma \ell_j^{\alpha}(1+j) + \gamma^{3/2}\ell_j^{1/2} p_j^3]$. The last part is bounded by (34.32) and the inequality $\mathsf{X}_{\alpha}^{a}(P_{\cdot}^{a} f) \le C\mathsf{H}_{\sigma}^{a}(f)$. Thus

$$\Big\| \sup_{m \le l \le K} \mathsf{X}_{\alpha}^{a}(\Delta x_l) \Big\|_p \le C_p\big[\sqrt{\gamma} + \gamma(1+|\log\gamma|)^d\big](1+m)^c B^{-s_0 m}. \tag{34.33}$$

By the triangle inequality, this bound holds with the supremum inside the expectation, and the sum over j of the $L^p(\mathsf{X}_{\alpha}^{a})$ norms of each of the four parts of $d_j - d_j^0$ is bounded by the same right side.

Applying (34.30) to each of the three ordered forms and using (34.31), we obtain

$$\begin{aligned} \sum_{j=m+1}^{K} \Big\| \mathsf{Y}_{\alpha}^{a}\big(T_{j,j-1}^{\omega}(\widehat{\theta}_{j-1}, \widehat{\theta}_{j-1}) - T_{j,j-1}^{\omega}(\widehat{\theta}_{j-1}^{0}, \widehat{\theta}_{j-1}^{0})\big) \Big\|_p \\ \le C_p\big[\sqrt{\gamma} + \gamma(1+|\log\gamma|)^d\big](1+m)^c B^{-s_0 m}, \end{aligned} \tag{34.34}$$

separately for $\omega = \mathsf{UV}, \mathsf{VU}, \mathsf{VV}$, with all conditional means included. We choose s_0 below the positive exponents listed in the statement and below the smaller exponents of the product estimates cited there. The other exponents in (34.31), such as $2\kappa - 1/2$ and κ, are positive and are accommodated by reducing s_0 further if necessary. The constants of all geometric sums depend on these fixed positive gaps, not on m.

Step 5: the cross products with the predictable term. There are two such products in each order. For the one containing $u_j - u_j^{\mathrm{cl},0}$, we use (34.6), Hölder's inequality, (34.26), and (34.32); its summed norm is at most a fixed multiple of the right side of (34.32). For the other one, the continuation satisfies the deterministic bound

$$\sum_{j>m} \mathsf{H}_{\sigma}^{a}\big(u_j^{\mathrm{cl},0}(0)\big) \le \frac{C\|\widehat{\theta}_m\|_{\infty}^2}{\ell_m} \le C\big[r^2 \ell_m^{2\kappa-1} + \gamma p_m^2\big], \tag{34.35}$$

given its input at level m. The first inequality sums the quadratic series of the zero-fluctuation maps with ratio $B\varrho^2 = \mathfrak{q}$, and the second uses (34.20). At $m = 0$ the last expression may be replaced by the constant Cr^2/H_0. The right side is not bounded uniformly in m at fixed γ, because of the term γp_m^2. We therefore multiply (34.35) by (34.33), using (34.6), before absorbing anything. The resulting term of order larger than γ is at most

$$C_p\big[\gamma^{3/2} p_m^2 + \gamma^2 p_m^2 (1+|\log\gamma|)^d\big](1+m)^c B^{-s_0 m}.$$

Since $p_m \le C(1+m)(1+|\log\gamma|)$, its additional polynomial in m is absorbed by $B^{-(s_0-s)m}$ for any fixed $0 < s < s_0$, and after enlarging d the term has coupling order at least γ. The deterministic part $r^2\ell_m^{2\kappa-1}$ of (34.35) keeps the positive power $2\kappa - 1$. This bounds both orders of the other cross product with the predictable term. In particular γp_m^2 is never bounded uniformly in m before its decaying factor has been restored.

Step 6: the remaining products. We follow the third column of Table 34.2. Each term is a difference from the zero-fluctuation counterpart, which is zero whenever s or z occurs, and the factor $(1+j)^c$ is suppressed in this step.

- (s,s): the centered part is at most $C_p\gamma\ell_j^{2\alpha-1}(1+j)$, and the conditional mean is at most $C_p\gamma[r\varrho^{j-1}+\mathfrak{g}_{j-1}\sqrt{1+j}]$, by Theorem 34.7 with the field moments (34.27).
- (s,z), (z,s), (z,z): the inequality (34.6) and Hölder's inequality under ν give the products of the $2p$-moment bounds $S_jZ_j^-$ or $Z_j^+Z_j^-$ of Theorem 34.7. Their coupling orders are at least $\gamma^{3/2}$ or γ^2, and their powers of ℓ_j include $\beta+\sigma>0$ and $\alpha+\sigma>0$. The factors of higher degree carry an additional $\ell_j^{1/2}$.
- (s,r), (r,s): conditionally on $\mathcal{F}_{j-1}$ we use the two mixed linear rows with the predictable background r_j. Its background bound has moments $C_p[r\ell_{j-1}^{\kappa+\alpha-1}+\sqrt{\gamma}\ell_{j-1}^{\alpha-1/2}\sqrt{1+j}]$. The resulting powers are $\sqrt{\gamma}\,r\ell_j^{\kappa+2\alpha-3/2}$ and $\gamma\ell_j^{2\alpha-1}$, each with a fixed polynomial factor.
- (z,r), (r,z): we put the norm H^a_σ of the initial value of z_j in (34.6) and use the moment bound for r_j just stated. The leading term is $\gamma r\ell_j^{\kappa+\alpha+\sigma-1}$; the rest has order at least $\gamma^{3/2}$ and the power $\alpha+\sigma-1/2>0$.
- (r,r): this is the difference of T^{VV} in (34.34), including its classical and conditional-mean parts.
- The seven pairs containing u: we use (34.7) and the identity with both arguments interchanged; for (u,u) this gives $\mathcal{Q}_a(u,u-u^{\mathrm{cl},0})+\mathcal{Q}_a(u-u^{\mathrm{cl},0},u^{\mathrm{cl},0})$. The individual norms of s_j, z_j, r_j, and u_j have bounded moments of order $2p$ by Theorem 34.7, and the sums of the moments of the differences $v-v^0$ are bounded by the statement following (34.33). We use (34.32) for the first term of (34.7), and (34.35) with the decaying factor of (34.33) for the second, as in Step 5.

There are also eight cross terms with x_{j-1}. Those with s are bounded by (34.19), the bounded moments of the norm (34.14) of x_{j-1}, and $\sqrt{\gamma}\ell_j^\beta$. Those with z use the norm H^a_σ of the initial value of z_j and $\mathsf{X}^a_\alpha(x_{j-1})$; they have order at least γ and a positive power of the mesh. For those with r, the two exact identities $T^{\mathsf{UV}}-T^{\mathsf{VV}}$ and $T^{\mathsf{VU}}-T^{\mathsf{VV}}$ of (34.2) reduce the differences to (34.34). For the two orders with u we use the identity

$$\mathcal{Q}_a(x_{j-1},u_j)-\mathcal{Q}_a(x^0_{j-1},u^{\mathrm{cl},0}_j)=\mathcal{Q}_a(x_{j-1},u_j-u^{\mathrm{cl},0}_j)+\mathcal{Q}_a(\Delta x_{j-1},u^{\mathrm{cl},0}_j)$$

and its reversed order, which were bounded in Step 5. None of these terms requires a bilinear estimate of two rough heat paths in the norm X^a_α; the products of z_j with r_j use only the initial-array norm of the centered nonlinear heat term, the norm of the signed defect, and (34.6).

By bilinearity, $y_K-y^0_K$ is the sum over $m<j\le K$ of these differences, and we apply the Minkowski inequality to this finite sum. The terms of order $\sqrt{\gamma}$ listed above keep a

positive power of the mesh and contain no logarithm of the coupling; their sum is at most $C_p\sqrt{\gamma}(1+m)^c B^{-sm}$. All terms containing a logarithm of the coupling have order at least γ, and the geometric sums above bound them by $C_p\gamma(1+|\log\gamma|)^d$, where dropping a remaining decaying factor only weakens the bound. Together with (34.33), this proves the final estimate of the theorem, and (34.32), (34.33), and (34.34) prove the other estimates. Each application of Hölder's inequality used higher fixed moments under the same measure; for a final moment p it suffices to use moments up to order $6p$, since a cubic difference has three factors and a product has two. These moments were proved in Theorem 34.7 and in Step 1. The exponents and all constants are fixed before γ, and they are independent of K, m, and the prior depths. □

34.6 Holonomy comparison at the weak-coupling scale

We now transfer the comparison of flow data to the holonomy matrices of the flowed configurations. For a pair $\mathcal{E} = (x, y)$ of heat paths on the lattice of mesh a we write $\|\mathcal{E}\|_{\mathrm{fl}} = \mathsf{X}^a_\alpha(x) + \mathsf{Y}^a_\alpha(y)$ for the flow-data norm of Definition 24.3, with the fixed mesh a suppressed, and we abbreviate $\mathscr{L}_\gamma = 1 + |\log\gamma|$.

Theorem 34.10. *For the triples of Definition 34.1, let $D_{K,m} = \max_i \|\mathcal{H}_i^K - \Xi_{m,i}^K\|_{\mathrm{op}}$. There exist $C, c, \epsilon, d > 0$ and, for every fixed $p \geq 1$, a constant $C_p < \infty$, all independent of $K \geq m \geq 0$ and $0 < \gamma \leq \gamma_0$, such that*

$$\mathbb{E}_\nu \min(1, D_{K,m})^2 \leq C\gamma\delta_m + C\gamma^2\mathscr{L}_\gamma^{2d}, \qquad \delta_m = (1+m)^c B^{-\epsilon m},$$

$$\mathbb{E}_\nu \min(1, D_{K,m})^p \leq C_p\gamma^{p/2}.$$

For every fixed m, the second term in the first bound is $o(\gamma)$ as $\gamma \to 0$, uniformly in K.

In particular the moments of order at most eight used in Section 35 have constants independent of m. The estimates hold under the conditioned measure, whose coarse field ranges over neighborhoods of all flat connections, regular and central.

Proof. Let $\mathcal{E} = (x_K, y_K)$, let $\mathcal{E}_m^0 = (x_K^0, y_K^0)$ be the flow data of the zero-fluctuation continuation after level m, and let $\mathcal{E}_{\mathrm{cl}}$ be the flow data of the zero-fluctuation continuation from the same coarse field, that is, the case $m = 0$. All three live on the finest lattice. By Lemma 34.4, $\|\mathcal{E}_{\mathrm{cl}}\|_{\mathrm{fl}} \leq R_{\mathrm{cl}}$ deterministically for every coarse field in the reconstruction domain, including every flat coarse field.

By Theorem 34.9, for every fixed p we have

$$\big\|\,\|\mathcal{E} - \mathcal{E}_m^0\|_{\mathrm{fl}}\big\|_p \leq C_p\sqrt{\gamma}(1+m)^c B^{-sm} + C_p\gamma\mathscr{L}_\gamma^d. \tag{34.36}$$

The function $\gamma^{1/2}\mathscr{L}_\gamma^d$ is bounded on $(0, \gamma_0]$ by the calculation in the proof of Lemma 34.6, and $\sup_m (1+m)^c B^{-sm} < \infty$ by (34.15). Thus the right side of (34.36) is at most $C_p\sqrt{\gamma}$,

uniformly in m. Its case $m = 0$ bounds $\mathcal{E} - \mathcal{E}_{\mathrm{cl}}$ by the same quantity, and the triangle inequality then bounds $\mathcal{E}^0_m - \mathcal{E}_{\mathrm{cl}}$ by $C_p\sqrt{\gamma}$ as well.

Let $R = R_{\mathrm{cl}} + 2$. For any real $q \geq 1$, the preceding bounds at moment $2q$ and Markov's inequality imply that

$$\nu\{\|\mathcal{E}\|_{\mathrm{fl}} > R \text{ or } \|\mathcal{E}^0_m\|_{\mathrm{fl}} > R\} \leq C_q\gamma^q. \tag{34.37}$$

This bound holds for each m with the same constant; there is no union over m. On the complementary event we apply Remark 34.8 with $t_- = t_+ = \theta L^2$ to the configurations $\exp\widehat{\theta}_K$ and $\exp\widehat{\theta}^0_K$. They have the common initial frame by construction, and their difference of flow data is exactly the one in (34.36). Hence

$$D_{K,m} \leq \Lambda_{R,\theta L^2,T}\|\mathcal{E} - \mathcal{E}^0_m\|_{\mathrm{fl}}$$

on that event. On the exceptional event we use $\min(1, D_{K,m}) \leq 1$. Squaring (34.36), using $(u+v)^2 \leq 2u^2 + 2v^2$, and taking $q = 2$ in (34.37), we obtain

$$\mathbb{E}_\nu \min(1, D_{K,m})^2 \leq C\gamma(1+m)^{2c}B^{-2sm} + C\gamma^2\mathscr{L}_\gamma^{2d} + C\gamma^2.$$

After increasing d to a positive value if necessary, the last term is absorbed into the second, and relabeling $2c$ and $2s$ as c and ϵ gives the first assertion. For a fixed $p \geq 1$ we use $(u+v)^p \leq 2^{p-1}(u^p + v^p)$, choose $q \geq \max(1, p/2)$ in (34.37), and use the bound $C_p\sqrt{\gamma}$ on the right side of (34.36); this gives $\mathbb{E}_\nu \min(1, D_{K,m})^p \leq C_p\gamma^{p/2}$. The stability estimate of Remark 34.8 covers the finitely many coarse meshes; no further event depending on the mesh has been discarded. Finally $\gamma\mathscr{L}_\gamma^{2d} \to 0$, again because $e^{-v}(1+v)^{2d} \to 0$ as $v = |\log\gamma| \to \infty$. Thus the second term in the bound on the mean square is $o(\gamma)$ uniformly in K for every fixed m; in fact its constant is independent of m. □

The next theorem gives the same comparison for every prescribed coarse field, uniformly over a time interval. It is used in Section 36, where the conditional estimate is multiplied by the small probability of a neighborhood of a central triple.

Theorem 34.11. *Fix the data of Definition 34.1 and $0 < \tau \leq T < \infty$, with the same three coordinate cycles. For each $K \geq 0$ and every coarse field $v = e^{\theta_0}$ in the reconstruction domain with $\|\theta_0\|_\infty \leq r$, define the probability*

$$\mathbb{Q}^K_v(dw_1 \cdots dw_K) = \prod_{j=1}^{K} k^K_j(\theta_{j-1}, dw_j), \qquad \theta_j = \widehat{\Phi}_j(\theta_{j-1}, g_{j,\cdot}w_j),$$

as an iterated integral: w_1 has the law $k^K_1(\theta_0, \cdot)$, and given $w_1, \ldots, w_{j-1}$ the vector w_j has the law $k^K_j(\theta_{j-1}, \cdot)$. Here k^K_j are the conditional fluctuation kernels of Theorem 15.9 and Lemma 15.10 at prior depth $J(K-j)$, written in the gauge of the reconstruction maps of Theorem 15.12; for

$K = 0$ the product is the unit point mass. Let $\theta_j^0 = P_j \cdots P_1 \theta_0$, and let $\mathcal{H}_t^K$ and $\mathcal{H}_{0,t}^K(v)$ be the based holonomy triples of $\Psi_t^{(N)}(\exp \theta_K)$ and $\Psi_t^{(N)}(\exp \theta_K^0)$, in their common initial frame. Set

$$d_{K,[\tau,T]} = \min\Big(1, \sup_{\tau \le t \le T} \max_i \|\mathcal{H}_{t,i}^K - \mathcal{H}_{0,t,i}^K(v)\|_{\mathrm{op}}\Big).$$

There exists $\gamma_W \in (0, \gamma_0]$, independent of K and v, such that for every fixed $p \ge 1$ there exists $C_{p,\tau,T} < \infty$ with

$$\sup_{K \ge 0} \sup_v \mathbb{E}_{\mathbb{Q}_v^K} d_{K,[\tau,T]}^p \le C_{p,\tau,T} \gamma^{p/2} \qquad (0 < \gamma \le \gamma_W).$$

The constants depend in addition on p, τ, T, and the loops, but not on the coarse field, which ranges over the set of initial fields specified in the theorem, including every flat coarse field. The ceiling γ_W is chosen before the moment order. The theorem is a statement about the probability $\mathbb{Q}_v^K$ itself, and it does not follow by conditioning Theorem 34.10 on the coarse field, which would only give a statement for almost every coarse field under the coarse marginal of ν.

Proof. Given the coarse field, the conditioned Wilson measure has the same conditional structure as $\mathbb{Q}_v^K$. We first construct $\mathbb{Q}_v^K$ for every v and check that all conditional estimates of Theorem 34.7 hold under it. The proof of Theorem 34.9 then applies with $m = 0$ and a deterministic coarse field; we repeat its steps in this setting, since the averaged statement cannot be quoted. The only change is that the sum of the classical predictable terms is now bounded by a deterministic constant. Finally we localize to a fixed ball of flow data and apply the matrix stability over the whole interval $[\tau, T]$.

Step 1: construction and coupling ceiling. The initial fields in the statement satisfy $\|\theta_0\|_\infty \le r$. The kernel formula of Theorem 15.9 extends continuously to this closed ball: its product with the fluctuation cutoff domain lies strictly inside the common analytic domains, and its positive normalizer is the integral of a bounded positive density. The gauge change of Theorem 15.12 changes neither this density nor its product of balls. By item (2) of Theorem 15.12, with the closed-product image conditions verified in its proof, the reconstruction maps this product into B_r. Inductively, every later incoming field lies in B_r, and Theorem 15.9 gives each successive kernel. Iterated integration therefore defines $\mathbb{Q}_v^K$, including at initial fields to which the coarse marginal of ν assigns no mass. By the amplitude bound in Lemma 15.10, all intermediate fields also stay in the working ball, and

$$\|\theta_j\|_\infty \le C\{r\varrho^j + \mathfrak{g}_j p_j\}, \qquad p_j \le C(1 + j + |\log \gamma|).$$

We reduce γ_W so that the Hessian lower bound and the bounds on the conditional means of the kernels hold at all these fields. This is possible because $t_j \le t_1 = \sqrt{\gamma/(Mn)}$ and $t^{a'} \log^{b'}(1/t) \to 0$ as $t \to 0$ for $a' > 0$. The hierarchy and the cutoffs of the fluctuation variables are not changed.

Step 2: transfer of conditional estimates. Let $\mathcal{F}_j = \sigma(w_1, \dots, w_j)$ on this probability space; the coarse field v is deterministic. Given $\mathcal{F}_{j-1}$, the law of the next vector is exactly $k_j^K(\theta_{j-1}, \cdot)$. Thus every estimate of Theorem 34.7 for a fixed incoming field holds here with the same constants. Explicitly, if $\mathbb{E}(|A|^q \mid \mathcal{F}_{i-1}) \le C_q^q b(\theta_{i-1})^q$ is one of those estimates, then the tower property implies that

$$\|A\|_{L^q(\mathbb{Q}_v^K)} \le C_q \|b(\theta_{i-1})\|_{L^q(\mathbb{Q}_v^K)}. \tag{34.38}$$

No coarse marginal enters this inequality.

Step 3: moments of the fields. We write $\delta_j = \theta_j - \theta_j^0$ and $\epsilon_j = \widehat{\Phi}_j(\theta_{j-1}, g_{j,\cdot} w_j) - P_j \theta_{j-1}$. The bound on the gradient in the fluctuation variables and Theorem 5.4, applied for a fixed incoming field to the at most $C_J(nB^j)^3$ scalar outputs, imply that

$$\big\| \|\epsilon_j - \mathbb{E}(\epsilon_j \mid \mathcal{F}_{j-1})\|_\infty \big\|_{L^q(\cdot \mid \mathcal{F}_{j-1})} \le C_q \mathfrak{g}_j \sqrt{1+j}.$$

The conditional mean is bounded by (34.13): $\|\mathbb{E}(\epsilon_j \mid \mathcal{F}_{j-1})\|_\infty \le C r \mathfrak{g}_j^2$. Since the segment between the two incoming fields lies in the convex working ball, we have

$$\big\| \|\delta_j\|_\infty \big\|_q \le \varrho \big\| \|\delta_{j-1}\|_\infty \big\|_q + C_q \mathfrak{g}_j \sqrt{1+j} + C r \mathfrak{g}_j^2.$$

We start at $\delta_0 = 0$ and sum, using $\mathfrak{g}_i = \mathfrak{g}_j B^{(j-i)/2}$, $\varrho\sqrt{B} < 1$, and, for the quadratic term, $\mathfrak{g}_i^2 \le \mathfrak{g}_1 \mathfrak{g}_i$. For every fixed $q < \infty$ we obtain

$$\big\| \|\delta_j\|_\infty \big\|_q \le C_q \mathfrak{g}_j \sqrt{1+j}, \qquad \big\| \|\theta_j\|_\infty \big\|_q + \|\theta_j^0\|_\infty \le C_q \{ r\varrho^j + \mathfrak{g}_j \sqrt{1+j} \}. \tag{34.39}$$

The continuation is deterministic and $\|\theta_j^0\|_\infty \le r\varrho^j$.

Step 4: the pulled-back forms. Let $A_{j,i}$ be the quadratic initial form $S_{j,i}$ or one of the three ordered forms $T_{j,i}^\omega$, and recall $K_{ji} = \mathfrak{q}^{j-1-i}/\ell_i$; fixed polynomial factors in $1+j$ are allowed below. With $L_i = DP_i(0)$, we define

$$\begin{aligned} Z_{j,i} &= A_{j,i}(\theta_i, \theta_i) - \mathbb{E}\big[A_{j,i}(\theta_i, \theta_i) \mid \mathcal{F}_{i-1}\big], \\ C_{j,i}(u) &= A_{j,i}(P_i u, P_i u) - A_{j,i}(L_i u, L_i u), \\ M_{j,i}(u) &= \mathbb{E}_{k_i^K(u,\cdot)} A_{j,i}(\theta_i, \theta_i) - A_{j,i}(P_i u, P_i u), \end{aligned}$$

where in the last line $\theta_i = \widehat{\Phi}_i(u, g_{i,\cdot} w_i)$ with w_i distributed according to $k_i^K(u, \cdot)$. By the difference estimate of Theorem 34.9, which follows from (34.28), we have

$$\|C_{j,i}(u) - C_{j,i}(u')\|_{\mathrm{out}} \le C(1+j)^c K_{ji} (\|u\|_\infty + \|u'\|_\infty)^2 \|u - u'\|_\infty.$$

By the splitting into classical and conditional-mean parts in Theorems 27.5 and 27.7, we have

$$\|M_{j,i}(u)\|_{\mathrm{out}} \le C(1+j)^c K_{ji} \big(\mathfrak{g}_i^2 \|u\|_\infty + \mathfrak{g}_i^3 p_i^3 \big). \tag{34.40}$$

Here the output of the quadratic initial form uses the initial-array norm H^a_σ and the ordered outputs use the norm Y^a_α; there is no classical cubic term in $M_{j,i}$. As in Step 3 of the proof of Theorem 34.9, the exact pullback telescopes to

$$A_{j,j-1}(\theta_{j-1},\theta_{j-1}) - A_{j,j-1}(\theta^0_{j-1},\theta^0_{j-1}) = \sum_{i=1}^{j-1}\big\{Z_{j,i} + C_{j,i}(\theta_{i-1}) - C_{j,i}(\theta^0_{i-1}) + M_{j,i}(\theta_{i-1})\big\}. \tag{34.41}$$

The term at level zero cancels because both starting fields are θ_0.

Step 5: sizes and summation. As before, let $q_i = 1 + i + |\log\gamma|$. Applying (34.38), (34.39), the conditional fiber bound $b_i(u) = C_J(\varrho\|u\|_\infty + \mathfrak{g}_i p_i)$, and Hölder's inequality under $\mathbb{Q}^K_v$, we find that the four bounds of (34.31) hold in $L^q(\mathbb{Q}^K_v)$, up to the factor $C_q(1+j)^c\mathfrak{q}^{j-1-i}$, for $Z_{j,i}$ (for the quadratic initial form and each ordered form), for $C_{j,i}(\theta_{i-1}) - C_{j,i}(\theta^0_{i-1})$, and for $M_{j,i}(\theta_{i-1})$. The verification is the one given after (34.31). For example, at moment $3q$ the difference of the classical terms is at most $C_q\ell_i^{-1}[r\varrho^{i-1} + \mathfrak{g}_{i-1}\sqrt{1+i}]^2\mathfrak{g}_{i-1}\sqrt{1+i}$; the bounds on $Z_{j,i}$ follow from the conditional bounds $\mathfrak{g}_i b_i \ell_i^{\sigma-1}$ and $\mathfrak{g}_i b_i \ell_i^{2\alpha-2}$; and the bound on $M_{j,i}$ is (34.40).

Since all the exponents of the mesh are positive, the geometric sums of Lemma 34.2 sum (34.41) separately for the quadratic initial form and for each of the ordered forms. The remaining local terms of the predictable part are the classical cubic term and the conditional mean of (34.12) and (34.13), which are bounded by the third and fourth lines of (34.31). The first differences in the initial-array norm are controlled by Theorem 27.7, including for $t \le a^2$. We obtain

$$\sum_j \big\|\mathsf{H}^a_\sigma\big(u_j(0) - u_j^{\mathrm{cl},0}(0)\big)\big\|_q + \sum_j \|\mathsf{X}^a_\alpha(d_j - d_j^0)\|_q + \sum_{j,\omega}\|\mathsf{Y}^a_\alpha(\Delta T_j^\omega)\|_q \le C_q\big[\sqrt{\gamma} + \gamma\mathscr{L}^d_\gamma\big], \tag{34.42}$$

where ΔT_j^ω is the left side of (34.41) for the form T^ω, and every sum runs over $1 \le j \le K$. For the linear heat evolution, the bound on s_j is $C_q\sqrt{\gamma}\ell_j^{\alpha-1/2}\sqrt{1+j}$, the bound on z_j is $C_q(\gamma\ell_j^\alpha(1+j) + \gamma^{3/2}\ell_j^{1/2}p_j^3)$, the bound on $r_j - r_j^0$ follows from (34.11) and (34.39), and the inequality $\mathsf{X}^a_\alpha(P^a_\cdot f) \le C\mathsf{H}^a_\sigma(f)$ bounds $u_j - u_j^{\mathrm{cl},0}$. Since these are the four parts of $d_j - d_j^0$, (34.42) also bounds $\|\sup_j \mathsf{X}^a_\alpha(x_j - x_j^0)\|_q$.

Step 6: products. We use only the pointwise ordered inequality (34.6); the averaged conclusions at fixed coupling of Lemma 28.5 are not needed. We denote the q-moment

bounds by

$$\begin{aligned} S_j &= C_q\sqrt{\gamma}\ell_j^{\alpha-1/2}\sqrt{1+j}, \\ Z_j^- &= C_q(\gamma\ell_j^{\sigma}(1+j)+\gamma^{3/2}\ell_j^{1/2}p_j^3), \\ Z_j^+ &= C_q(\gamma\ell_j^{\alpha}(1+j)+\gamma^{3/2}\ell_j^{1/2}p_j^3), \\ R_j &= C_q(r\ell_{j-1}^{\kappa+\alpha-1}+\sqrt{\gamma}\ell_{j-1}^{\alpha-1/2}\sqrt{1+j}), \end{aligned}$$

and use moments of order $2q$ in products. The norms $\mathsf{H}^a_\sigma(u_j(0))$ and the norms (34.14) of x_{j-1} at its input mesh have uniformly bounded moments. This follows from the same estimates for the quadratic initial terms without subtraction, after adding the deterministic initial term and the classical cubic term, whose powers of the mesh are $2\kappa-1>0$ and $3\kappa-1>0$, besides the positive powers already listed. The initial cardinal field costs only $C_{H_0}r$. The sixteen ordered differences $\mathcal{Q}_a(v_j,w_j)-\mathcal{Q}_a(v_j^0,w_j^0)$ and the eight cross terms are then estimated as in Step 6 of the proof of Theorem 34.9, following the third column of Table 34.2, with the following bounds.

- (s,s): the centered part is at most $C_q\gamma\ell_j^{2\alpha-1}(1+j)$ and the conditional mean at most $C_q\gamma[r\varrho^{j-1}+\mathfrak{g}_{j-1}\sqrt{1+j}]$, by Theorem 34.7.
- (s,z), (z,s), (z,z): respectively $CS_jZ_j^-$, $CS_jZ_j^-$, and $CZ_j^+Z_j^-$, by (34.6) and Hölder's inequality under $\mathbb{Q}_v^K$.
- (s,r), (r,s): CS_jR_j, by the conditional mixed linear rows of Theorem 34.7; the powers are $\kappa+2\alpha-3/2$ and $2\alpha-1$.
- (z,r), (r,z): $CZ_j^-R_j$ in each order, using the initial-array norm of the centered nonlinear heat term. The leading powers include $\kappa+\alpha+\sigma-1$ and $\alpha+\sigma-1/2$.
- (r,r): the difference of the form T^{VV} in (34.41) and (34.42).
- The seven pairs containing u: we use (34.7) and the identity with both arguments interchanged; for (u,u) this gives $\mathcal{Q}_a(u,u-u^{\mathrm{cl},0})+\mathcal{Q}_a(u-u^{\mathrm{cl},0},u^{\mathrm{cl},0})$. The first part is summed using the bound on the predictable term in (34.42) and the bounded norms. For the second part, the quadratic series of the zero-fluctuation maps and $B\varrho^2<1$ give the deterministic bound

$$\sum_{j\ge1}\mathsf{H}^a_\sigma\big(u_j^{\mathrm{cl},0}(0)\big)\le C\|\theta_0\|_\infty^2/H_0\le Cr^2/H_0,$$

  which we multiply by the summed bounds on the first component in (34.42). Since $m=0$ and the coarse field is deterministic, there is no term γp_m^2 here.

There are eight cross terms with x_{j-1}, two for each argument. For s, the conditional mixed linear rows give $C_q\sqrt{\gamma}\ell_j^{\alpha-1/2}$ times a bounded norm of x_{j-1}. For z, the two orders

of (34.6) give $C_q Z_j^-$ times that norm. For r, the two exact differences $T^{\mathsf{UV}} - T^{\mathsf{VV}}$ and $T^{\mathsf{VU}} - T^{\mathsf{VV}}$ are bounded in (34.42). For u we use

$$\mathcal{Q}_a(x_{j-1}, u_j) - \mathcal{Q}_a(x_{j-1}^0, u_j^{\mathrm{cl},0}) = \mathcal{Q}_a(x_{j-1}, u_j - u_j^{\mathrm{cl},0}) + \mathcal{Q}_a(x_{j-1} - x_{j-1}^0, u_j^{\mathrm{cl},0})$$

and its reversed order, which are bounded by the two estimates on the predictable terms just used. This accounts for all eight cross terms and all sixteen ordered products.

Step 7: the difference of flow data. The smallest exponents of the mesh in these sums are

$$\alpha - \tfrac{1}{2}, \quad \sigma, \quad 2\alpha - 1, \quad \kappa + \sigma - \tfrac{1}{2}, \quad \kappa + 2\alpha - \tfrac{3}{2}, \quad 2\kappa - 1, \quad \kappa + \alpha + \sigma - 1,$$

and $-\log \mathfrak{q} / \log B$, all strictly positive. Every term with a logarithm of the coupling has order at least γ, and Lemma 34.2 sums each fixed polynomial times its geometric decay. By bilinearity and the Minkowski inequality, under $\mathbb{Q}_v^K$,

$$\big\| \|\mathcal{E}_K - \mathcal{E}_K^0\|_{\mathrm{fl}} \big\|_q \le C_q \big(\sqrt{\gamma} + \gamma \mathscr{L}_\gamma^d \big) \le C_q' \sqrt{\gamma}, \tag{34.43}$$

where $\mathcal{E}_K = (x_K, y_K)$ and $\mathcal{E}_K^0 = (x_K^0, y_K^0)$, and in the last inequality we used that $\sqrt{\gamma}\mathscr{L}_\gamma^d$ is bounded. The bookkeeping of moments uses at most order $6q$: three factors in a cubic difference and two in a product. Thus the final moments $q = 1, 2$ require only the finitely many moment bounds up to order 12, all of which were obtained for fixed incoming fields before the tower integration.

Step 8: localization and the interval estimate. By Lemma 34.4, $\|\mathcal{E}_K^0\|_{\mathrm{fl}} \le R_{\mathrm{cl}}$ uniformly in v. With $R = R_{\mathrm{cl}} + 2$, (34.43) at moment q and Markov's inequality imply that

$$\mathbb{Q}_v^K \big\{ \|\mathcal{E}_K\|_{\mathrm{fl}} > R \big\} \le C_q \gamma^{q/2}.$$

On the complementary event we apply Remark 34.8 directly with $t_- = \tau$ and $t_+ = T$. It bounds the supremum over $t \in [\tau, T]$ by $\Lambda_{R,\tau,T} \|\mathcal{E}_K - \mathcal{E}_K^0\|_{\mathrm{fl}}$. On the exceptional event we use $d_{K,[\tau,T]} \le 1$. Taking $q \ge p$ and using (34.43) at moment p, we obtain the asserted bound $C_{p,\tau,T} \gamma^{p/2}$. The finitely many coarse meshes are included in the stability estimate. For $p = 1, 2$, the choice $q = 2$ suffices for the localization, and moments up to order 12 suffice for the whole argument. □

34.7 Linear Gaussian response near a fixed flat connection

In this section, we prove the estimate used in Section 35 to calibrate the normal covariance near regular commuting triples. We fix a regular flat coarse field and differentiate the deterministic reconstruction and the Wilson flow at this field with respect to the fluctuation inputs of the steps after level m. We divide the coupling factors by $\sqrt{\gamma}$,

and only then insert independent standard Gaussian vectors in place of the fluctuation variables. The lemma bounds the covariance, in the normal space, of the resulting Gaussian vector. Three points need care. First, the inputs $q_j = g_{j,\cdot} w_j$ are the arguments of the reconstruction maps. The normalization by the inverse square root of the constrained Hessian, which depends on the field, is already inside these maps, and the derivative therefore includes all normalizing matrices and their dependence on the field through the later reconstruction. Second, we recall from Definition 4.11 that at a point $y = (\vartheta_i u)_{i=1}^3$ of a compact regular patch of the cone of commuting triples, the normal space is $\mathcal{N}_y = \{b = (b_i)_{i=1}^3 : b_i \perp u,\ \sum_i \vartheta_i b_i = 0\}$, of dimension four, and $P_{\mathcal{N}_y}$ denotes the Euclidean orthogonal projection onto it in the fixed coordinates of cycle logarithms. Third, the identity $\mathbb{E}_G|\sum_j \mathsf{A}_{j,K} G_j|^2 = \sum_j \operatorname{tr}(\mathsf{A}_{j,K}\mathsf{A}_{j,K}^{\mathsf{T}})$ concerns only the contribution of the omitted steps. The covariance of the normal fluctuations of the coarse field is a separate contribution, which is not set to zero, and for this reason the lemma cannot be replaced by an averaged estimate for the conditioned measure.

Lemma 34.12. *Use the hierarchy, the side n, the time θL^2, and the reconstruction maps of Definition 34.1. Fix a compact regular patch of the cone of commuting triples and margins for the logarithm and for the normal coordinates as in Theorem 33.11. For a flat coarse field V_y whose cycle holonomies lie in this patch, let $\mathcal{H}_K(y,q)$ be the based holonomy triple, around the three coordinate cycles, of the configuration on the finest lattice reconstructed from V_y with fluctuation inputs $q = (q_1, \dots, q_K)$, flowed for the time θL^2. At $q = 0$ it equals $\mathrm{Hol}(V_y)$, in the original frame. Put*

$$\mathsf{A}_{j,K}(y) = P_{\mathcal{N}_y} D_{q_j}(\mathrm{Log} \circ \mathcal{H}_K)(y,0)\ \mathrm{diag}_{r,e}(g_{j,r}/\sqrt{\gamma}), \qquad 1 \le j \le K,$$

where the diagonal matrix has the entry $g_{j,r}/\sqrt{\gamma}$ at every scalar coordinate (r,e) of the fluctuation variables of step j; these ratios do not depend on γ. Equivalently, $\mathsf{A}_{j,K} = \gamma^{-1/2} P_{\mathcal{N}_y} D_{w_j}(\mathrm{Log} \circ \mathcal{H}_K)$ at zero fluctuation, with the full zero-fluctuation continuation at the later levels and every normalizing matrix included. Let G_j be independent standard real Gaussian vectors indexed like w_j. Then there exist $C, c, \epsilon > 0$ such that

$$\sup_y \mathbb{E}_G \Big| \sum_{j=m+1}^{K} \mathsf{A}_{j,K}(y) G_j \Big|^2 \le C(1+m)^c B^{-\epsilon m} \qquad (K \ge m \ge 0).$$

The constants may depend on the fixed n, L, θ, M, J, the parameters Θ of Theorem 23.2, the patch, and the fixed bounds on the coefficients and the flow, but not on m, K, the prior depths, or $\gamma \in (0, \gamma_0]$. Before the flow is applied, the first-order variation of the flow data in these directions, measured in both full norms with their first differences, has a bound $C(1+m)^c B^{-sm}$ in $L^2(G)$ for some $s > 0$.

Only linear maps are evaluated at the unbounded Gaussian vectors; no nonlinear reconstruction is evaluated outside its cutoff domain. For $j \ge 1$, the matrices $\mathsf{A}_{j,K}$ are the

linear response matrices $A_{j,K}$ of Definition 35.7, on the same normal patch and with the same gauge and basepoint, as the second expression for $\mathsf{A}_{j,K}$ shows; the coarse response $A_{0,K}$ there is a separate contribution.

Proof. The proof uses only deterministic coefficient estimates and independent Gaussian vectors; in particular, it does not use Theorems 34.9 and 34.10 as probability estimates. Throughout, we keep the zero-fluctuation base point and the direction of differentiation separate. We first set up and bound the linear recursion for the derivative of the reconstruction. We then write the first-order variation of the flow data as a sum over levels, bound each term by deterministic rows and Gaussian chaining, and sum. Finally, we pass to the holonomies through the derivative of the flow and the logarithm.

Step 1: the base point and the linear recursion. We write $\varrho = a_{\mathrm{map}}$ and $H_0 = L/n$. In one of the finitely many fixed charts covering the compact patch, let $v_0(y)$ be the logarithmic representative of V_y in the reconstruction domain, and set

$$v_i = P_i v_{i-1}, \qquad b_i^{\mathrm{fl}} = r\varrho^i, \qquad X_i = P_\cdot^a I_{\ell_i \to a}(v_i/\ell_i), \qquad Y_i = \mathcal{Q}_a(X_i, X_i). \tag{34.44}$$

The condition on flat fields was checked at the beginning of Section 34.2. By Lemma 14.9, at every side and prior depth, each constrained minimizer is an exact flat lift, its free coordinates vanish, and the gauges of the reconstruction maps preserve the prescribed cycle holonomies. The Wilson flow is stationary at each resulting flat field. It follows that $\mathcal{H}_K(y,0) = \mathrm{Hol}(V_y)$ exactly, in the original frame; this uses the refinement of flat fields, not a property of cardinal interpolation. By the bound on DP_i and Lemma 34.4,

$$\|v_i\|_\infty \le b_i^{\mathrm{fl}}, \qquad \sup_{K,i,y} \{\mathsf{X}_\alpha^a(X_i) + \mathsf{Y}_\alpha^a(Y_i)\} \le R_{\mathrm{cl}}. \tag{34.45}$$

The same domains serve every chart of the finite cover.

Let D_i be the diagonal matrix with the entries $g_{i,r}/\sqrt{\gamma}$ at all scalar coordinates of the fluctuation variables of step i. We write

$$W_i = D_q \widehat{\Phi}_i(v_{i-1}, 0) D_i, \qquad \eta_m = 0, \qquad \eta_i = DP_i(v_{i-1})\eta_{i-1} + W_i G_i \quad (i > m), \tag{34.46}$$

and we set $\eta_i = 0$ for $i < m$ as well. By the coefficient bounds of the reconstruction maps, we have

$$\|DP_i(v_{i-1})\|_{\infty\to\infty} \le \varrho, \qquad \sup_e \|W_i(e,\cdot)\|_2 \le C_J d_i, \qquad d_i = \mathfrak{g}_i/\sqrt{\gamma} = \sqrt{\ell_i/L}.$$

The ratios of the couplings within one step are kept in D_i; replacing them by d_i costs only a constant depending on J. All these linear maps are independent of the coupling. Their derivatives contain the positive inverse square roots of the constrained Hessians used to

normalize the fluctuation variables, including the dependence of these matrices on the field through the subsequent zero-fluctuation maps.

A scalar Gaussian row $c \cdot G$ has the Laplace transform $\mathbb{E}e^{tc\cdot G} = e^{t^2|c|_2^2/2}$, by completing the square in each one-dimensional Gaussian integral. Hence its two-sided tail at the threshold $u|c|_2$ is at most $2e^{-u^2/2}$. There are at most $C_J(nB^i)^3$ scalar outputs at level i. By the finite-family clause of Lemma 16.4, with $N \le C_J(nB^i)^3$, scale Cd_i, $b = 0$, and $e = 0$, we have $\|\|W_iG_i\|_\infty\|_{L^2(G)} \le Cd_i\sqrt{1+i}$. Applying the Minkowski inequality to (34.46), we obtain

$$\big\|\|\eta_i\|_\infty\big\|_{L^2(G)} \le C \sum_{l=m+1}^{i} \varrho^{i-l} d_l \sqrt{1+l} \le C\sqrt{\ell_i}(1+i)^{1/2}, \tag{34.47}$$

where we used $d_l = d_i B^{(i-l)/2}$ and $\varrho\sqrt{B} < 1$. This bound is uniform in m, the cutoff, and the flat field.

Step 2: first-order identities on the common lattice. In this proof V_i and Z_i denote first variations of the flow data; they are unrelated to the flat coarse field V_y. Define

$$V_i = P_\cdot^a I_{\ell_i\to a}(\eta_i/\ell_i), \qquad Z_i = \mathcal{Q}_a(X_i, V_i) + \mathcal{Q}_a(V_i, X_i). \tag{34.48}$$

Both are linear in $G_{m+1}, \dots, G_i$. They are the first derivatives of the flow data (x_i, y_i) when only the fluctuation inputs of the steps after m vary, in the directions D_lG_l. This is an identity between finite-dimensional linear maps: we first differentiate at zero in deterministic directions, and only afterwards apply the derivatives to the Gaussian vectors.

We use the uncentered deterministic Taylor expansion in the fluctuation inputs,

$$\widehat{\Phi}_i(v, q) = P_i v + D_q\widehat{\Phi}_i(v, 0)q + O(q^2).$$

Along the deterministic reconstruction $\theta_i(q) = \widehat{\Phi}_i(\theta_{i-1}(q), q_i)$ from $\theta_0 = v_0$, with flow data $x_i(q)$ and $y_i(q)$, the increment splits exactly into four uncentered summands,

$$x_i(q) - x_{i-1}(q) = \tilde{s}_i + \tilde{z}_i + \tilde{r}_i + \tilde{u}_i,$$

where, with $\theta = \theta_{i-1}(q)$,

$$\tilde{s}_i = \ell_i^{-1} P_\cdot^a I_{\ell_i\to a} D_q\widehat{\Phi}_i(\theta, 0)q_i, \qquad \tilde{z}_i = \ell_i^{-1} P_\cdot^a I_{\ell_i\to a}\big[\widehat{\Phi}_i(\theta, q_i) - P_i\theta - D_q\widehat{\Phi}_i(\theta, 0)q_i\big],$$
$$\tilde{r}_i = P_\cdot^a \mathscr{D}_i\theta, \qquad \tilde{u}_i = P_\cdot^a I_{\ell_i\to a} U_i^{\mathrm{cl}}(\theta).$$

These are not the centered summands s_i and z_i of (34.1), which are defined under the conditioned measure by an expansion at the conditional mean; the present expansion is at zero, and no conditional mean enters. At $q = 0$ the four summands are $(0, 0, R_i, U_i)$, defined below, and their first variations in the directions D_lG_l are $(\xi_i, 0, \rho_i, v_i)$. Thus the first-order part of the increment splits exactly as

$$V_i - V_{i-1} = \xi_i + \rho_i + v_i, \tag{34.49}$$

where

$$\xi_i = \ell_i^{-1} P_\cdot^a I_{\ell_i \to a} W_i G_i, \qquad \rho_i = P_\cdot^a \mathscr{D}_i \eta_{i-1}, \qquad v_i = P_\cdot^a I_{\ell_i \to a} D U_i^{\mathrm{cl}}(v_{i-1})[\eta_{i-1}].$$

Here $\mathscr{D}_i$ and U_i^{cl} are the signed defect and the classical predictable term of Lemma 34.2, including the quadratic terms and the terms of higher degree of the zero-fluctuation map. At order zero the same split is $X_i - X_{i-1} = R_i + U_i$, with $R_i = P_\cdot^a \mathscr{D}_i v_{i-1}$ and $U_i = P_\cdot^a I_{\ell_i \to a} U_i^{\mathrm{cl}}(v_{i-1})$. Terms with two fluctuation factors have zero first derivative at zero. The zero-fluctuation continuation agrees with the base point through level m and has zero derivative afterwards, because $\eta_m = 0$. Thus

$$V_l = \sum_{i=m+1}^{l} (\xi_i + \rho_i + v_i), \qquad Z_l = \sum_{i=m+1}^{l} (Z_i - Z_{i-1}),$$

and all initial terms at level m vanish exactly.

Step 3: linear rows and the background on two lattices. We apply Lemma 34.5 to the deterministic linear pullbacks, with the coefficient covers of Lemma 34.3. The values at the reference point have the Gaussian tail bounds just described. A difference of two linear Gaussian rows is a centered Gaussian variable whose variance is the squared coefficient distance, and it satisfies the conditions (1) of Lemma 34.5 exactly. We use only the deterministic coefficient part of Theorem 26.10, at zero fluctuation: we evaluate the coefficient at $(v_{i-1}, 0)$, divide its derivative in the fluctuation variables by $\sqrt{\gamma}$, and use the matrix D_i. Its weighted linear row scale is $C\ell_i^{\alpha - 1/2}$. The normalized coefficient metric has bounded diameter and a cover at the input mesh, and the Gaussian Laplace transform gives the tails of the increments and at the reference point. Applying Lemma 34.5 under the Gaussian measure, we obtain

$$\|\mathsf{X}_\alpha^a(\xi_i)\|_{L^2(G)} \le C(1+i)^c \ell_i^{\alpha - 1/2}, \qquad \|\mathsf{X}_\alpha^a(\rho_i)\|_{L^2(G)} \le C(1+i)^{1/2} \ell_{i-1}^{\alpha - 1/2}. \tag{34.50}$$

The second bound follows from (34.11) and (34.47).

We verify the stronger background conditions for the mixed rows used below. Let $H = \ell_{i-1} = B\ell_i$. Lemma 27.1 gives the signed heat estimate for difference orders 0, 1, and 2. For orders 3 and 4 and $t \ge H^2$, we put the additional differences on a half heat step in the estimate of order two, using Lemma 34.2. For $t \le H^2$, we put all differences on the two smooth cardinal inputs, whose input meshes are H and H/B; since their ratio is the fixed B, this costs only a constant $C_{J,q}$. For every $0 \le q \le 4$ this proves

$$\|D_a^q R_i(t)\|_\infty \le C_q \frac{b_{i-1}^{\mathrm{fl}}}{H} (t + H^2)^{-q/2} \frac{H}{\sqrt{t + H^2}} \le C_{J,q} b_{i-1}^{\mathrm{fl}} H^{\alpha - 1} (t + \ell_i^2)^{-(\alpha+q)/2}. \tag{34.51}$$

The last inequality follows by maximizing $(t + H^2)^{\alpha/2} H / \sqrt{t + H^2}$, whose maximum is H^α since $\alpha < 1$. Since every refinement ratio of the common lattice is an integer, the

statements about signed columns and cardinal interpolation apply. This background is a heat path built from two lattices, not a single cardinal interpolation of the parent field. The other background X_{i-1} has bounded norm at its input mesh by (34.14) and (34.45), and its differences through order four are bounded by the last assertion of item (6) of Lemma 34.2. Its correction term in (34.14) is $Cb_{i-1}^{\mathrm{fl}}H^{\alpha-1}$, which is bounded since $\kappa+\alpha-1>0$.

Thus both orders of the version of Theorem 26.10 with four differences apply, with the deterministic background bounds C for X_{i-1} and $Cb_{i-1}^{\mathrm{fl}}H^{\alpha-1}$ for R_i. Its envelopes of order four give the normalized space-time cover, independently of a/ℓ_i, and the heat equation gives the time increments. Using its separate linear rows and Lemma 34.5, we obtain, for each order separately,

$$\|\mathsf{Y}_\alpha^a(\mathcal{Q}_a(X_{i-1},\xi_i))\|_2+\|\mathsf{Y}_\alpha^a(\mathcal{Q}_a(\xi_i,X_{i-1}))\|_2\le C(1+i)^c\ell_i^{\alpha-1/2}, \tag{34.52}$$

$$\|\mathsf{Y}_\alpha^a(\mathcal{Q}_a(R_i,\xi_i))\|_2+\|\mathsf{Y}_\alpha^a(\mathcal{Q}_a(\xi_i,R_i))\|_2\le Cr(1+i)^c\ell_i^{\kappa+2\alpha-3/2}, \tag{34.53}$$

where $\|\cdot\|_2$ is the norm of $L^2(G)$. These are not the conditional maxima at fixed coupling of Theorem 26.10: we use only its deterministic rows and normalized covers, and the maximum is taken here for a linear Gaussian process.

Step 4: the pulled-back forms at first order. Let $T_{j,i}^{\omega}$ be the three ordered forms and $S_{j,i}$ the quadratic initial form, including its physical prefactor and its cardinal interpolation. For either type we write $F_{j,i}(v)=A_{j,i}(v,v)$, and we set

$$C_{j,i}(v)=F_{j,i}(P_iv)-F_{j,i}(L_iv),\qquad B_{j,i}=DF_{j,i}(v_i)W_i.$$

The calculation that proved (34.28) implies that

$$\|DC_{j,i}(v)[w]\|_{\mathrm{out}}\le C(1+j)^c\frac{\mathfrak{q}^{j-1-i}}{\ell_i}\|v\|_\infty^2\|w\|_\infty. \tag{34.54}$$

The output norm is Y_α^a for an ordered form and the initial-array norm H_σ^a for a quadratic initial form. Differentiating the finite telescope given by (34.3), or applying the chain rule term by term, we obtain exactly

$$DF_{j,j-1}(v_{j-1})[\eta_{j-1}]=\sum_{i=m+1}^{j-1}\big\{B_{j,i}G_i+DC_{j,i}(v_{i-1})[\eta_{i-1}]\big\}. \tag{34.55}$$

Indeed, the part of the chain rule that comes from P_i is $DF_{j,i}(v_i)DP_i(v_{i-1})\eta_{i-1}$; subtracting the derivative of the pullback, $DF_{j,i}(L_iv_{i-1})L_i\eta_{i-1}$, leaves $DC_{j,i}(v_{i-1})[\eta_{i-1}]$, and the remaining part is $DF_{j,i}(v_i)W_iG_i$. The derivative of $F_{j,m}(v_m)$ is zero because $\eta_m=0$.

We now bound the Gaussian norm of $B_{j,i}G_i$ by deterministic rows at the base point. Let $H=\ell_{j-1}$, $G=\ell_i=B^kH$ with $k=j-1-i$, and $K_{ji}=\mathfrak{q}^k/G$. For the form T^{UV} the two terms in the derivative of the source are

$$\mathcal{N}_a(\mathsf{U}W_iG_i,\mathsf{V}v_i)+\mathcal{N}_a(\mathsf{U}v_i,\mathsf{V}W_iG_i),$$

where $\mathsf{U} = \mathsf{U}_{j,i}$, $\mathsf{V} = \mathsf{V}_{j,i}$, and $\mathcal{N}_a$ is the quadratic source of the Duhamel term. For T^{VU} we interchange U and V, and for T^{VV} we put V in both arguments of these two terms. Thus each of the three derivatives has one differentiated argument and one deterministic argument bounded by b_i^{fl}. By the product inequalities for rows and volume-normalized columns in Lemma 27.1, followed by the bounds on the time-indexed rows of heat-kernel coefficients in Theorem 27.5, we have

$$\begin{aligned}
\sup_x \|B_{j,i}(t,x,\cdot)\|_2 &\le C K_{ji} d_i b_i^{\mathrm{fl}} \log(1 + t/H^2), \qquad t \le G^2,\\
\sup_x \|D_a B_{j,i}(t,x,\cdot)\|_2 &\le C K_{ji} d_i b_i^{\mathrm{fl}} J_H(t), \qquad t \le G^2,\\
\sup_x \|D_a^{\iota} B_{j,i}(t,x,\cdot)\|_2 &\le C K_{ji} d_i b_i^{\mathrm{fl}} G^{3/2} t^{-3/4-\iota/2} \ell_H(T), \qquad t \ge G^2,\ \iota = 0,1.
\end{aligned}$$

Here J_H and ℓ_H are the functions defined in Theorem 27.5. The conversion of the Schur row-column estimate with volume-normalized columns uses the input volume G^3 and the output volume a^3; its factor $(G/a)^{3/2}$ cancels the factor $a^{3/2}$ of the row of heat-kernel coefficients and leaves $G^{3/2}$. The undifferentiated argument is evaluated at v_i, and only its deterministic size enters this calculation. We do not use b_i^{fl} as a bound on a conditional fiber with nonzero fluctuation variables, which is why no term $d_i p_i$ appears. The Jacobian at zero fluctuation has been substituted in the differentiated argument, with $\mathfrak{g}_i$ replaced by d_i through the diagonal matrix D_i; all other heat and signed-column operations are unchanged.

Taking the two weighted maxima of these early and late row bounds gives the scale $C(1+j)^c K_{ji} d_i b_i^{\mathrm{fl}} G^{2\alpha-1}$. The crude space and time derivatives of the coefficients have the amplitude $C_{\mathrm{CP}}^{2k} d_i b_i^{\mathrm{fl}}/G^2$ and cost fixed powers of H^{-1}. Their ratio to the weighted amplitude is bounded as in (34.21), with the same factor $(q_{\mathrm{anc}}/\mathfrak{q})^k \le 1$. Therefore their normalized coefficient metrics have bounded diameter and polynomial covering numbers at the input mesh, including at time zero, and Lemma 34.5 proves, for each ordered form separately,

$$\|\mathsf{Y}_\alpha^a(B_{j,i}G_i)\|_2 \le C r (1+j)^c \mathfrak{q}^{j-1-i} \ell_i^{\kappa+2\alpha-3/2}. \tag{34.56}$$

For the quadratic initial form we use the rows of Theorem 27.7 with respect to the fluctuation variables, with the same differentiated and deterministic arguments. Its value row is at most

$$C K_{ji} d_i b_i^{\mathrm{fl}} \min\bigl\{1, G^{3/2}(t+G^2)^{-3/4}\bigr\}.$$

After the weight with exponent $\sigma/2$ its scale is $C K_{ji} d_i b_i^{\mathrm{fl}} G^{\sigma}$. Its crude parameter derivatives keep the same factor $K_{ji} d_i b_i^{\mathrm{fl}}$, and division gives a fixed power of ℓ_j^{-1} and the cover at the input mesh. Lemma 34.5 for the value process, followed by the deterministic half-splitting of the heat semigroup for its linear initial field, proves

$$\|\mathsf{H}_\sigma^a(B_{j,i}G_i)\|_2 \le C r (1+j)^c \mathfrak{q}^{j-1-i} \ell_i^{\kappa+\sigma-1/2}. \tag{34.57}$$

The half-splitting above a^2 and the bound by the initial value below a^2 are the two deterministic inequalities of Step 3 of the proof of Theorem 34.7, and this bound includes the first difference on every finer lattice.

Finally, (34.54) and (34.47) imply that, for both types of output,

$$\big\| \|DC_{j,i}(v_{i-1})[\eta_{i-1}]\|_{\mathrm{out}} \big\|_2 \le Cr^2(1+j)^c \mathfrak{q}^{j-1-i} \ell_i^{2\kappa-1/2}. \tag{34.58}$$

The part of degree at least three of the predictable term at level j satisfies the same bound with its own coefficient, by (34.12). There is no conditional-mean remainder in (34.55).

Step 5: summation of both components. Let $s_0 > 0$ be strictly smaller than each of

$$\alpha - \tfrac{1}{2}, \quad \kappa + \sigma - \tfrac{1}{2}, \quad \kappa + 2\alpha - \tfrac{3}{2}, \quad 2\kappa - \tfrac{1}{2}, \quad -\frac{\log \mathfrak{q}}{\log B}.$$

All these numbers are positive, and we reduce s_0 further if a fixed exponent of the product estimates requires it. For the predictable term, the initial value of its first-order variation is exactly

$$v_j(0) = DS_{j,j-1}(v_{j-1}, v_{j-1})[\eta_{j-1}] + I_{\ell_j \to a} DC_j^{\mathrm{loc}}(v_{j-1})[\eta_{j-1}],$$

where C_j^{loc} is the part of degree at least three of U_j^{cl} at its input mesh, so that $I_{\ell_j \to a} C_j^{\mathrm{loc}} = V_j$ in the notation of Lemma 34.2. The first term is given by the identity (34.55) for the quadratic initial form and the second by the bound on the part of degree at least three, with no conditional mean added to either. Summing both in the norm of the initial value, using (34.57), (34.58), and geometric summation, we obtain

$$\sum_{j=m+1}^{K} \|\mathsf{H}_\sigma^a(v_j(0))\|_2 \le C(1+m)^c B^{-s_0 m}. \tag{34.59}$$

Combining this with (34.50), we obtain

$$\Big\| \sup_{m \le l \le K} \mathsf{X}_\alpha^a(V_l) \Big\|_2 + \sum_{j=m+1}^{K} \big[\|\mathsf{X}_\alpha^a(\xi_j)\|_2 + \|\mathsf{X}_\alpha^a(\rho_j)\|_2 + \|\mathsf{X}_\alpha^a(v_j)\|_2 \big] \le C(1+m)^c B^{-s_0 m}. \tag{34.60}$$

For the ordered forms, (34.55), (34.56), and (34.58) imply the same summed tail, separately for each of the three forms. These estimates use the Minkowski inequality, not independence between an earlier field and a later coefficient.

We now treat the products, following the fourth column of Table 34.2, for the uncentered summands of Step 2. Their values at zero fluctuation are $(0, 0, R_j, U_j)$ and their first variations are $(\xi_j, 0, \rho_j, v_j)$. Thus the product $(\tilde{s}, \tilde{s})$ and all seven products containing $\tilde{z}$ vanish at first order. The two products $(\tilde{s}, \tilde{r})$ and $(\tilde{r}, \tilde{s})$ are exactly (34.53). The product $(\tilde{r}, \tilde{r})$ and the two cross terms with $\tilde{r}$ are the derivatives of T^{VV}, $T^{\mathsf{UV}} - T^{\mathsf{VV}}$, and

$T^{\mathsf{VU}} - T^{\mathsf{VV}}$, which have the separate tails just proved. For the seven products containing $\tilde{u}$, each nonzero derivative has one linear factor and one deterministic classical factor. For example, the derivative of $\mathcal{Q}_a(\tilde{r}, \tilde{u})$ is $\mathcal{Q}_a(\rho, U) + \mathcal{Q}_a(R, v)$, and the reversed order reverses both brackets; the derivative of $\mathcal{Q}_a(\tilde{u}, \tilde{u})$ is $\mathcal{Q}_a(v, U) + \mathcal{Q}_a(U, v)$; the derivatives for $(\tilde{s}, \tilde{u})$ and $(\tilde{u}, \tilde{s})$ pair ξ with U; and those for $(\tilde{z}, \tilde{u})$ and $(\tilde{u}, \tilde{z})$ vanish, as already counted among the products with $\tilde{z}$. This accounts for all sixteen products.

We use the two ordered inequalities (34.6). The deterministic norms of X_j and R_j are bounded by (34.45) and (34.11), and the linear predictable terms are summed by (34.59). For the factors paired with a deterministic predictable term, the series of the zero-fluctuation maps gives the sharper deterministic sum

$$\sum_{j=m+1}^{K} \mathsf{H}^a_\sigma(U_j(0)) \le C \sum_{j>m} \frac{r^2 \varrho^{2(j-1)}}{\ell_{j-1}} \le C \frac{r^2 \varrho^{2m}}{\ell_m} = C r^2 H_0^{-2\kappa} \ell_m^{2\kappa-1}. \tag{34.61}$$

The ratio in this sum is $B\varrho^2 = \mathfrak{q} < 1$, and there is no term $d_m p_m$ at this base point. Multiplication by (34.60) bounds all the remaining products. It also bounds both orders of the cross terms with the predictable term,

$$\mathcal{Q}_a(V_{j-1}, U_j) + \mathcal{Q}_a(X_{j-1}, v_j) \qquad \text{and} \qquad \mathcal{Q}_a(U_j, V_{j-1}) + \mathcal{Q}_a(v_j, X_{j-1}).$$

The two cross terms with s are (34.52), and the two cross terms with z vanish. This covers both orders of every cross term. The constant in (34.6) is valid at every mesh $a = L/N$, including the finitely many coarse meshes at fixed L; no condition $a \le 1$ is needed.

Differentiating the finite telescope (34.5) and summing these bounds geometrically, we obtain, with $s < s_0$ if a polynomial factor is absorbed,

$$\big\| \mathsf{X}^a_\alpha(V_K) + \mathsf{Y}^a_\alpha(Z_K) \big\|_{L^2(G)} \le C(1+m)^c B^{-sm}. \tag{34.62}$$

This proves the asserted bound on the first-order variation of the flow data, before the flow is applied.

Step 6: the derivative of the flow. We check the hypotheses of Theorem 25.13 without assuming a uniform bound on second derivatives for an unbounded Gaussian family. We fix a deterministic finite vector of inputs of the steps after m, let η_K be the solution of (34.46) with G replaced by this vector, and let $v = I_{a\to a}(\eta_K/a)$ be the corresponding direction of the initial potential. Let $V = P^a_\cdot v$ and $Z = \mathcal{Q}_a(X_K, V) + \mathcal{Q}_a(V, X_K)$; these are V_K and Z_K when the deterministic vector is subsequently replaced by G. We write $\mathscr{H}_a(A_0)$ for the based cycle triple of the Wilson flow started from $\exp(aA_0)$. By the chain rule, the derivative of $\mathcal{H}_K(y, q)$ in these directions is $D\mathscr{H}_a(v_K/a)[\eta_K/a]$.

At a fixed cutoff, we consider the family of initial potentials $v_K/a + \varsigma\tau v$, where $\varsigma \in (-2, 2)$ and $\tau > 0$ is deterministic. Its flow data are

$$\big(X_K + \varsigma\tau V,\ Y_K + \varsigma\tau Z + \varsigma^2\tau^2 \mathcal{Q}_a(V, V)\big).$$

We choose τ so that $\tau[\mathsf{X}_\alpha^a(V)+\mathsf{Y}_\alpha^a(Z)]\le 1/16$, $\tau^2\mathsf{Y}_\alpha^a(\mathcal{Q}_a(V,V))\le 1/16$, and the perturbation of the initial link variables stays within one quarter of the fixed margin of the logarithmic chart. Such a $\tau>0$ exists for each deterministic direction, and the zero direction needs no restriction. The flow data and their first two derivatives in ς are then bounded by $R_2=R_{\mathrm{cl}}+C$ on $U_1=(-2,2)$, uniformly in the mesh, and we take $U_0=(-1,1)$. The parameter space has dimension one, the parameter domains and chart margins are fixed, the loops and the positive observation time are the given ones, and all damping gauges start at the identity in the same frame. These are the hypotheses of Theorem 25.13. Its restart at a positive time uses the local chart and the C_a^1 bound already proved, and its fixed restarts include the conjugations at the basepoint. Thus its real differential is the differential of the based holonomy matrices of the Wilson flow used here.

To obtain a bound independent of the rescaling τ, we apply Remark 34.8 on the fixed ball of radius $R_{\mathrm{cl}}+1$ to the configurations of the family at ς and at 0, divide by $|\varsigma|\tau$, and let $\varsigma\to 0$. The difference of the flow data divided by $|\varsigma|\tau$ tends in both norms to (V,Z); the remaining term is bounded by $|\varsigma|\tau\mathsf{Y}_\alpha^a(\mathcal{Q}_a(V,V))$ and tends to zero at this fixed cutoff. We obtain

$$\max_i\big|D\mathscr{H}_{a,i}(v_K/a)[\eta_K/a]\big|\le C\big\{\mathsf{X}_\alpha^a(V_K)+\mathsf{Y}_\alpha^a(Z_K)\big\}. \tag{34.63}$$

The constant depends on R_{cl} and the fixed time and reference data, not on the rescaling, the direction, the cutoff, or m. The finitely many coarse meshes are included in both results on the flow. Differentiating the reconstruction instead of the straight line of initial potentials gives the same first derivative by the chain rule, and higher derivatives at the initial time do not enter (34.63).

Step 7: the logarithm and the conclusion. At the base point the cycle holonomies are exactly $\mathrm{Hol}(V_y)$. The compact regular patch has the margin for the logarithm of Theorem 33.11, and the differential of Log is uniformly bounded there. In the notation of that theorem, its differential on the right-trivialized variation $\delta H_i H_i^{-1}$ is J_i^{-1}, with $J_i=\int_0^1 e^{s\vartheta_i\,\mathrm{ad}_u}\,ds$, where $u\in S^2$ is the color axis of the background. The projection $P_{\mathcal{N}_y}$ has norm at most one. Composing (34.63) with this differential and this projection, we obtain the pointwise bound

$$\Big|\sum_{j=m+1}^{K}\mathsf{A}_{j,K}(y)G_j\Big|\le C\big\{\mathsf{X}_\alpha^a(V_K)+\mathsf{Y}_\alpha^a(Z_K)\big\}.$$

By the definition of the diagonal matrices D_j in (34.46), these are exactly the blocks of the statement. Equivalently, the chain rule gives $D_{w_j}(\mathrm{Log}\circ\mathcal{H}_K)=D_{q_j}(\mathrm{Log}\circ\mathcal{H}_K)\,\mathrm{diag}_{r,e}(g_{j,r})$, and multiplication by $\gamma^{-1/2}P_{\mathcal{N}_y}$ gives exactly the first expression for $\mathsf{A}_{j,K}$ in the statement. Squaring, taking the Gaussian expectation, and using (34.62), we obtain the claim with $\epsilon=2s$, after relabeling the polynomial exponent.

For comparison with the covariance notation of Section 35, independence and $\mathbb{E} G_j G_l^{\mathsf{T}} = \mathbf{1}_{j=l} I$ give exactly

$$\mathbb{E}_G \Big| \sum_{j=m+1}^{K} \mathsf{A}_{j,K} G_j \Big|^2 = \sum_{j=m+1}^{K} \operatorname{tr}\big(\mathsf{A}_{j,K} \mathsf{A}_{j,K}^{\mathsf{T}}\big).$$

The transpose here is the Euclidean transpose in the counting coordinates of the fluctuation variables, not an adjoint with respect to physical volumes; the physical volumes are already contained in the deterministic rows. Every bound above is uniform over the finite cover of the compact patch, the prior depths, K, m, and the coupling. This completes the proof. □

34.8 Flat support of weak-coupling subsequential limits

In this section, we prove that the continuum measures concentrate on flat connections as $\gamma \to 0$. We fix the data of Definition 34.1 before varying $0 < \gamma \le \gamma_0 \le 1$; the hierarchy is the one fixed by Theorem 23.2. Here we choose the common input horizon $T = T_0 \ge \max\{1, L^2, \theta L^2\}$, and all flow-data norms and the preceding comparison estimates are evaluated on $[0, T_0]$. Later observation times need not lie in this interval: they are reached by the monotonicity of the energy after a short initial comparison. Let $n_* \in 4\mathbb{N}$ define the lattice refinement sequence $n_* B^K$, $K \ge 0$. We use a comparison side $n = n_* B^{k_0}$ of this sequence which satisfies the minimum-side condition, the condition on flat fields, and the conditions on the working radius above; in particular $2\pi/n < r_{\mathrm{flat}}/4$. The sequence, the hierarchy, the side n, and all the bounds are fixed before the coupling and do not change as $\gamma \to 0$. We write $N_K = nB^K$, $a_K = L/N_K$, and $\nu_{K,\gamma} = \nu_{N_K,n,\gamma}$. The law of the coarse field $V = V^{JK}$ under $\nu_{K,\gamma}$ is the stopped measure $\widehat{\nu}_{n,JK,\gamma}$, by item (9) of Theorem 14.8. Let $\lambda_\gamma = \lambda_{L,\gamma,[n_*]}$ be the continuum measure of Corollary 29.26. Constants have the dependence described in items (6) and (7) of Definition 4.14.

Theorem 34.13. *Fix $L > 0$, the hierarchy, $n_* \in 4\mathbb{N}$, and a ceiling $0 < \gamma_0 \le 1$, all before varying the coupling, and consider the lattice refinement sequence $n_* B^K$. Comparison sides $n = n_* B^{k_0}$ are required to satisfy the conditions of Definition 34.1. Let $\lambda_\gamma = \lambda_{L,\gamma,[n_*]}$ be the continuum measures of Corollary 29.26. Then the following statements hold.*

1. *For every $t > 0$ and $\delta > 0$,*

$$\lambda_\gamma\{X : E_L(X(t)) > \delta\} \longrightarrow 0 \qquad (\gamma \to 0). \tag{34.64}$$

   More precisely, for every comparison side n as above, fixed before the coupling, there exist $\gamma_1 > 0$ and $C_{n,t,\delta} < \infty$ such that this probability is at most $C_{n,t,\delta}(\sqrt{\gamma} + \gamma)$ for $0 < \gamma \le \gamma_1$.
2. *For every $\eta > 0$ there exist finite $R_j \ge 0$ such that*

$$\inf_{0<\gamma\le\gamma_0} \lambda_\gamma\big\{X : E_L(X(L^2 2^{-j})) \le R_j \text{ for all } j \ge 1\big\} \ge 1 - \eta.$$

The set in this display is compact for $\mathcal{T}_W$ and for d_c. Every sequence $\gamma_k \to 0$ has a subsequence along which λ_{γ_k} converges, against all bounded $\mathcal{T}_W$-continuous functions and weakly for d_c, to the same Borel probability measure. Along this subsequence the images of λ_{γ_k} in the Sobolev trajectory space of Definition 29.1 also converge against every bounded $\mathcal{T}_{1,2}$-continuous function.

3. *Every subsequential limit, in either of the topologies of item (2), is supported on the set*

$$\mathcal{F}_L^{\mathrm{stat}} = \big\{X : X(t) = [A] \text{ for all } t > 0,\ F_A = 0\big\}$$

of stationary flat trajectories. This set is compact, and the cycle holonomies identify it with

$$\mathcal{F}_L \simeq \mathrm{Hom}(\mathbb{Z}^3, \mathrm{SU}(2))/\mathrm{SU}(2) \simeq (\mathbb{R}/4\pi\mathbb{Z})^3/\{\boldsymbol{\vartheta} \sim -\boldsymbol{\vartheta}\},$$

including the eight central triples. Every subsequential limit is the image of a Borel probability measure on this compact space.

The constants in item (1) have the dependence described in item (6) of Definition 4.14, with the displayed additional parameters, and the ultraviolet limit has been taken at each fixed coupling before $\gamma \to 0$. The theorem does not identify the probability measure on the moduli space: it asserts neither uniqueness of the subsequential limit nor a density on the moduli space, and it makes no assertion about unbounded moments of the energy or about ultraviolet convergence uniform down to zero coupling.

The proof combines four facts. The effective classical action of the coarse field has moments of order γ. The zero-fluctuation reconstruction from the coarse field has lattice energy exactly proportional to this action. The flow data of the reconstruction differ from those of the zero-fluctuation reconstruction by $O(\sqrt{\gamma})$ in every moment. Finally, a short-time comparison of the two Wilson flows, followed by the monotonicity of the energy, transfers this to the energy at positive times. We first prove two lemmas.

The coarse effective action and the zero-fluctuation reconstruction

Lemma 34.14. *Use the data above and the families of coarse densities of Theorem 33.8. On the support of the stopped measure write $E_d(V) = E_{d,\mathrm{sat}}(V)$, and put $g^2 = \gamma/n$ and $D_n = 6n^3 - 2$. There exists $\gamma_1 \in (0, \gamma_0]$, independent of the depth, such that for every fixed real $p > 0$ and every depth d allowed in Theorem 33.8,*

$$\mathbb{E}_{\widehat{\nu}_{n,d,\gamma}} E_d^p \le C_{n,p} g^{2p}, \qquad \mathbb{E}_{\widehat{\nu}_{n,d,\gamma}} E_0^p \le C_{n,p} g^{2p} \qquad (0 < \gamma \le \gamma_1),$$

where $E_0 = S_W$ is the Wilson action of Definition 4.1 on the lattice of side n. At $d = JK$, start from the same representative $\widehat{\theta}_0(V)$ of the coarse field as the reconstruction, and set $\widehat{\theta}_j^0 = P_j \cdots P_1 \widehat{\theta}_0(V)$. Then the configuration $U_K^0(V) = \exp \widehat{\theta}_K^0$ on the finest lattice satisfies

$$E_0(U_K^0(V)) = B^{-K} E_{JK}(V), \qquad \mathsf{E}_{a_K}(U_K^0(V)) = \frac{2n}{L} E_{JK}(V), \tag{34.65}$$

where on the left E_0 is the Wilson action on the finest lattice and E_{a_K} is the lattice energy (2.2)*. In particular, the expected initial lattice energy of $U_K^0(V)$ under the stopped measure is at most $C_n\gamma$, and the expectation of its p-th power is at most $C_{n,p}\gamma^p$.*

The constants depend in addition on p and on the fixed bounds on the coarse density, and they are independent of the coupling and of the depth. The identities (34.65) are exact for every finite K, including $K = 0$, with the prior depths $J(K-j)$ ending at depth zero.

Proof. By Theorem 33.8, the stopped measure has the density

$$\widehat{Z}^{-1}\mathbf{1}_{D_r}e^{-E_d/g^2-\overline{R}_{d,\gamma}}\,dH_n, \qquad E_d \geq \kappa E_0 \geq 0, \quad |\overline{R}_{d,\gamma}| \leq C_n,$$

where $\kappa > 0$ is the constant of Theorem 33.8; in this proof κ denotes this constant, not the contraction exponent of Definition 34.1. These bounds apply to the law of the coarse field under the conditioned measure itself, not to an interior stopped measure in its place. The lower bound of Theorem 33.10 is $\widehat{Z} \geq c_n g^{D_n}$ for $g \leq g_0(n)$. We choose $\gamma_1 \leq \min\{\gamma_0, ng_0(n)^2\}$, so that also $g \leq 1$. Since $u^p e^{-u} \leq C_p e^{-u/2}$ for $u \geq 0$, we have

$$\begin{aligned}\mathbb{E}_{\widehat{\nu}}E_d^p &\leq C_{n,p}g^{2p-D_n}\int_{D_r} e^{-E_d/(2g^2)}\,dH_n \\ &\leq C_{n,p}g^{2p-D_n}\int_{\mathcal{U}_n} e^{-\kappa E_0/(2g^2)}\,dH_n \leq C_{n,p}g^{2p}.\end{aligned}$$

In the first inequality we used the bound on $\overline{R}_{d,\gamma}$ and the lower bound on $\widehat{Z}$. In the last inequality we used the upper bound for the integral over the compact configuration space in Theorem 33.10, with the coefficient $\kappa/2$. The lower bound $E_d \geq \kappa E_0$ then implies the bound for E_0^p. In particular, the stopped measure concentrates near the set of all flat coarse fields: outside any fixed open neighborhood of $\{E_0 = 0\}$ the continuous function E_0 has a positive minimum, and Markov's inequality applies.

We now check that the configuration in the identity is the zero-fluctuation continuation of Definition 34.1. At level j the prior depth is $d_j = J(K-j)$. By Theorems 15.12 and 15.13, P_j is the constrained minimization of the renormalization group step followed by its based gauge transformation, which depends only on the coarse field. It preserves the gauge orbit of the minimizer and the value of the effective classical action. Iterating the nested minimization identity $E_{d+1}(c) = M\min_z E_d(b(c,z))$ of Theorem 10.10 through the J averaging steps of the renormalization group step, we obtain, at every zero-fluctuation input in the reconstruction domain,

$$E_{d_j}\big(e^{\widehat{\theta}_j^0}\big) = B^{-1}E_{d_j+J}\big(e^{\widehat{\theta}_{j-1}^0}\big).$$

For the chosen representative of the coarse field, the initial value on the right is $E_{JK,\mathrm{sat}}(V)$; the extension $E_{JK,\mathrm{sat}}$ agrees with E_{JK} on the support and does not change it. All changes

of representative are compact gauge transformations, which preserve this value. Iterating over $j = 1, \dots, K$ ends at $d_K = 0$ and proves the first identity. The continuation sets the fluctuation variables w to zero, not the centered variables $w - \mathbb{E}(w \mid \mathcal{F})$, and no conditional mean is substituted for the minimizer. Finally, by Lemma 29.14 we have $\mathsf{E}_{a_K} = 2E_0/a_K$. Since $a_K = (L/n)B^{-K}$, this proves the second identity, and the moment bounds follow from the first part of the lemma and $g^2 = \gamma/n$. The identity also covers $K = 0$, without iteration. □

Early-time comparison and energy monotonicity

Lemma 34.15. *Fix $L, R > 0$, $1/2 < \alpha < 2/3$, $T_0 \geq 1$, and $\tau > 0$. There exist $a_* > 0$ and $C < \infty$ with the following property. Let $a = L/N \leq a_*$, and let $U = e^{aA_0}$ and $U' = e^{aA'_0}$ be configurations on the lattice of mesh a, represented in the same initial frame, whose flow data $\mathcal{E}_a = (x_a, y_a)$ and $\mathcal{E}'_a = (x'_a, y'_a)$ as in Definition 24.3 have norms at most R on $[0, T_0]$. Put*

$$d_a = \mathsf{X}^a_\alpha(x_a - x'_a) + \mathsf{Y}^a_\alpha(y_a - y'_a),$$

with both full norms on this lattice and this horizon. Then, for the Wilson flow run for the lattice flow time $4t/a^2$,

$$\sup_{t \geq \tau} \mathsf{E}_a\big(\Psi^{(N)}_t U\big) \leq \mathsf{E}_a(U') + C d_a, \qquad \sup_{t \geq \tau} \mathsf{E}_a\big(\Psi^{(N)}_t U\big) \leq C.$$

The second bound requires only the bound on the norm of $\mathcal{E}_a$.

The constants have the dependence described in item (7) of Definition 4.14 on the displayed parameters and on the fixed chart and stencil; they are independent of the coupling, of any probability measure, of the depth, and of the configurations.

Proof. Let $T_R \leq 1$ be the lifetime in Theorem 24.5, and choose $s = \min\{\tau, T_R\}/2 > 0$. Applied to the two flow data, that theorem yields local damped representatives A_a and A'_a with

$$\|A_a(s) - A'_a(s)\|_{C^1_a} \leq C_{R,s} d_a, \qquad \|A_a(s)\|_{C^1_a} + \|A'_a(s)\|_{C^1_a} \leq K_{R,s}.$$

The second bound follows from $A = x + y + r$, the two weighted norms, and the bound on the remainder r in that theorem at the fixed positive time s. Its constants and its restriction on the mesh are independent of the coupling. The exponentials of $A_a(s)$ and $A'_a(s)$ are gauge representatives of the two Wilson flows at time s started from U and U'. By gauge invariance and the C^1_a estimate for the lattice energy in Lemma 29.14,

$$\mathsf{E}_a\big(\Psi^{(N)}_s U\big) \leq \mathsf{E}_a\big(\Psi^{(N)}_s U'\big) + C d_a \leq \mathsf{E}_a(U') + C d_a,$$

where in the last inequality we used that the energy does not increase along the flow. The same monotonicity from s to every $t \geq \tau$ proves the first assertion. The uniform bound on the energy on a bounded C^1_a ball in Lemma 29.14 gives $\mathsf{E}_a(\Psi^{(N)}_s U) \leq C$, and monotonicity proves the second assertion. □

Proof of the support theorem

Proof of Theorem 34.13. Step 1: the coarse action and the zero-fluctuation reconstruction. By Lemma 34.14, for $0 < \gamma \le \gamma_1$ the expectation of $(2n/L)E_{JK}(V)$ under $\nu_{K,\gamma}$ is at most $C_n\gamma$, uniformly in K, and this quantity is exactly the initial lattice energy of the zero-fluctuation reconstruction $U_K^0(V)$.

Step 2: the distance between the flow data. We take $m = 0$ in Theorem 34.9 and denote by

$$D_K = \mathsf{X}_\alpha^{a_K}(x_K - x_K^0) + \mathsf{Y}_\alpha^{a_K}(y_K - y_K^0)$$

the distance between the flow data of the reconstruction and of the zero-fluctuation continuation from the coarse field. By that theorem, for every fixed $p \ge 1$ we have

$$\|D_K\|_{L^p(\nu_{K,\gamma})} \le C_{n,p}\big\{\sqrt{\gamma} + \gamma(1 + |\log\gamma|)^d\big\} \le C'_{n,p}\sqrt{\gamma},$$

uniformly in K and in the coupling; the last inequality uses the bound on $\sqrt{\gamma}(1+|\log\gamma|)^d$ from the proof of Lemma 34.6. By Lemma 34.4, the norm of the flow data of the continuation is at most R_{cl}, deterministically for every coarse field in the reconstruction domain and independently of K and γ.

Step 3: comparison of energies. On the event $G_K = \{D_K \le 1\}$ both flow data have norm at most $R_{\mathrm{cl}} + 1$. The two configurations to which we apply Lemma 34.15 are $\exp\widehat{\theta}_K$ and $U_K^0(V)$, in the same initial frame on the finest lattice. Indeed $I_{a_K \to a_K}$ is the identity in Definition 34.1, and both pairs consist of the linear heat evolution and the quadratic Picard term of these fine arrays. The zero-fluctuation configuration is the one in (34.65), with the same representative $\widehat{\theta}_0(V)$ of the coarse field; it is neither a flow started on the lattice of side n nor a separately chosen flat approximation. For every K large enough that $a_K \le a_*$, a threshold independent of the coupling, Lemma 34.15 and (34.65) imply that

$$\mathsf{E}_{a_K}\big(\Psi_t^{(N_K)}U\big) \le \frac{2n}{L}E_{JK}(V) + C_{n,t}D_K \qquad \text{on } G_K.$$

The configuration $\exp\widehat{\theta}_K$ is a gauge transform of U by Theorem 15.13, and the inequality concerns the gauge-invariant lattice energy of U. By Step 1, Step 2, and Markov's inequality,

$$\nu_{K,\gamma}\big\{\mathsf{E}_{a_K}\big(\Psi_t^{(N_K)}U\big) > \delta\big\} \le \nu_{K,\gamma}(G_K^c) + \delta^{-1}\mathbb{E}_{\nu_{K,\gamma}}\Big[\frac{2n}{L}E_{JK}(V) + C_{n,t}D_K\Big] \le C_{n,t,\delta}(\sqrt{\gamma} + \gamma).$$

Only the coarse action and the distance between flow data were integrated in this estimate; no unbounded quantity was transferred from the Wilson measure.

Step 4: transfer to the Wilson measure and to the continuum. For a Borel event A, the definition of the conditioned measure gives $\mu_{N_K,\gamma}(A) \le \nu_{K,\gamma}(A) + \mu_{N_K,\gamma}(S^c_{N_K,n,\gamma})$. By Corollary 23.11 with $q = 1$, at this fixed n, the last probability is at most $C_n\gamma$. We apply

this to the event in Step 3. For the ultraviolet limit we use the bounded continuous function

$$f_\delta(v) = \min\{1, \max\{0, 2v/\delta - 1\}\}, \qquad v \geq 0,$$

which equals one for $v \geq \delta$ and vanishes for $v \leq \delta/2$. By Theorem 30.4, at each fixed γ the lattice energy at time t converges in distribution to $E_L(X(t))$ under λ_γ, and the sequences based at n and at n_* have the same limit by Corollary 29.26. Hence

$$\lambda_\gamma\{E_L(X(t)) > \delta\} \leq \mathbb{E}_{\lambda_\gamma} f_\delta(E_L(X(t))) = \lim_{K\to\infty} \mathbb{E}_{\mu_{N_K,\gamma}} f_\delta\big(\mathsf{E}_{a_K}(\Psi_t^{(N_K)} U)\big) \leq C_{n,t,\delta}(\sqrt{\gamma} + \gamma),$$

where in the last inequality we used Step 3 with $\delta/2$ in place of δ and the transfer just described. The limit in the middle is taken at fixed γ, after the uniform estimates at finite K. This proves item (1).

Step 5: common compact containment. We argue directly on the whole interval of small couplings. For each fixed comparison side n, Step 2 implies that

$$\lim_{R\to\infty} \sup_{K\geq 0,\, 0<\gamma\leq\gamma_0} \nu_{K,\gamma}\big\{\|(x_K, y_K)\|_{\mathrm{fl}} > R\big\} = 0,$$

with constants that may depend on n. The second assertion of Lemma 34.15, applied on the event where this norm is at most R, bounds the lattice energy at each fixed $t > 0$ by a finite constant on all sufficiently fine lattices. The finitely many remaining lattices have a deterministic finite maximum of the energy on their compact configuration spaces. Therefore, for each fixed n,

$$\lim_{H\to\infty} \sup_{K\geq 0,\, 0<\gamma\leq\gamma_0} \nu_{K,\gamma}\big\{\mathsf{E}_{a_K}\big(\Psi_t^{(N_K)} U\big) > H\big\} = 0.$$

The comparison side may now be enlarged to reach a prescribed tolerance, always before the coupling is chosen. By Theorem 23.9 and Corollary 23.11,

$$\epsilon_n = \sup_{K\geq 0,\, 0<\gamma\leq\gamma_0} \mu_{nB^K,\gamma}\big(S^c_{nB^K,n,\gamma}\big) \longrightarrow 0 \qquad (n = n_* B^{k_0},\ k_0 \to \infty).$$

Indeed, the bound of Theorem 23.9 is the sum of $C' n^3 e^{-\bar{c} n/\gamma}$ and $C_{\mathrm{w}} n^3 e^{-a_{\mathrm{w}} \log^2 \sqrt{Mn/\gamma}}$; both terms are largest at $\gamma = \gamma_0$ and tend to zero as $n \to \infty$. We choose n so that ϵ_n is small, and then the radius and the energy threshold for the conditioned measure. The transfer of bounded events gives uniform tails of the lattice energy under the Wilson measure along the sequence nB^K, and the finitely many initial terms of the sequence $n_* B^K$ below n have deterministic finite energy bounds as well. Thus

$$\lim_{H\to\infty} \sup_{K\geq 0,\, 0<\gamma\leq\gamma_0} \mu_{n_* B^K,\gamma}\big\{\mathsf{E}_{L/(n_* B^K)}\big(\Psi_t^{(n_* B^K)} U\big) > H\big\} = 0.$$

For each γ separately, the convergence of the energy at fixed coupling used in Step 4 and the portmanteau inequality for the open set $\{v > H\}$ give the same uniform tails for $\lambda_\gamma\{E_L(X(t)) > H\}$. No ultraviolet limit uniform in the coupling was used.

We now apply Theorem 29.6. We choose R_j such that the energy tail at time $s_j = L^2 2^{-j}$ is smaller than $\eta 2^{-j-1}$, uniformly in the coupling, and use the union bound. The compact set $\mathcal{K}(R)$ of that theorem, with $R = (R_j)_j$, gives the asserted common containment and the extraction of subsequences for $\mathcal{T}_W$ and for d_c. This proves item (2), except for the Sobolev images, which we treat in the next step.

Step 6: identification of the support. Let λ_* be a subsequential limit obtained from this extraction. All finite joint laws of regularized Wilson loops converge along the subsequence, since these coordinates are bounded and $\mathcal{T}_W$-continuous. The general sequence clause of Theorem 30.5 applies: the energies at every positive time are tight, as just proved, and the joint limit of the Wilson loops is given by the Borel probability measure λ_*. That clause gives convergence of the Sobolev images to $(i^{1,2})_\# \lambda_*$. By Lemma 29.7, for any $s, \delta > 0$ the function

$$Z \longmapsto \min\{1, E_L(Z(s))/\delta\}$$

is bounded and continuous in the Sobolev trajectory topology. Its expectation under λ_γ tends to zero by item (1): for every $\varepsilon > 0$, it is at most $\varepsilon/\delta + \lambda_\gamma\{E_L(X(s)) > \varepsilon\}$. Its expectation under the limit is therefore zero. At each time s_j we obtain $E_L(X(s_j)) = 0$, λ_*-almost surely. We take the countable intersection of these events of full measure. Since the energy does not increase along the flow (Theorem 29.6) and $s_j \downarrow 0$, we have $E_L(X(t)) = 0$ for every $t > 0$ on this event.

Since the energy is the sum of the squared norms of the curvature components, every smooth orbit at these times is flat. For a flat smooth connection the right side of the Yang–Mills heat equation vanishes, and the uniqueness of smooth solutions in Theorem 24.10 makes its future orbit constant. The trajectory relation then makes X a single stationary flat trajectory on $(0, \infty)$.

This proves the support property for every subsequential limit for $\mathcal{T}_W$. If a subsequence converges only weakly for d_c, we apply the common compact containment again to extract a further subsequence that converges for $\mathcal{T}_W$. Since the identity map from $\mathcal{T}_W$ to d_c is continuous by Theorem 29.3, the limit for d_c coincides with the limit for $\mathcal{T}_W$; equivalently, their finite-dimensional laws of the determining coordinates agree, and the same theorem identifies the Borel probability measures. The limit for d_c is therefore supported on stationary flat trajectories as well.

Step 7: the moduli space. We include the classification of flat connections on the torus; it is standard, and we check its normalization. A smooth flat connection lifted to the universal cover $\mathbb{R}^3$ has a path-independent transport $P_A(x)$ from a fixed basepoint, with $dP_A = P_A A$ and $P_A(x + Le_i) = h_i P_A(x)$. Flatness makes the three matrices h_i commute.

Conversely, a commuting triple in $\mathrm{SU}(2)$ is simultaneously diagonalizable, and it is realized by the constant flat connection $A_i = \vartheta_i \tau_3 / L$ with $h_i = e^{\vartheta_i \tau_3}$. If two flat connections A and B have the same holonomies at the basepoint, then $k(x) = P_B(x)^{-1} P_A(x)$ is smooth and periodic and gives $A^k = B$, by the conventions for gauge transformations and transport in Definition 4.10. Conjugate holonomies are handled by a constant gauge transformation at the basepoint. Two simultaneously diagonal triples are conjugate exactly when they agree or are related by the common Weyl inversion $\boldsymbol{\vartheta} \mapsto -\boldsymbol{\vartheta}$, and each angle has period 4π. This proves the two displayed identifications, including the central points.

The map from the compact quotient of angles to stationary trajectories is continuous for $\mathcal{T}_W$, since every holonomy of a constant commuting connection around a loop depends continuously on the three cycle holonomies, through the integer winding vector of the loop. It is a bijection onto the stationary flat trajectories. The target is Hausdorff, since d_c separates points by Theorem 29.3. A continuous bijection from a compact space onto a Hausdorff space is a homeomorphism, so the identification holds for $\mathcal{T}_W$ and also for d_c. Alternatively, the set of stationary flat trajectories is exactly $\mathcal{K}(0)$ in Theorem 29.6. Pulling back a probability measure supported on this set gives the asserted probability measure on the moduli space, which proves item (3). □

Proof of Theorem 2.9. Fix $L > 0$, an odd integer $M \geq 3$, and n divisible by four, as in Theorem 2.9, and set $n_* = n$. Let the hierarchy, in particular the integer J, and a ceiling $\gamma_0 \in (0, 1]$ be as in Theorem 23.2. We choose an integer $k_0 \geq 0$ such that the comparison side $\bar{n} = n_* B^{k_0}$ satisfies the minimum-side condition and the condition on flat fields of Definition 34.1, and we apply Theorem 34.13 with the original base n_* and this comparison side. All these choices precede the coupling. By item (4) of Theorem 29.28, for every $0 < \gamma \leq \gamma_0$ the measure $\lambda_{L,\gamma,[n]_M}$ of Theorem 2.3 coincides with the measure $\lambda_{L,\gamma,[n_*]}$ of Corollary 29.26 built from this hierarchy. Parts (1), (2), and (3) of Theorem 2.9 are therefore items (1), (2), and (3) of Theorem 34.13. □

Terms	The terms themselves (Theorem 34.7)	Difference from the zero-fluctuation counterpart (Theorems 34.9 and 34.11)	First derivative at a flat base point, for the uncentered summands (Lemma 34.12)

Table 34.2. The tools used for the sixteen ordered products and the eight cross terms in (34.5). Both orders of every pair are estimated separately. In the fourth column, s, z, r, and u stand for the uncentered summands $\tilde{s}_j$, $\tilde{z}_j$, $\tilde{r}_j$, and $\tilde{u}_j$ of the deterministic reconstruction in the proof of Lemma 34.12, whose values at zero fluctuation are $(0,0,R_j,U_j)$ and whose first variations are $(\xi_j,0,\rho_j,v_j)$; they are not the centered summands of (34.1).

SECTION 35

Normal fluctuations near regular commuting holonomies

This section studies the continuum measure λ_γ of Theorem 2.3 at weak coupling near a regular point of the space of flat connections, and proves Theorem 2.10. We observe the holonomies $H = (H_1, H_2, H_3)$ of a trajectory at the fixed time $t = \theta L^2$ around the three coordinate cycles of $\mathbb{T}^3_L$, and their logarithms $X = \operatorname{Log} H \in \mathfrak{su}(2)^3 \simeq \mathbb{R}^9$ in a fixed identity chart. Commuting triples correspond to the cone $\mathcal{M}$. Away from the origin it is a five-dimensional manifold whose normal space $\mathcal{N}_y$ at y has dimension four, and near a regular point we write $X = y + b$ with $y \in \mathcal{M}$ and $b \in \mathcal{N}_y$. We prove three results. After localization to a fixed regular patch, the normalized normal component $\gamma^{-1/2}\Sigma_\theta(y)^{-1/2}b$ is compared, in the weighted normal-bundle sense, with a standard Gaussian vector in $\mathcal{N}_y$ and the same γ-dependent tangential marginal, where Σ_θ is the explicit covariance of (4.12) (Theorem 35.4). The localized quadratic form $q_*/\gamma = b^{\mathsf{T}}\Sigma_\theta(y)^{-1}b/(2\gamma)$ has the limit law with density se^{-s} on $[0,\infty)$ (Theorem 35.3). The normalized regression residual variance $\mathscr{C}_\gamma$ of Theorem 2.10 equals $2\gamma^2 + o(\gamma^2)$ (Theorem 35.2).

The following heuristic explains the coefficient. If $z = \gamma^{-1/2}\Sigma_\theta(y)^{-1/2}b$ were exactly a standard Gaussian vector in four dimensions, independent of y, then $q_*/\gamma = |z|^2/2$ would have mean 2, second moment 6, and variance 2. The observables of Theorem 2.10 are $B_{\mathrm{obs}} = \psi$ and $A_{\mathrm{obs}} = \psi q_*$, where $\psi = \psi_0(y)\chi(b)$ is a fixed tangential cutoff times a normal cutoff equal to one near $b = 0$. Omitting the normal cutoff, we set $B = \psi_0(y)$ and $A = \gamma B|z|^2/2$. If z is standard Gaussian and independent of y, the best affine predictor of A from B is $2\gamma B$, with mean square error $2\gamma^2\mathbb{E}B^2$, and dividing by $\mathbb{E}B^2$ gives $2\gamma^2$. The proofs control the effect of the normal cutoff. The coefficient 2 is a property of four-dimensional Gaussian vectors, and a conditional normal Gaussian measure with the same covariance reproduces it (Lemma 35.17). The theorems show that the continuum measure has this Gaussian behavior in the normal directions, with the precise covariance $\gamma\Sigma_\theta(y)$, while its tangential marginal is not identified and may depend on γ. For comparison, the same statistic vanishes for the Abelian Maxwell measure with Haar cycle holonomies, and it is a positive constant independent of γ for Gaussian holonomies with independent Haar factors (Lemma 35.17).

Near a regular point the flat connections form a nondegenerate critical manifold of the action in the sense of Bott [31], and the $\sqrt{\gamma}$ scaling in the normal directions is

the usual Laplace asymptotics transverse to such a manifold (see [155]). The uniform versions on the coarse lattice that we use are proved in Section 33. The treatment of zero-momentum contributions to Wilson loops in finite periodic volume by Coste, González-Arroyo, Jurkiewicz, and Korthals Altes [62] is a related antecedent; the observables, normalization, and regression functional used here are defined below.

The proof works at a finite lattice cutoff, under the conditioned Wilson measure $\nu = \nu_{N,n,\gamma}$ with $N = nB^K$ and the coarse side n fixed before γ varies. It rests on two ideas. First, we compare with a Gaussian only finitely many scale variables: the coarse field and the normalized fluctuation variables of the first m renormalization group steps, counted from the coarse side. Their joint law is close to a Gaussian law in a space of fixed dimension, with error of order $\sqrt{\gamma}|\log\gamma|$ (Lemma 35.8). Second, the remaining steps are controlled directly at the scale $\sqrt{\gamma}$ by Section 34: Theorem 34.10 compares the flowed holonomies of the fine configuration with those of the finite-scale reconstruction, and Lemma 34.12 bounds the part of the Gaussian covariance coming from the omitted steps. The Gaussian covariance of all K steps is exactly the normal covariance of the finest lattice (Proposition 33.12), which converges to Σ_θ as $N \to \infty$ (Theorem 33.11). The resulting normalized moment errors have the form

$$C\big(\delta_m^{1/2} + \delta_m + N^{-2}\big) + e_m(\gamma), \qquad e_m(\gamma) \to 0 \text{ as } \gamma \downarrow 0 \text{ for each fixed } m,$$

where $\delta_m \to 0$ is a fixed geometric envelope and C does not depend on m. We then let $K \to \infty$ at fixed γ and m, after removing the conditioning with Corollary 23.11 and passing to the continuum with Theorem 29.25; then $\gamma \downarrow 0$ at fixed m; and finally $m \to \infty$. The constant C_m in the finite-dimensional comparison may be very large; this is harmless because m is fixed before $\gamma \to 0$. The other inputs are the conditional fluctuation kernels and their means (Theorems 13.8 and 13.10), the reconstruction maps (Theorem 15.12), the flat refinements (Lemma 14.9), the parameter derivatives of the Wilson flow (Theorem 25.13), the Laplace estimates and the normalization on the coarse lattice (Proposition 33.12, Corollary 33.4, , and Theorem 33.10), and the trace coordinates and conditioning identities of Lemmas 5.5 and 5.6.

Besides Theorem 2.10, two results of this section are used in Section 36: the uniform regularity of the finite-scale flowed holonomy map near every flat configuration, including the central triples (Theorem 35.9), and the comparison measures (Lemmas 35.16 and 35.17).

The three main theorems are stated in Section 35.1 and proved in Sections 35.6 to 35.8, after the auxiliary results of Sections 35.2 to 35.5; the section ends with the comparison measures (Section 35.9) and the proof of Theorem 2.10.

35.1 Setting and main results

Fixed data. Throughout this section we fix $L > 0$, $\theta > 0$, a horizon $T \geq \theta L^2$, an odd integer $M \geq 3$, an integer $J \geq 1$, $B = M^J$, a coupling ceiling $0 < \gamma_0 \leq 1$, and the construction parameters of Definition 34.1: the cutoff amplitude A_{w}, the radii $r < \rho$, the reconstruction maps of Theorem 15.12, the flow exponents $1/2 < \alpha_{\mathrm{fl}} < 2/3$ and σ_{sm}, and the contraction constant a_{map} with $a_{\mathrm{map}}\sqrt{B} < 1$ and $\mathfrak{q} = Ba_{\mathrm{map}}^2 < 1$. All of these are chosen before γ varies. We fix $n \in 4\mathbb{N}$ satisfying the minimum-side conditions of Definition 34.1; in particular

$$2\pi/n < r_{\mathrm{flat}}/4,$$

where $r_{\mathrm{flat}} < r$ is the flat margin of Lemma 14.9. For $K \geq 0$ we set $N = nB^K$, let $\nu = \nu_{N,n,\gamma}$ be the conditioned Wilson measure of Definition 4.4, and let $\mu = \mu_{N,\gamma}$ be the Wilson measure. The renormalization group steps of the hierarchy are indexed by $j = 1, \dots, K$, counted from the coarse side: the j-th step relates the lattices of sides nB^{j-1} and nB^j. We write $w_j = (w_{j,r,e})_{r,e}$ for the normalized fluctuation variables of the j-th step, indexed by its J intermediate scales r and the links e, and $g_{j,r}$ for the coupling at the intermediate scale r, so that $g_{j,r}^2/\gamma$ is the reciprocal of a fixed lattice side.

Let $\mathcal{H}^K = (\mathcal{H}_i^K)_{i=1}^3$ be the triple of coordinate-cycle holonomies, based at the origin, of the Wilson-flowed fine configuration at time θL^2 (lattice time $4\theta L^2/a_N^2 = 4\theta N^2$), computed for the reconstructed configuration $\exp \widehat{\theta}_K$ of Definition 34.1 in the gauge frame at the basepoint fixed by the reconstruction maps. We call $\mathcal{H}^K$ the flowed holonomy triple. For $0 \leq m \leq K$ let Ξ_m^K be the same triple for the finite-scale reconstruction $\exp \widehat{\theta}_K^0$, in which the coarse field and the normalized fluctuation variables of the first m steps are those of the same sample and all normalized fluctuation variables of the steps after the m-th are set to zero. Both triples are random variables under ν, defined in the same gauge frame at the basepoint, and both are flowed on the finest lattice.

Finally, $\lambda_\gamma = \lambda_{L,\gamma,[n_*]}$ denotes the continuum measure on the trajectory space associated with the sequence nB^K (Corollary 29.26); by Theorem 29.28 it is the measure $\lambda_{L,\gamma,[n]_M}$ of Theorem 2.3. For a trajectory $X \in \mathcal{X}_L$, the coordinate-cycle holonomies of $X(\theta L^2)$ are defined up to simultaneous conjugation, and so are the coordinates introduced below; all observables we evaluate are invariant under simultaneous conjugation.

Constants. Unless stated otherwise, constants c, C and thresholds in this section have the dependence described in item (6) of Definition 4.14. They may depend on n, L, θ, M, J, the construction parameters, the horizon, the flow exponents, the loop lengths, and the patches, tubes, test functions, and extensions fixed below, but not on K, N, the preceding classical depths, the index m, or γ below the relevant threshold. A subscript m, as in C_m or γ_m, allows additional dependence on m (through the first m steps and their finite dimensions); constants without this subscript do not depend on m. Further subscripts indicate dependence on moment orders, powers of γ, or test functions.

Regular coordinates. In the fixed identity chart we write $X = (x_1, x_2, x_3) = \operatorname{Log} H \in \mathbb{R}^9$, identifying $\mathfrak{su}(2)$ with $\mathbb{R}^3$ so that the bracket becomes the cross product. The cone of commuting triples is

$$\mathcal{M} = \{y = (\vartheta_1 u, \vartheta_2 u, \vartheta_3 u) : \boldsymbol{\vartheta} \in \mathbb{R}^3,\ u \in S^2\}, \qquad (\boldsymbol{\vartheta}, u) \sim (-\boldsymbol{\vartheta}, -u).$$

On the regular region $0 < r_0 \le |\boldsymbol{\vartheta}| \le r_1 < \pi$ it is a smooth five-dimensional manifold, parametrized by the three angles $\boldsymbol{\vartheta}$ and the direction u. Its normal space at $y = (\vartheta_i u)_i$ is

$$\mathcal{N}_y = \Big\{ b = (b_1, b_2, b_3) :\ b_i \perp u,\ \sum_i \vartheta_i b_i = 0 \Big\}.$$

The conditions $b_i \perp u$ leave six dimensions, and the relation $\sum_i \vartheta_i b_i = 0$ removes two of them, which gives $\dim \mathcal{N}_y = 4$. Simultaneous conjugation $H_i \mapsto g H_i g^{-1}$ acts on $\mathbb{R}^9$ by the same rotation $\mathrm{Ad}(g)$ in each component; it preserves $\mathcal{M}$ and maps $\mathcal{N}_y$ isometrically onto $\mathcal{N}_{\mathrm{Ad}(g)y}$. Two of the five tangential directions of $\mathcal{M}$ are orbits of this action, which is not removed by fixing a gauge at the basepoint.

We write $\Pi_{\boldsymbol{\vartheta}} = I - \boldsymbol{\vartheta}\boldsymbol{\vartheta}^{\mathsf{T}}/|\boldsymbol{\vartheta}|^2$ and let $\Sigma_\theta(y)$ be the positive definite matrix on $\mathcal{N}_y$ defined in (4.12). By Theorem 33.11, $\gamma\Sigma_\theta(y)$ is the covariance of the linearized flowed cycle logarithms, projected to $\mathcal{N}_y$, under the Gaussian measure of the Maxwell quadratic form around the flat connection with holonomy logarithms y. It does not depend on γ, depends smoothly on y, is equivariant under simultaneous conjugation, and satisfies $cI \le \Sigma_\theta \le CI$ on the regular region. For comparisons of vectors in $\mathbb{R}^9$ we extend the inverse covariance to the ambient matrix $P_{\mathcal{N}_y}\Sigma_\theta(y)^{-1}P_{\mathcal{N}_y}$, which is smooth on the regular region and has the same quadratic form on $\mathcal{N}_y$. Normal matrices are expressed in smooth orthonormal frames of a finite bundle atlas.

For a positive semidefinite matrix Σ we write G_Σ for a centered Gaussian vector with covariance Σ, realized as a linear image of a standard Gaussian vector, so that Σ may be singular. We write G_d for a standard Gaussian vector in a d-dimensional Euclidean space and Γ_y for the standard Gaussian measure on $\mathcal{N}_y$. For a bounded Lipschitz function f we write $\|f\|_{\mathrm{BL}} = \|f\|_\infty + \operatorname{Lip} f$. Its dual distance is not the bounded-Lipschitz distance of Section 4.10, which uses the maximum of the two terms, but differs from it by at most a factor two.

Definition 35.1. Fix compact regular patches $\mathsf{P} \subset \mathsf{P}^+ \subset \mathsf{P}^{++}$ in $\mathcal{M} \cap \{r_0 \le |\boldsymbol{\vartheta}| \le r_1\}$, invariant under simultaneous conjugation, each with nonempty relative interior and contained in the relative interior of the next, and radii $0 < b_{\mathrm{o}} < b^+ < b^{++}$. Put

$$\mathcal{U} = \{y + b :\ y \in \mathsf{P},\ b \in \mathcal{N}_y,\ |b| < b_{\mathrm{o}}\},$$

and define $\mathcal{U}^+$ and $\mathcal{U}^{++}$ in the same way with (P^+, b^+) and $(\mathsf{P}^{++}, b^{++})$. The radius b^{++} is so small that $X = y + b$ are unique coordinates on $\mathcal{U}^{++}$ and that the closure of $\mathcal{U}^{++}$ lies in the identity chart at positive distance from its boundary. The following objects are fixed once, before γ varies.

1. On the whole tube $\mathcal{U}^{++}$ put
$$q_*(y+b) = \frac{1}{2}\, b^{\mathsf{T}} \Sigma_\theta(y)^{-1} b.$$
Outside $\mathcal{U}^{++}$, q_* is a fixed bounded continuous nonnegative function, invariant under simultaneous conjugation; on $\mathrm{SU}(2)^3$ it is evaluated through $X = \operatorname{Log} H$ and extended outside the identity chart by the same bounded function.
2. Let $\psi_0 : \mathsf{P} \to [0,1]$ be smooth and invariant, with compact support in the relative interior of P, and suppose that there exist nonempty open subsets O_0, O_+ of P, invariant under simultaneous conjugation, and $b_* > 0$ with $\psi_0 = 0$ on O_0 and $\psi_0 \geq 2b_*$ on O_+. Let χ be a fixed smooth invariant normal cutoff with $0 \leq \chi \leq 1$, equal to one near the zero section and supported in $\{|b| < b_{\mathrm{o}}\}$; it is a smooth function on the normal bundle. Put $\psi(y+b) = \psi_0(y)\chi(b)$ on $\mathcal{U}$ and $\psi = 0$ elsewhere.
3. Put $B_{\mathrm{obs}} = \psi$ and $A_{\mathrm{obs}} = \psi q_*$, regarded as functions on $\mathrm{SU}(2)^3$ through $X = \operatorname{Log} H$ and extended by zero outside the identity chart.
4. A localizing weight is a function $\widetilde{w}(y+b) = w(y)\chi_w(b)$, extended by zero outside $\mathcal{U}$, where $w \geq 0$ is smooth and invariant with compact support in the relative interior of P, and $0 \leq \chi_w \leq 1$ is smooth, invariant, equal to one near $b = 0$, and supported in $\{|b| < b_{\mathrm{o}}\}$.

For a probability measure P and bounded real random variables A, B with $\mathbb{E}_P B^2 > 0$ and $\operatorname{Var}_P B > 0$, define
$$\mathscr{C}(P; A, B) = \frac{\operatorname{Var}_P A - \operatorname{Cov}_P(A,B)^2 / \operatorname{Var}_P B}{\mathbb{E}_P B^2}, \tag{35.1}$$
and set $\mathscr{C}_\gamma = \mathscr{C}(\lambda_\gamma; A_{\mathrm{obs}}, B_{\mathrm{obs}})$, with $A_{\mathrm{obs}}, B_{\mathrm{obs}}$ evaluated at the coordinate-cycle holonomies of $X(\theta L^2)$.

Every localizing weight, ψ, and ψ^2 are supported in $\mathcal{U} \subset \mathcal{U}^{++}$, so the products $\widetilde{w} q_*^l$, ψq_*^l, and $\psi^2 q_*^l$ involve only the exact quadratic form $b^{\mathsf{T}} \Sigma_\theta(y)^{-1} b/2$, which is nonnegative. The extension of q_* outside $\mathcal{U}^{++}$ plays no role in any of the results. All further patches and tubes used in the proofs (the coarse tubes, the output tubes, and the auxiliary tubes) are chosen before γ varies, nested and with positive margins, between $\mathcal{U}$ and $\mathcal{U}^{++}$ (respectively over patches contained in P^{++}). By Lemma 35.12 below, $\mathscr{C}(P; A, B)$ is the minimal mean square error of an affine predictor of A from B, divided by $\mathbb{E}_P B^2$.

The envelope δ_m. We fix $c, \epsilon > 0$ such that
$$\delta_m = (1+m)^c B^{-\epsilon m}, \qquad m \geq 0,$$
dominates the envelopes in Theorem 34.10 and Lemma 34.12, which have the same form. Then $\sup_m \delta_m < \infty$ and $\delta_m \to 0$ as $m \to \infty$. This choice does not change the dependence of any constant on m.

Main results.

Theorem 35.2. *Evaluate $A_{\mathrm{obs}} = \psi q_*$ and $B_{\mathrm{obs}} = \psi$ at the coordinate-cycle holonomies of $X(\theta L^2)$. These are bounded continuous functions of the seven normalized traces of Lemma 5.6, and they do not depend on γ. There exists $c > 0$ such that, for all sufficiently small $\gamma > 0$,*

$$\mathbb{E}_{\lambda_\gamma} B_{\mathrm{obs}}^2 \geq c, \qquad \mathrm{Var}_{\lambda_\gamma} B_{\mathrm{obs}} \geq c.$$

For $f = \psi$ and $f = \psi^2$,

$$\mathbb{E}_{\lambda_\gamma}[f q_*] = 2\gamma\, \mathbb{E}_{\lambda_\gamma} f + o(\gamma), \qquad \mathbb{E}_{\lambda_\gamma}[f q_*^2] = 6\gamma^2\, \mathbb{E}_{\lambda_\gamma} f + o(\gamma^2),$$

and the normalized regression residual variance satisfies

$$\mathscr{C}_\gamma = 2\gamma^2 + o(\gamma^2) \qquad (\gamma \downarrow 0).$$

Further, there exists C such that for every fixed $m \geq 0$,

$$\limsup_{\gamma \downarrow 0} \Big| \frac{\mathscr{C}_\gamma}{\gamma^2} - 2 \Big| \leq C\big(\delta_m^{1/2} + \delta_m\big),$$

and the right side tends to zero as $m \to \infty$.

Theorem 35.3. *Let $\widetilde{w} = w\chi_w$ be a localizing weight with w not identically zero, evaluated at the coordinate-cycle holonomies of $X(\theta L^2)$. There exist $c_w, \gamma_w > 0$ such that $D_\gamma = \mathbb{E}_{\lambda_\gamma} \widetilde{w} \geq c_w$ for $0 < \gamma \leq \gamma_w$. For such γ define the probability measure*

$$\pi_\gamma(A) = \frac{\mathbb{E}_{\lambda_\gamma}\big[\widetilde{w}\, \mathbf{1}_{\{q_*/\gamma \in A\}}\big]}{\mathbb{E}_{\lambda_\gamma} \widetilde{w}}, \qquad A \subset [0,\infty) \text{ Borel}.$$

As $\gamma \downarrow 0$, π_γ converges weakly to the law of $|G_4|^2/2$, which has density $s e^{-s}$ on $[0,\infty)$. Equivalently, for every bounded continuous $f : [0,\infty) \to \mathbb{R}$,

$$\frac{\mathbb{E}_{\lambda_\gamma}[\widetilde{w}\, f(q_*/\gamma)]}{\mathbb{E}_{\lambda_\gamma} \widetilde{w}} \longrightarrow \mathbb{E} f(|G_4|^2/2) = \int_0^\infty f(s)\, s e^{-s}\, ds.$$

Further, there exist C_w, independent of m, and for each fixed $m \geq 0$ a function $e_{m,w}$ with $e_{m,w}(\gamma) \to 0$ as $\gamma \downarrow 0$, such that for every bounded Lipschitz f and all sufficiently small γ, depending on m,

$$\Big| \int f\, d\pi_\gamma - \mathbb{E} f(|G_4|^2/2) \Big| \leq \|f\|_{\mathrm{BL}} \big[C_w(\delta_m^{1/2} + \delta_m) + e_{m,w}(\gamma) \big].$$

Since $q_* \geq 0$ on the support of $\widetilde{w}$, the measure π_γ is a probability measure on $[0,\infty)$.

Theorem 35.4. *Let $\widetilde{w}$, D_γ, c_w, and γ_w be as in Theorem 35.3. On $\{\widetilde{w} \neq 0\}$ write the logarithm of the coordinate-cycle holonomy triple of $X(\theta L^2)$ as $y_\gamma + b_\gamma$ and set*

$$z_\gamma = \gamma^{-1/2} \Sigma_\theta(y_\gamma)^{-1/2} b_\gamma \in \mathcal{N}_{y_\gamma},$$

where $\Sigma_\theta(y)^{-1/2}$ is the positive inverse square root on $\mathcal{N}_y$. These coordinates are defined up to simultaneous conjugation, and any representative may be used in the invariant expressions below. Let $\mathsf{P}' \subset \mathsf{P}^{++}$ be a compact invariant regular patch containing the support of w in its relative interior. For a bounded continuous function F on the normal bundle $\{(y,z) : y \in \mathsf{P}',\ z \in \mathcal{N}_y\} \subset \mathbb{R}^9 \times \mathbb{R}^9$, invariant under $(y,z) \mapsto (\mathrm{Ad}(g)y, \mathrm{Ad}(g)z)$ for $g \in \mathrm{SU}(2)$, put

$$\overline{F}(y) = \int_{\mathcal{N}_y} F(y,z)\, \Gamma_y(dz).$$

Products with $\widetilde{w}$ are defined to be zero where $\widetilde{w} = 0$. Then

$$\frac{\mathbb{E}_{\lambda_\gamma}[\widetilde{w}\, F(y_\gamma, z_\gamma)] - \mathbb{E}_{\lambda_\gamma}[\widetilde{w}\, \overline{F}(y_\gamma)]}{D_\gamma} \longrightarrow 0 \qquad (\gamma \downarrow 0). \tag{35.2}$$

Let $\mathsf{P}'_{\mathrm{orb}} = \mathsf{P}' / \mathrm{Ad}(\mathrm{SU}(2))$, with its quotient Borel σ-algebra, and write $[y]$ for the class of y. The tangential marginal of the localized measure is the probability measure

$$\rho_\gamma(A) = D_\gamma^{-1}\, \mathbb{E}_{\lambda_\gamma}\big[\widetilde{w}\, \mathbf{1}_{\{[y_\gamma] \in A\}}\big], \qquad A \subset \mathsf{P}'_{\mathrm{orb}} \text{ Borel},$$

the function $\overline{F}(y)$ depends only on $[y]$, and

$$D_\gamma^{-1}\, \mathbb{E}_{\lambda_\gamma}[\widetilde{w}\, \overline{F}(y_\gamma)] = \int_{\mathsf{P}'_{\mathrm{orb}}} \overline{F}(y)\, \rho_\gamma(d[y]).$$

If F is bounded Lipschitz for the Euclidean distance of $\mathbb{R}^9 \times \mathbb{R}^9$, then the absolute value of the left side of (35.2) *is at most*

$$\|F\|_{\mathrm{BL}} \big[C_w(\delta_m^{1/2} + \delta_m) + e_{m,w}(\gamma)\big] \tag{35.3}$$

for every sufficiently large fixed m and all sufficiently small γ, depending on m, where C_w does not depend on m or F, and $e_{m,w}(\gamma) \to 0$ as $\gamma \downarrow 0$ for each fixed m.

Remark 35.5. In the three theorems the continuum limit is taken first, at fixed γ. The proofs take the limits in the order $K \to \infty$ at fixed γ and m, then $\gamma \downarrow 0$ at fixed m, then $m \to \infty$. Only bounded observables, not divided by powers of γ, are compared between ν and μ, and no rate of convergence uniform in γ is used or asserted. The tangential marginal ρ_γ is not identified: Theorem 35.4 states that the normal fluctuations are Gaussian over this marginal, not that the pair (y_γ, z_γ) converges to a fixed limit law. Finally, Theorem 35.2 identifies no corrections to the coefficient 2, which is the coefficient of a four-dimensional Gaussian vector and is reproduced by the conditional normal Gaussian measure of Lemma 35.17(4).

Remark 35.6. Theorem 35.4 contains more information than the law of $|z_\gamma|^2/2 = q_*/\gamma$. For example,

$$F(y,z) = \frac{|z_1|^2 - |z_2|^2}{1+|z|^2}$$

is bounded, Lipschitz, and invariant, and it requires no choice of a color frame. At $y = (0,0,ru)$ with $r_0 < r < r_1$, its values at $(z_1,z_2,z_3) = (sv,0,0)$ and at $(0,sv,0)$, with $v \perp u$, are opposite, although the two points have the same radius. In general, writing $R = |G_4|$ and $\Pi = \Pi_{\vartheta}$,

$$\overline{F}(y) = \frac{\Pi_{11} - \Pi_{22}}{2}\,\mathbb{E}\frac{R^2}{1+R^2}.$$

Indeed, $\mathcal{N}_y = \vartheta^\perp \otimes u^\perp$, so the quadratic form $b \mapsto |b_i|^2$ has trace $2\Pi_{ii}$ on the four-dimensional space $\mathcal{N}_y$, and the conditional second moment of $|z_i|^2$ given $|z| = R$ under Γ_y is $R^2\Pi_{ii}/2$. In the theorem, both $\overline{F}$ and the normalization of b_γ are evaluated at y_γ, and the normalization is by D_γ.

35.2 The coarse marginal and the finite-dimensional Gaussian comparison

Definition 35.7. Let $\widehat{\nu} = (T_M^{JK})_\# \nu$ be the law of the coarse field $V = T_M^{JK} U$ under ν. It has the density

$$d\widehat{\nu} = \widehat{Z}^{-1} \mathbf{1}_{D_r}\, e^{-nE_{JK,\mathrm{sat}}/\gamma - \overline{R}_{K,\gamma}}\, dH_n, \qquad \overline{R}_{K,\gamma} = R_{K,\gamma} - R_{K,\gamma}(I),$$

where $E_{JK,\mathrm{sat}}$ is the gauge-invariant extension of the effective classical action E_{JK} from B_r to D_r of Theorem 11.6 (that is, $E_{JK,\mathrm{sat}}(U) = E_{JK}(U^k)$ whenever $U^k \in B_r$), $R_{K,\gamma}$ is the effective interaction after K renormalization group steps, of classical depth JK, $\overline{R}_{K,\gamma}$ is the centered effective interaction, and $\widehat{Z}$ is the normalizing constant of this density; it is the normalizing constant of Theorem 33.10.

Near the flat configurations of $\mathcal{U}_n$ whose holonomy logarithms lie in P^{++} we use the finite normal atlas $V = V(y,v)$ of Proposition 33.12. Here $y \in \mathcal{M}$ is the logarithm of the holonomy triple of the flat configuration $V(y,0)$, and v is a normal variable of dimension

$$d_{\mathrm{reg}} = 6n^3 - 2,$$

whereas $\dim \mathcal{N}_y = 4$. A coarse regular tube is a set $\{V(y,v) : y \in \mathsf{P}_{\mathrm{c}},\ |v| \le \varepsilon_{\mathrm{c}}\}$, where $\mathsf{P}_{\mathrm{c}} \subset \mathsf{P}^{++}$ is a compact invariant regular patch and $\varepsilon_{\mathrm{c}} > 0$ is fixed. Put

$$H_K(y) = D_v^2(nE_{JK})(V(y,0)), \qquad z_0 = \gamma^{-1/2} H_K(y)^{1/2} v.$$

Let $\mathscr{H}_K$ denote the triple of coordinate-cycle holonomies of the Wilson-flowed fine configuration at time θL^2, regarded as a function of the coarse coordinates (y,v) and of all normalized fluctuation variables $(w_1,\dots,w_K)$. Evaluate derivatives at the zero-fluctuation

reconstruction of the flat coarse field $V(y,0)$, that is, at the sequence of flat refinements of $V(y,0)$ obtained with $w=0$. Let $T_{0,K}$ be the derivative in v of $P_{\mathcal{N}_y}(\mathrm{Log}\circ\mathscr{H}_K)$ there, and define

$$A_{0,K}=T_{0,K}H_K^{-1/2},\qquad A_{j,K}=\gamma^{-1/2}P_{\mathcal{N}_y}D_{w_j}(\mathrm{Log}\circ\mathscr{H}_K)\big|_{\mathrm{flat}},\qquad 1\le j\le K.$$

The Hessian normalization of each step at the flat background and the factors $g_{j,r}/\sqrt{\gamma}$ are included in $A_{j,K}$, exactly once. These deterministic matrices do not depend on γ. Put

$$\Sigma_m^K(y)=A_{0,K}A_{0,K}^{\mathsf{T}}+\sum_{j=1}^{m}A_{j,K}A_{j,K}^{\mathsf{T}},\qquad 0\le m\le K.$$

The matrix $\Sigma_m^K(y)$ is the covariance of the image, under the linearized normal response, of independent standard Gaussian vectors placed in the coarse normal variable and in the first m steps. We call the matrices $A_{j,K}$ the linear response matrices. On a sample, $\mathscr{H}_K$ takes the value $\mathcal{H}^K$, the flowed holonomy triple of Definition 34.1, in the same gauge frame at the basepoint. In the notation of Proposition 33.12, $H_K=H_K^{\mathrm{act}}$, the Hessian of the action phase nE_{JK}. For $j\ge 1$ the matrices $A_{j,K}$ coincide with the matrices $\mathsf{A}_{j,K}$ of Lemma 34.12, as shown in the proof of Theorem 35.10.

Hypotheses of the earlier results. We record how the hypotheses of the results used below are met. None of these choices changes as γ varies.

Flat refinements. Since $2\pi/n<r_{\mathrm{flat}}/4$ and $r_{\mathrm{flat}}<r$ lies below every fixed margin of the constrained minimizers, of the inverse of the block averaging constraint, of the Haar disintegration densities, and of the gauge charts, every flat coarse field has a commuting representative with link logarithms of norm at most $2\pi/n$. By Lemma 14.9, its zero-fluctuation reconstruction is the sequence of flat refinements, and it lies inside all these coordinate domains with a positive margin at every depth. On the fixed coarse lattice the compact set of flat configurations has a neighborhood in D_r independent of the depth and of γ. This verifies the geometric hypothesis in every application of Proposition 33.12 below.

The coarse normal atlas. The dimension in the Laplace integral on the coarse lattice is $d_{\mathrm{reg}}=\mathfrak{d}_n=6n^3-2$, the regular normal rank of Proposition 33.12, not four, and $d_{\mathrm{reg}}/2=3n^3-1$. We take the finite normal atlas on relatively compact smooth subcharts, in rooted spanning-tree gauge coordinates, whose charts and gauge transformations extend smoothly to neighborhoods of their closures. Their representatives and the closed normal tubes lie strictly inside the outer ball B_ρ, hence inside $B_{(1-\eta)\rho}$ for a fixed $0<\eta<1$, and all chart and gauge jets are bounded on these closures. We use the derivative bounds for the amplitude of the coarse density only on these subcharts; their constants may depend on n, η, the chart and gauge jets, and the outer domains, but not on the depth or on γ. In this atlas the density of $\widehat{\nu}$ is

$$\widehat{Z}^{-1}a_{K,\gamma}(y,v)\,e^{-nE_{JK}(V(y,v))/\gamma}\,dy\,dv,\qquad a_{K,\gamma}=e^{-\overline{R}_{K,\gamma}}\,J(y,v),$$

where J is the density of the product Haar measure in these coordinates, including the partition of unity of the atlas. On each compact subpatch, before the partition is applied, $a_{K,\gamma}$ is bounded above and below by positive constants and is uniformly Lipschitz in v. These are hypotheses of the coarse family of Proposition 33.12, which also has $nE_{JK,\mathrm{sat}} \geq \kappa_n E_0$ on its support and $|\overline{R}_{K,\gamma}| \leq C_n$. The phase and amplitude are smooth in the fixed charts, and the derivative bounds on the effective interaction in that family imply the amplitude bounds uniformly in the depth and in γ. In particular all phase, amplitude, and cutoff data are jointly Borel, H_K is measurable, and the phase is coercive on each chosen cutoff support. These facts verify the measurability, spectral, Lipschitz, and coercivity hypotheses of Lemma 33.3, on which the coarse Laplace formula rests. The partition of the atlas is absorbed into the measurable tangential weights, after the positive bounds on the amplitude have been used.

Coordinate domains of the reconstruction. Every coarse field in the support of $\widehat{v}$ has a representative in B_r; the reconstruction maps take values in the inner coordinate domain, and the larger complex images lie inside $B_{\rho/2}$. The products of coarse and free coordinates lie strictly inside the nested domains $\mathscr{D}_{\mathrm{in}} \Subset \mathscr{D}_{\mathrm{mid}} \Subset \mathscr{D}_{\mathrm{out}}$ of Theorem 15.12, and every intervening constrained minimizer, inverse, logarithm, and Haar disintegration density is defined there. In terms of majorizing series, the radius of the coarse field plus the fixed radius of the free coordinates lies strictly below the radius of the outer domain and below the radius of convergence of the series. These are the hypotheses of Theorem 15.12 on the images of the reconstruction maps; no auxiliary integral is evaluated outside B_r.

Couplings and cutoffs. Let $t_* > 0$ be the common coupling ceiling in Theorems 13.8 and 13.10. At the j-th step we set

$$t_j = M^{(J-1)/2}\sqrt{\gamma/(nB^j)}, \qquad p_j = A_{\mathrm{w}} \log(1/t_j), \qquad t_1^2 = \gamma/(Mn). \tag{35.4}$$

We keep the ceiling γ_0 for the bound on the small-field failure probability and for the continuum limit theorem. At the fixed side n we fix a threshold

$$0 < \gamma_W(n) \leq \gamma_0, \tag{35.5}$$

and all estimates below are restricted to $0 < \gamma \leq \gamma_W(n)$. The threshold may depend on n and the fixed data, but not on K, m, or γ. It is so small that $t_1 \leq t_*$, $p_1 \geq 1$, $Ct_j p_j \leq 1/2$, and the Hessian bound of Theorem 13.8 and the smallness condition on $t_j p_j^3$ of Theorem 13.10 hold for every $j \geq 1$. One choice serves all j: we have $t_j \leq t_1$, and each function $t^a \log^b(1/t)$ needed here is increasing on a sufficiently small fixed interval, since its derivative has the sign of $a\log(1/t) - b$. We also require that $t_1 p_1$ fit within the fixed margin of the coordinate domains for the free coordinates. No radius, cutoff, reconstruction threshold, or side changes as γ varies. Later reductions of the threshold concern only $\gamma_W(n)$, and every threshold γ_m below is taken at most $\gamma_W(n)$.

The reconstruction maps preserve the conditional potential, the product of cutoff balls, the normalized conditional kernels, and the coarse field. In particular, the two theorems of Section 13 quoted above apply to every conditional kernel in this section, uniformly in the coarse field, the side, and the preceding depth. We write E for their common bound E_* on the effective interaction.

Disintegration. At finite K we have the backward disintegration

$$d\nu = d\widehat{\nu}(V) \prod_{j=1}^{K} k_j(V, w_1, \dots, w_{j-1}; dw_j), \tag{35.6}$$

where k_j is the conditional fluctuation kernel of the j-th step, given the coarse field and the earlier steps. Restricting ν to an event depending only on the coarse field multiplies the first factor by an indicator and leaves the kernels k_j unchanged. Each k_j still integrates to one, including its Haar disintegration density, its determinant, and the input effective interaction in its potential. Conditioning further on y changes the conditional law of v in the first factor and leaves the same finer kernels. All conditional statements are understood for a version defined for almost every y; their uniform bounds hold on the whole compact patch wherever that version is defined by the displayed smooth densities.

Lemma 35.8. *Use Definition 35.7, the disintegration* (35.6)*, and a fixed coarse regular tube, and condition on the coarse tangential coordinate y. For every fixed $m \geq 0$ there exists $\gamma_m > 0$ such that the following holds uniformly in $K \geq m$ and $0 < \gamma \leq \gamma_m$. Let $\mathcal{F}_{j-1}$ be the σ-algebra generated by the coarse field and the normalized fluctuation variables of the first $j-1$ steps, let $\bar{w}_j = \mathbb{E}(w_j \mid \mathcal{F}_{j-1})$ be the conditional mean under the conditional fluctuation kernel k_j, and put*

$$Z_{K,m} = A_{0,K}(y) z_0 + \sum_{j=1}^{m} A_{j,K}(y)(w_j - \bar{w}_j).$$

For every fixed $s \geq 0$ and every jointly Borel family of real functions F_y on $\mathcal{N}_y$ with $|F_y(z)| \leq C_F(1 + |z|^s)$ in the finite smooth bundle atlas,

$$\left|\mathbb{E}[F_y(Z_{K,m}) \mid y] - \mathbb{E}F_y(G_{\Sigma_m^K(y)})\right| \leq C_{m,s} C_F \sqrt{\gamma}\,(1 + |\log \gamma|).$$

All fixed moments of $Z_{K,m}$ and of its partial sums are bounded by constants $C_{m,s}$. More strongly, the same polynomially weighted comparison holds for the joint vector $(z_0, w_1 - \bar{w}_1, \dots, w_m - \bar{w}_m)$ against a standard Gaussian vector of the same fixed finite dimension. The restriction to the coarse tube changes only the first factor of (35.6)*; no conditional kernel and no nonlinear reconstruction is evaluated at a Gaussian argument.*

Proof. We first bound each conditional kernel and the probability that its variables come close to the boundary of the cutoff product (Steps 1 and 2). We then control the linear term of the conditional potential (Step 3), compare each conditional density with a Gaussian

density in a weighted norm (Step 4), and treat the coarse variable (Step 5). Finally, a telescoping argument replaces the variables one at a time by Gaussian variables (Step 6), and we pass to the linear image (Step 7).

Step 1: the conditional kernels. Fix the coarse field and the first $j-1$ steps in the coordinate domains. By Theorem 13.8, whose conclusions are preserved by Theorem 15.12, the kernel k_j on the product $\Omega_j \subset \mathbb{R}^{D_j}$ of cutoff balls satisfies

$$k_j(dw) = Z_j^{-1}\mathbf{1}_{\Omega_j}e^{-V_j(w)}\,dw, \qquad \|D^2V_j - I\| \le \epsilon_j,$$
$$\operatorname{Var} F \le 2\mathbb{E}|\nabla F|^2, \qquad \operatorname{Ent}(F^2) \le 4\mathbb{E}|\nabla F|^2,$$

where $\epsilon_j \le C\{t_jp_j + t_j^2(1+E)\}$ under the condition $Ct_jp_j < 1/2$, with t_j, p_j as in (35.4), and $D_j \le 9J(nB^j)^3$. By Theorem 13.10, the conditional mean satisfies

$$\|\bar w_j\|_\infty \le Ct_j\|\widehat\theta_{j-1}\|_\infty \le Ct_jr, \tag{35.7}$$

where $\widehat\theta_{j-1}$ is the logarithm of the reconstructed field after $j-1$ steps. For $j \le m$ the dimension D_j is fixed, and we have $|\bar w_j| \le C_m\sqrt{\gamma}$ and $\epsilon_j \le C_m\sqrt{\gamma}(1+|\log\gamma|)$. These bounds are uniform over all earlier variables in the coordinate domains and over K.

Step 2: concentration and an interior cutoff. Let f be a 1-Lipschitz function of w, and let $\Lambda(\lambda) = \log \mathbb{E}e^{\lambda(f-\mathbb{E}f)}$. Inserting $e^{\lambda f/2}$ into the logarithmic Sobolev inequality, we find $\lambda\Lambda' - \Lambda \le \lambda^2$, which implies $\Lambda(\lambda) \le \lambda^2$. Applying this also to $-f$ and choosing $\lambda = u/2$ in Markov's inequality, we obtain $\mathbb{P}\{|f-\mathbb{E}f| \ge u\} \le 2e^{-u^2/4}$; this is the Herbst argument (see [123, Section 2.3]). Lipschitz functions are covered by smooth approximation on the compact product. Since $t_j = c_{n,M,J}\sqrt{\gamma}B^{-j/2}$ and $p_j = A_{\mathrm w}\log(1/t_j)$, we may decrease γ_m so that $Ct_jr \le p_j/(4\sqrt{3})$ and $p_j \ge 1$ for $j \le m$. If a three-dimensional block w_a has $|w_a| \ge p_j/2$, then one of its scalar coordinates deviates from its conditional mean by at least $p_j/(4\sqrt{3})$. A union bound over the scalar coordinates yields

$$\mathbb{P}\Big\{\max_a |w_a| \ge p_j/2\Big\} \le 2D_je^{-p_j^2/192}.$$

Let $0 \le \chi \le 1$ be the product radial cutoff equal to one on the balls of half the cutoff radius and zero outside the balls of three quarters of it. Then $\chi \in C_c^\infty(\Omega_j)$, $|\nabla\chi| \le C\sqrt{D_j}/p_j$, and $q_j^{\mathrm{cut}} = \mathbb{P}(\chi < 1) \le CD_je^{-cp_j^2}$. At fixed m we have $p_j \ge c|\log\gamma| - C_m$. This implies that q_j^{cut} and the standard Gaussian mass outside Ω_j are $O_{m,q}(\gamma^q)$ for every fixed $q > 0$; polynomially weighted Gaussian tails have the same property, with the fixed moment order in the constant. Decreasing γ_m further, we may assume $q_j^{\mathrm{cut}} \le 1/2$, $|\bar w_j| \le 1$, and $\epsilon_j \le 1/4$ for $j \le m$.

Step 3: the linear term. We write $D = D_j$, $\mu = \bar{w}_j$, $\epsilon = \epsilon_j$, and

$$V_j(w) - V_j(0) = |w|^2/2 + \ell \cdot w + R(w), \qquad \ell = \nabla V_j(0),$$
$$|\nabla R(w)| \le \epsilon |w|, \qquad |R(w)| \le \epsilon |w|^2/2.$$

The bounds on R follow from Taylor's formula along radial segments, since the product is convex and contains zero. Applying the Poincaré inequality to each coordinate, we have $\mathbb{E}|w|^2 \le 2D + |\mu|^2$. Integrating $\nabla(\chi e^{-V_j})$ over Ω_j, which gives zero because χ has compact support in the interior, even at the corners of the product, we obtain

$$\ell\, \mathbb{E}\chi = \mathbb{E}\nabla\chi - \mu + \mathbb{E}[(1-\chi)w] - \mathbb{E}[\chi \nabla R(w)]. \tag{35.8}$$

Since $\nabla\chi$ is supported on $\{\chi < 1\}$, we have $|\mathbb{E}\nabla\chi| \le C\sqrt{D}\, q_j^{\mathrm{cut}}/p_j$. By the Cauchy–Schwarz inequality, $|\mathbb{E}[(1-\chi)w]| \le \sqrt{q_j^{\mathrm{cut}}}(\mathbb{E}|w|^2)^{1/2}$, and $|\mathbb{E}[\chi\nabla R(w)]| \le \epsilon(\mathbb{E}|w|^2)^{1/2}$. Since $\mathbb{E}\chi \ge 1/2$, we obtain

$$|\ell| \le C_m\{\sqrt{\gamma} + \epsilon + \sqrt{q_j^{\mathrm{cut}}}\} \le C_m\sqrt{\gamma}(1 + |\log\gamma|).$$

Here we used the bound on the conditional mean μ from Step 1, not that μ vanishes. A bound on $D^2V_j - I$ alone would not control the linear coefficient ℓ.

Step 4: weighted density comparison. Let $U = V_j - V_j(0)$. When $\epsilon \le 1/4$, the preceding bounds imply $U(w) \ge |w|^2/4 - C|\ell|^2$. After a further reduction of γ_m we have $|\ell| \le 1$, and the exponential-difference identity (33.6), used in the proof of Corollary 33.4, gives on Ω_j

$$\bigl|e^{-U(w)} - e^{-|w|^2/2}\bigr| \le C\bigl(|\ell||w| + \epsilon|w|^2\bigr)e^{-c|w|^2}.$$

We extend e^{-U} by zero outside Ω_j, integrate against $1 + |w|^s$, bound the Gaussian mass of the complement of Ω_j by Step 2, and compare the two normalizing constants. Since the Gaussian integral is $(2\pi)^{D/2}$, both normalizing constants have a common positive lower bound at this fixed D. Then the normalized conditional density r_j of w_j satisfies

$$\int (1 + |w|^s)|r_j(w) - \phi_D(w)|\, dw \le C_{m,s}\sqrt{\gamma}(1 + |\log\gamma|), \tag{35.9}$$

where ϕ_D is the standard Gaussian density in $\mathbb{R}^D$. In particular all fixed uncentered conditional moments are bounded. The same bound holds for $x = w - \mu$ against $\phi_D(x)$. Indeed, translation changes the polynomial weights by a bounded factor when $|\mu| \le 1$, and

$$\phi_D(x+\mu) - \phi_D(x) = \int_0^1 \mu \cdot \nabla\phi_D(x + u\mu)\, du$$

has weighted L^1 norm at most $C_{D,s}|\mu|$. No derivative of the mean in the earlier variables is needed.

Step 5: the coarse variable. We condition on y in the coarse tube. The weighted comparison of the conditional density of z_0 with $\phi_{d_{\mathrm{reg}}}$ is given by Corollary 33.4, together with the extension to the whole tube established in its proof. That proof verifies the coercivity of the phase on the whole tube, the bounds on the amplitude, and the lower bound on the normalizing constant of the tube for the coarse family of Proposition 33.12, uniformly in K. The chart and amplitude checks recorded above supply the data on the subcharts. The comparison error for the coarse variable is $C_{n,s}\sqrt{\gamma}$. As noted after (35.6), the restriction to the coarse tube leaves the finer kernels unchanged; this also follows from the fixed-target statement of Theorem 13.8. All bounds of Steps 1–4 hold under this conditional probability.

Step 6: substitution of Gaussian variables. Let $X_0 = z_0$ and $X_j = w_j - \bar{w}_j$ for $1 \le j \le m$, and let F be a Borel function of $(X_0, \dots, X_m)$ bounded by $1 + |(X_0, \dots, X_m)|^s$. For $0 \le j \le m$ let I_j be the expectation of F when the arguments $0, \dots, j$ are $X_0, \dots, X_j$ and the arguments $j+1, \dots, m$ are replaced by independent standard Gaussian vectors, independent of everything else. For $j \ge 1$, integrating out these Gaussian vectors gives a function of the current variable bounded by

$$C_{m,s}\big(1 + |(X_0, \dots, X_{j-1})|^s + |X_j|^s\big).$$

For fixed values of the earlier variables, (35.9) in its translated form bounds the change from a Gaussian j-th argument to X_j by $C_{m,s}\sqrt{\gamma}(1 + |\log\gamma|)$ times $1 + |(X_0, \dots, X_{j-1})|^s$. Taking expectations, we find that $|I_j - I_{j-1}|$ is at most $C_{m,s}\sqrt{\gamma}(1 + |\log\gamma|)$ times $\mathbb{E}(1 + |(X_0, \dots, X_{j-1})|^s)$. This expectation is uniformly bounded: the moments of the coarse variable follow from the corollary of Step 5, each conditional variable has all fixed moments by Step 4, and finite-dimensional norm inequalities bound the whole vector. The centered variables are measurable functions of the earlier variables, so no inverse transformation of a Gaussian argument is required. Finally the coarse argument in I_0 is replaced by a Gaussian one using Step 5. Summing the finitely many differences proves the joint weighted comparison. The Gaussian arguments enter only F, never a reconstruction, a conditional mean, or a conditional kernel.

Step 7: the linear image. The exact Gaussian decomposition of Proposition 33.12 includes the bound

$$\|A_{0,K}\|_{\mathrm{HS}}^2 + \sum_{j=1}^{K} \|A_{j,K}\|_{\mathrm{HS}}^2 \le C. \tag{35.10}$$

This implies that the linear map $(X_0, \dots, X_m) \mapsto A_{0,K}X_0 + \sum_{j=1}^{m} A_{j,K}X_j$ has operator norm bounded uniformly in K and m. Applying the joint comparison to F_y composed with this map, which has polynomial growth with a fixed bound, proves the stated estimate. The Gaussian image has covariance $\Sigma_m^K(y)$ by definition, and the argument covers singular covariances. The same norm bound and the moments of each argument give the bounds

on all moments of the partial sums. The kernels and the conditional means are Borel, as normal integrals of smooth conditional densities, and the Borel hypothesis on F_y together with Fubini's theorem justifies every substitution of a test function and every integration in y. □

35.3 Finite-scale reconstructions and the normal covariance

The proofs in this subsection use coordinates $q_{j,r} = g_{j,r} w_{j,r}$ on fixed finite lattices; as coordinates they do not depend on γ, and all domains below are chosen independently of γ and of the number of later steps.

Theorem 35.9. *Fix $m \geq 0$, and express the triple Ξ_m^K as a function of the coarse coordinates and of the coordinates $q_{j,r} = g_{j,r} w_{j,r}$, $1 \leq j \leq m$, of the first m steps. There exist a neighborhood of its flat inputs (the inputs whose coarse field is flat and whose coordinates of the first m steps vanish) and a constant C_m such that, on this neighborhood,*

$$\sup_{K \geq m} \|\Xi_m^K\|_{C^{1,1}} \leq C_m.$$

The derivatives are taken in smooth rooted spanning-tree gauge coordinates; no derivative of a measurable choice of gauge representatives is taken. The neighborhood and C_m may depend on m and on the fixed lattices of the first m steps, but not on K, on γ, or on the preceding and later classical depths.

Moreover, Ξ_m^K extends to a fixed neighborhood of the set of all inputs $(V_0, 0)$ with $V_0 \in \mathcal{U}_n$ flat, and there exists a function ω_m with $\omega_m(s) \to 0$ as $s \downarrow 0$ such that, for every flat V_0,

$$\max_i \|\Xi_{m,i}^K(V, z_{\leq m}) - \mathrm{Hol}_i(V_0)\|_{\mathrm{op}} \leq \omega_m\big(d_{\mathrm{in}}((V, z_{\leq m}), (V_0, 0))\big).$$

Here $z_{\leq m}$ denotes the physical coordinates $q_{j,r}$ of the first m steps. For this comparison with the zero section, $d_{\mathrm{in}}((V, z_{\leq m}), (V_0, 0))$ is the sum of the distance between the based gauge classes of V and V_0 in one fixed product Riemannian metric on the compact coarse quotient in rooted spanning-tree coordinates and the Euclidean norm of $z_{\leq m}$. The triangular orthogonal transitions preserve this norm. This distance to a flat input is uniformly equivalent, on the finite cover used below, to the corresponding local product distances, with constants independent of K. Every chart uses the same gauge frame at the basepoint. Finally, $\Xi_m^K(V_0, 0) = \mathrm{Hol}(V_0)$ for every finite $K \geq m$ and every flat V_0, including those whose holonomy triple is one of the central triples $(\pm I, \pm I, \pm I)$.

Proof. Fix m. All parameter norms in this proof are norms on the coarse lattice and on the finite lattices of the first m steps; their dimensions and the constants comparing different norms may depend on m, n, M, J. We write u for these parameters. As arguments of the successive Hessian normalization we use the coordinates $q_{j,r} = g_{j,r} w_{j,r}$, which do not depend on γ. The changes of variables between these coordinates and the free logarithmic

coordinates have uniformly bounded charts and inverse charts on each fixed set of first m steps. On the coarse lattice we use analytic link coordinates or rooted spanning-tree gauge coordinates, keeping the initial gauge frame at the basepoint. The smooth normal atlas is composed with these coordinates only after the real derivative bounds have been obtained.

Step 1: a domain for the inputs. By Lemma 14.9 and the condition $2\pi/n < r_{\mathrm{flat}}/4$, each of the first m zero-fluctuation steps at a flat input is flat and lies strictly inside every margin of the constrained minimizers, of the inverse of the block averaging constraint, of the Haar disintegration densities, and of the gauge charts. Each fixed finite composition of reconstruction maps has uniformly bounded weighted analytic coefficients on the nested domains of Theorem 15.12; in particular its first derivative is bounded there independently of the later depth. Let $F_m^K(u)$ be the field at the end of the m-th step, which is the input of the zero-fluctuation reconstruction of the later steps. At each flat chart center u_0 we start from a small commuting representative with link logarithm of norm at most $2\pi/n$, keeping the gauge frame at the basepoint. The reconstruction maps preserve flatness and the based cycle holonomies. Their zero-fluctuation maps P_j satisfy $P_j(0) = 0$ and $\|DP_j\| \le a_{\mathrm{map}} < 1$ on the convex working ball, by Lemma 15.15 and Definition 34.1. Integrating along segments and iterating therefore gives

$$\|F_m^K(u_0)\|_\infty \le a_{\mathrm{map}}^m \frac{2\pi}{n} \le \frac{2\pi}{n} < \frac{r_{\mathrm{flat}}}{4} < \frac{r}{4}.$$

This bound applies to the actual reconstructed representative, which may differ from the constant commuting refinement by a based gauge transformation. The derivative bound just obtained gives a constant $C_{\mathrm{in},m}$ for $D_u F_m^K$, uniform in K and in the depths, before any of the later steps is applied. Let U_{larger} be a real neighborhood of the flat inputs, of radius ϵ_m, such that $C_{\mathrm{in},m}\epsilon_m < r/4$ and the derivative bound times ϵ_m is less than half of every image margin of the first m steps. By the mean value formula, we have, in these fixed charts,

$$\sup_{K \ge m,\, u \in U_{\mathrm{larger}}} \|F_m^K(u)\|_\infty \le r/4 + C_{\mathrm{in},m}\epsilon_m < r/2 < r, \tag{35.11}$$

and every intermediate image stays in its coordinate domain. The same holomorphic coefficient bounds allow a larger complex polydisc, on which the complex image has norm below $3r/4$, and two smaller polydiscs. Indeed, the complex derivative bound times the added radius may be chosen below $r/4$ and below half of the remaining image margins. A finite cover of the compact set of flat inputs gives common positive radii and margins. These choices depend on m and on the coefficient bounds, but not on K, on γ, or on the number of later steps. In particular, (35.11) verifies the bound $\|\theta_0\|_\infty \le r$ on the initial field required in Lemma 34.4, independently of the larger radius and of the cutoffs.

Step 2: the flow data of the zero-fluctuation reconstruction. Let $a = \ell_K = (L/n)B^{-K}$. Let $\mathcal{E}_K(u)$ be the linear and quadratic flow data, in the sense of Definition 4.8, of the zero-fluctuation reconstruction from $F_m^K(u)$ down to the mesh a, including both weighted components and their first differences. We apply parts (1)–(3) of Lemma 34.4, including the analytic coefficient estimates and the finite-scale composition clause in part (3), starting at the mesh ℓ_m with this finite input. Its hypotheses are the bound (35.11), the contraction condition $a_{\mathrm{map}}\sqrt{B} < 1$, the complex domain of Step 1, and zero fluctuation variables at all later steps; they hold by Step 1 and Definition 34.1. We obtain a fixed smaller complex domain, a bound R_m, and a number $0 < \tau < 1$ such that, for every fixed $l \geq m$,

$$\sup_{K\geq l,\,u} \|\mathcal{E}_K(u)\|_{\mathrm{fl},a} \leq R_m, \qquad \sup_{K\geq l,\,u} \|\mathcal{E}_K(u) - \mathcal{E}_{K,l}(u)\|_{\mathrm{fl},a} \leq C_m(1+l)^c\tau^{l-m}. \tag{35.12}$$

Here $\mathcal{E}_{K,l}$ is the flow data of the field at the end of the l-th step, embedded on the same finest lattice, and $\|\cdot\|_{\mathrm{fl},a}$ is the sum of the four weighted value and first-difference norms of Definition 4.8. One can take $\tau = \max\{a_{\mathrm{map}}B^{1-\alpha_{\mathrm{fl}}}, \mathfrak{q}\}$; both terms are less than one, since $\alpha_{\mathrm{fl}} > 1/2$, $a_{\mathrm{map}}\sqrt{B} < 1$, and $\mathfrak{q} = Ba_{\mathrm{map}}^2 < 1$. Starting at ℓ_m only changes C_m and R_m, and the smaller complex domain does not shrink with the number of later steps.

Step 3: parameter derivatives of the flow data. Let $U_0 \Subset U_1$ be real bounded parameter domains inside that complex domain, and let $s_m > 0$ be a common complex distance from U_1 to its boundary. Applying Cauchy's integral formula for Banach-valued holomorphic functions in each input coordinate, we obtain

$$\sup_{K,\,u\in U_1} \sum_{r=0}^{2} \|D_u^r\mathcal{E}_K(u)\|_{\mathrm{fl},a} \leq C_{\dim u}R_m\big(1 + s_m^{-1} + s_m^{-2}\big) = R_{2,m}. \tag{35.13}$$

For a mixed second derivative we use two coordinate circles of radius at most $s_m/2$, which only changes the finite-dimensional constant. The estimate covers the first-difference components as well as the values. Complex continuation is used only for the reconstruction and the flow data, not for the nonlinear Wilson flow.

Step 4: real variations of the Wilson flow. We apply Theorem 25.13 with the parameter domains U_0, U_1, dimension $\dim u$, bound $R_{2,m}$ on the flow data, horizon T, and smallest observation time $t_* = \theta L^2/2$. The flow data are twice continuously differentiable by (35.13) and are bounded in the norms required there. Every damping gauge transformation starts at the identity in the same initial gauge frame at the basepoint. The early parameter variations given by that theorem satisfy the first-difference bound

$$C_m\big\{(s+a^2)^{-(\alpha_{\mathrm{fl}}+1)/2} + (s+a^2)^{-\alpha_{\mathrm{fl}}} + (s+a^2)^{\kappa_{\mathrm{fl}}-1/2}\big\},$$

which is integrable in s near zero, uniformly in a, since $(\alpha_{\mathrm{fl}}+1)/2<1$, $\alpha_{\mathrm{fl}}<1$, and $\kappa_{\mathrm{fl}}>0$. The condition keeping the links in the compact chart is

$$a\sup_{s\le T_{R_{2,m}}}\|A(s)\|_\infty\le C_m\{a^{1-\alpha_{\mathrm{fl}}}+a^{2-2\alpha_{\mathrm{fl}}}+a(T_{R_{2,m}}+a^2)^{\kappa_{\mathrm{fl}}}\}\longrightarrow 0\qquad(a\to 0).$$

At a positive early restart time the same theorem gives smooth bounds at the restart and a finite reference family of smooth DeTurck solutions, joined by fixed gauge transformations, on an open neighborhood of the compact family of smooth restart configurations. We check its hypothesis that this family has a compact smooth closure, using the gauge transformations at the restart and the bounds on all fixed spatial differences given by the smoothing at positive time. For each restart array, the coefficients of its periodic trigonometric interpolant are bounded by $C_q(1+|k|)^{-q}$ for every fixed q. To see this, we apply q differences in a coordinate with maximal $|k_i|$ and use $|a^{-1}(e^{2\pi i a k_i/L}-1)|\ge c_L|k_i|$ on the centered Brillouin representatives, and at $k=0$ we use the bound on the values. The tails of the coefficients therefore tend to zero uniformly in each C^s norm, taking $q>s+3$. Finite Fourier truncations have compact sets of coefficients, and successive finite nets in these truncations, followed by a diagonal subsequence, give a compact smooth closure, uniformly over the compact parameter domains. Taking real parts at the unpaired Nyquist modes preserves real arrays and the estimates. This verifies the compactness hypothesis. We use the fixed gauge transformations of that theorem at the restart for the varying input, keeping their conjugations at the basepoint. The theorem then bounds the first and second real parameter derivatives of the three cycle matrices at time θL^2 by C_m. Since the initial configurations are the finest configurations of the zero-fluctuation reconstruction that define Ξ_m^K, and the lattice flow time is $4\theta L^2/a^2$, this bounds the derivatives of the map Ξ_m^K itself. The finitely many meshes for which the smallness conditions of that theorem fail are covered by its clause on compact smooth ordinary differential equations. Integrating the second derivative on smaller convex coordinate balls, we obtain $\sup_{K\ge m}\|\Xi_m^K\|_{C^{1,1}}\le C_m$.

Step 5: all flat configurations. We repeat Steps 1–4 in ambient charts given by rooted spanning-tree gauges, covering the set of flat configurations, which is compact on the coarse lattice. Its quotient by gauge transformations fixed at the basepoint is parametrized by finitely many matrices on the non-tree links, because rooted spanning-tree gauges are unique and have no residual stabilizer. Hence smooth ambient charts exist also at flat configurations with central holonomies, although the set of flat configurations is singular there.

For each flat chart center V_*, fix a periodic coarse gauge transformation h_* with $h_*(0)=I$ taking V_* to a small constant commuting representative, as in Lemma 14.9, and use this same fixed transformation on its whole ambient neighborhood. The strict margins at the center from Step 1 and the uniform coefficient bounds for the first m

steps give a neighborhood independent of K. On an overlap, transport both the coarse field and the first m fluctuation coordinates by the triangular transitions $q'_{j,r} = O_{j,r} q_{j,r}$ of Theorems 13.4 and 14.3, where $O_{j,r}$ depends on the coarser inputs. By (15.28), the corresponding reconstructions are related by a fine gauge transformation whose restriction to the coarse vertices is the original coarse transformation. It therefore equals I at the common basepoint. Iterating this identity transports the whole prefix, and every subsequent zero fluctuation coordinate remains zero. The finest zero-fluctuation configurations and their Wilson flows thus have identical based cycle matrices on the overlap. These transitions also preserve the cutoff balls, the normalized conditional kernels, and the selected event. The uniform coefficient bounds on the first m fixed lattices control the finite input charts; exact equality of the based matrices requires no derivative of a gauge transformation composed through the later steps.

We take finitely many larger charts covering the compact flat set and smaller charts with compact closures inside them. Steps 1–4 then give a common constant C_m and a common positive neighborhood on this finite cover. This construction chooses each center gauge once and uses neither a logarithm of a varying central matrix nor a regular normal Hessian.

Step 6: exact values and the modulus. At a flat input with zero fluctuation variables, Lemma 14.9 identifies the successive constrained minimizers up to based gauge transformations with commuting flat refinements, which preserve the cycle holonomies. By Theorem 15.12, the gauge transformations of the reconstruction maps are the identity at the roots and therefore preserve these values. The gradient of the Wilson action vanishes on the refinements, so the Wilson flow does not move them. We conclude that $\Xi_m^K(V_0, 0) = \mathrm{Hol}(V_0)$ for every finite K, for central as well as regular flat configurations.

It remains to obtain the modulus from the uniform first-derivative bounds. We take coordinate balls whose doubled closures lie in the larger charts, cover the set of flat configurations by finitely many of the corresponding half-balls, and let $\varrho_m > 0$ be a common smaller radius. An input and a flat zero-section input at distance at most ϱ_m lie in one of these charts, where the local product distance is bounded by a fixed multiple of d_{in}. The norm of the transported fluctuation input is unchanged, so the first-derivative estimate and the fixed gauge frame at the basepoint bound their matrix difference by $C'_m d_{\mathrm{in}}$. For larger distances the difference is at most two. After increasing C'_m so that $C'_m \geq 2/\varrho_m$, the function $\omega_m(s) = \min(2, C'_m s)$ is a common modulus. On overlaps the gauge transformations keep the same initial gauge frame at the basepoint. This proves the statement near all flat configurations. □

Theorem 35.10. *For y in the regular patch P^{++} and $N = nB^K$ we have the exact identity*

$$\Sigma_K^K(y) = \Sigma_\theta^N(y),$$

where $\Sigma_\theta^N(y)$ is the normal covariance, divided by γ, of the linearized flowed cycle logarithms under the Gaussian measure of the lattice Maxwell form of the finest lattice around the flat configuration y (Theorem 33.11 and Proposition 33.12). There exists C, independent of m, K, and y, such that

$$0 \le \Sigma_\theta^N(y) - \Sigma_m^K(y) \le C\delta_m\, I_{\mathcal{N}_y} \qquad (K \ge m).$$

Put $\widetilde{\Sigma}_m^K(y) = \Sigma_\theta(y)^{-1/2}\Sigma_m^K(y)\Sigma_\theta(y)^{-1/2}$. With constants independent of m, K, and y,

$$\sup_y \|\widetilde{\Sigma}_m^K(y) - I\|_{\mathrm{op}} \le C\delta_m + C(nB^K)^{-2}, \qquad K \ge m. \tag{35.14}$$

The continuum covariance satisfies $cI \le \Sigma_\theta \le CI$ and $\Sigma_\theta(y) \ge |\boldsymbol{\vartheta}|^{-2}e^{-2\theta|\boldsymbol{\vartheta}|^2} I_{\mathcal{N}_y}$. For every fixed m, in the finite smooth normal atlas,

$$\sup_{K\ge m} \sum_{j=0}^{m} \big(\|A_{j,K}\|_\infty + \mathrm{Lip}_y\, A_{j,K}\big) \le C_m. \tag{35.15}$$

Finally, if $H_K^E = D_v^2 E_{JK}(V(y,0))$, then $H_K = nH_K^E$ and

$$A_{0,K}A_{0,K}^{\mathsf{T}} = n^{-1}T_{0,K}(H_K^E)^{-1}T_{0,K}^{\mathsf{T}}.$$

Proof. The exact identity is the Gaussian quadratic identity of Proposition 33.12, applied to the linear response matrices of Definition 35.7. Its hypotheses concern the same reconstruction maps, the Hessians at the flat background, the coarse normal variable, and the derivative of the flowed cycle logarithms. In particular,

$$\Sigma_\theta^N - \Sigma_m^K = \sum_{j=m+1}^{K} A_{j,K}A_{j,K}^{\mathsf{T}} \ge 0. \tag{35.16}$$

If G_j are independent standard Gaussian vectors, this positive matrix has trace

$$\mathrm{tr}\big(\Sigma_\theta^N - \Sigma_m^K\big) = \mathbb{E}\Big|\sum_{j=m+1}^{K} A_{j,K}G_j\Big|^2. \tag{35.17}$$

To bound this trace we identify our matrices with those of Lemma 34.12. Its flat coarse field V_y is $V(y,0)$ here. Its coordinates $q_{j,r}$ are our $g_{j,r}w_{j,r}$, taken before the Hessian normalization of each step at the flat background; that normalization and the zero-fluctuation reconstruction of all finer steps are included in the differentiated reconstruction on both sides. The two response matrices therefore agree:

$$\mathsf{A}_{j,K} = P_{\mathcal{N}_y}D_{q_j}(\mathrm{Log}\circ\mathscr{H}_K)\ \mathrm{diag}_{r,e}(g_{j,r}/\sqrt{\gamma}) = \gamma^{-1/2}P_{\mathcal{N}_y}D_{w_j}(\mathrm{Log}\circ\mathscr{H}_K)\big|_{\mathrm{flat}} = A_{j,K}.$$

The diagonal contains the coupling of every intermediate scale and every scalar color component. Its entries do not depend on γ, since each $g_{j,r}^2/\gamma$ is the reciprocal of a fixed

lattice side. Both response maps use the Wilson flow at time θL^2 (lattice time $4\theta N^2$), the same based coordinate cycles, and the same initial gauge frame at the basepoint. Our patch is regular and has the margins of the identity chart and of the normal charts required by that lemma. Its flat refinements satisfy the coordinate-domain conditions by the condition $2\pi/n < r_{\mathrm{flat}}/4$ and Lemma 14.9, and $D\,\mathrm{Log}$ is the bounded differential of the identity chart. Thus every hypothesis of Lemma 34.12 holds, and we obtain

$$\sup_{K\geq m,\,y} \mathbb{E}\Big| \sum_{j=m+1}^{K} A_{j,K}(y) G_j \Big|^2 \leq C\delta_m. \tag{35.18}$$

Only a linear map acts on the independent Gaussian vectors, and the bound holds at each fixed flat y; it is not deduced from an averaged estimate for the interacting measure. A positive semidefinite matrix is bounded above by its trace times the identity, as one sees by diagonalizing it. Combining (35.16), (35.17), and (35.18), we obtain the bound $0 \leq \Sigma_\theta^N - \Sigma_m^K \leq C\delta_m I$.

We next prove the derivative bounds at finite cutoff. The spectral bounds $c_n I \leq H_K \leq C_n I$ follow from Proposition 33.12. By the uniform bounds on the derivatives of the effective classical action in Theorem 10.11, composed with the fixed compact normal atlas, we have $\|H_K\|_{C^1(y)} \leq C_n$; only three derivatives of the action are needed. For the steps $j \geq 1$ we use the coordinates $q_{j,r} = g_{j,r} w_{j,r}$ of Theorem 12.13. The Hessian normalization of each step is part of the map in these coordinates and is preserved by Theorem 15.12; these are the coordinates used in the proof of Theorem 35.9, and no limit of a normalization matrix or of its derivative is needed.

For the inverse square root, let S be a symmetric matrix with $cI \leq S \leq CI$, choose $C' > C$ and write $S = C'(I - Q)$, so that $\|Q\| \leq 1 - c/C' < 1$. The binomial series for $(I-Q)^{-1/2}$ and its term-by-term derivative converge uniformly: the derivative of Q^k is a sum of k terms bounded by $\|Q\|^{k-1}\|DQ\|$, and the coefficients of the series are bounded. This bounds $S^{-1/2}$ and its first tangential derivative without constructing any limit. Applied to $S = H_K$, it bounds $H_K^{-1/2}$ and its first tangential derivative.

At the flat input, the derivative of $\mathrm{Log} \circ \Xi_m^K$ in the variables of a step $j \leq m$ equals the corresponding derivative of $\mathrm{Log} \circ \mathscr{H}_K$ with all other fluctuation variables set to zero. Indeed, setting the later variables to zero does not change the derivative in an earlier variable at the flat refinements. For $j \geq 1$ this gives the identity

$$A_{j,K} = P_{\mathcal{N}_y} D_{q_j} (\mathrm{Log} \circ \Xi_m^K)\big|_{\mathrm{flat}}\, \mathrm{diag}_{r,e}(g_{j,r}/\sqrt{\gamma}),$$

with a fixed diagonal independent of y, K, and γ. Using the $C^{1,1}$ bounds of Theorem 35.9 in these coordinates, the bounds on the first two derivatives of the logarithm on the identity chart, and the smoothness of the embedding of the flat configurations, we bound each $A_{j,K}$ and its first tangential derivative. For $A_{0,K}$ we compose the corresponding coarse derivative with $H_K^{-1/2}$ and use the preceding bounds. Each step carries exactly one

Hessian normalization, already included in the differentiated map, and the derivatives of the orthonormal frames and of the projections in the finite atlas are bounded. This proves (35.15), and hence a Lipschitz bound for Σ_m^K at each fixed m.

By Theorem 33.11 we have $\|\Sigma_\theta^{nB^K} - \Sigma_\theta\| \le C(nB^K)^{-2}$, together with the spectral bounds $cI \le \Sigma_\theta \le CI$. Adding this lattice error to the bound on the positive remainder proved above and conjugating by $\Sigma_\theta^{-1/2}$, we obtain (35.14). By the same theorem, the constant off-diagonal color modes alone contribute $e^{-2\theta|\vartheta|^2}|\vartheta|^{-2} I_{\mathcal{N}_y}$ to $\Sigma_\theta(y)$; since all other contributions are positive semidefinite, this gives the stated lower bound.

Finally, $H_K = D_v^2(nE_{JK}) = nH_K^E$, so

$$A_{0,K}A_{0,K}^{\mathsf{T}} = T_{0,K}H_K^{-1}T_{0,K}^{\mathsf{T}} = n^{-1}T_{0,K}(H_K^E)^{-1}T_{0,K}^{\mathsf{T}}.$$

In particular the contribution of the coarse normal variable is included in Σ_m^K for every m. □

35.4 Finite-scale moments and localization

This subsection combines the Gaussian comparison of Lemma 35.8 with the deterministic results of Section 35.3. Two facts about the coarse lattice drive the argument. First, the normalizing constant $\widehat{Z}$ is of order γ^{3n^3-1} (Theorem 33.10). This is also the order of the Laplace mass of any fixed regular patch, so a fixed regular neighborhood has probability bounded below, uniformly in γ. Second, the action has a positive gap at a fixed distance from the flat configurations. Together with the uniform modulus of Theorem 35.9, this shows that, with overwhelming probability, an output in a fixed regular tube comes from a coarse field near the corresponding regular flat configurations, and not from a neighborhood of other flat configurations, such as those with central holonomies.

Theorem 35.11. *Fix nested tubes as in Section 35.1. For every fixed $m \ge 0$ there exist $K_0(m)$ and $\gamma_m > 0$ such that the following statements hold uniformly for $K \ge K_0(m)$ and $0 < \gamma \le \gamma_m$.*

1. *Fix bounded Borel functions on $\mathrm{SU}(2)^3$ that agree with the local maps $H \mapsto b(\operatorname{Log} H)$ and $H \mapsto y(\operatorname{Log} H)$ on a smaller fixed regular output tube; we denote them again by $b(\operatorname{Log} H)$ and $y(\operatorname{Log} H)$. Under the restriction of ν to a larger coarse regular tube, normalized by its own mass, we have for every fixed finite r'*

$$\frac{b(\operatorname{Log}\Xi_m^K)}{\sqrt{\gamma}} = A_{0,K}(y)z_0 + \sum_{j=1}^{m} A_{j,K}(y)w_j + \mathcal{R}_{K,m},$$

$$\|\mathcal{R}_{K,m}\|_{L^{r'}} \le C_{m,r'}\sqrt{\gamma}(1+|\log\gamma|)^2, \qquad \|y(\operatorname{Log}\Xi_m^K) - y\|_{L^{r'}} \le C_{m,r'}\sqrt{\gamma}(1+|\log\gamma|).$$

The same integrated estimates hold for the expectation under ν with any bounded measurable multiplicative factor supported in the coarse tube. Replacing w_j by $w_j - \bar{w}_j$ changes $\mathcal{R}_{K,m}$ by a term of norm $O_m(\sqrt{\gamma})$ in $L^{r'}$.

2. *Let w be any fixed real smooth tangential weight compactly supported in the relative interior of P, and let χ_w be a fixed smooth normal cutoff supported in $\{|b| < b_{\mathrm{o}}\}$ and equal to one near the zero section. Set $\widetilde{w}(y+b) = w(y)\chi_w(b)$, with the fixed zero extension; for this part, nonnegativity and invariance of w and χ_w are not required. Choose a smooth normal cutoff ζ equal to one near the support of χ_w and supported in $\{|b| < b^+\}$, and set $w^+(H) = w(y(\operatorname{Log} H))\zeta(b(\operatorname{Log} H))$, extended by zero. For $l = 0, 1, 2$,*

$$\begin{aligned}&\mathbb{E}_\nu\Big[\widetilde{w}(\operatorname{Log}\Xi_m^K)\Big(\frac{q_*(\operatorname{Log}\Xi_m^K)}{\gamma}\Big)^l\Big]\\&\qquad = \mathbb{E}_\nu\Big[w^+(\Xi_m^K)\,\mathfrak{m}_l\big(\widetilde{\Sigma}_m^K(y(\operatorname{Log}\Xi_m^K))\big)\Big] + O_{m,w}\big(\sqrt{\gamma}(1+|\log\gamma|)^{k_m}\big),\end{aligned}$$

where k_m is a fixed exponent, $\widetilde{\Sigma}_m^K = \Sigma_\theta^{-1/2}\Sigma_m^K\Sigma_\theta^{-1/2}$, and

$$\mathfrak{m}_0(C) = 1, \qquad \mathfrak{m}_1(C) = \frac{1}{2}\operatorname{tr} C, \qquad \mathfrak{m}_2(C) = \frac{1}{4}\big\{(\operatorname{tr} C)^2 + 2\operatorname{tr}(C^2)\big\}. \tag{35.19}$$

Only values in the support of w^+ are used on the right.

3. *For every fixed r', the normal moments of the coarse variable satisfy $\mathbb{E}_\nu[|v|^{r'}\mathbf{1}_{\{V \text{ in the coarse tube}\}}] \le C_{r'}\gamma^{r'/2}$, and for every fixed larger regular output tube $\mathcal{V}$,*

$$\mathbb{E}_\nu\big[|b(\operatorname{Log}\Xi_0^K)|^{r'}\mathbf{1}_{\{\Xi_0^K\in\mathcal{V}\}}\big] \le C_{r'}\gamma^{r'/2},$$

where $C_{r'}$ depends on $\mathcal{V}$ but not on m.

4. *There exists $c_* > 0$, independent of K, m, and γ, such that, after possibly decreasing γ_m,*

$$\nu\{\psi(\operatorname{Log}\Xi_m^K) = 0\} \ge c_*, \qquad \nu\{\psi(\operatorname{Log}\Xi_m^K) \ge b_*\} \ge c_*.$$

5. *For every compact regular output tube $\mathcal{O}$ over a patch in the relative interior of P^{++} there exists a larger coarse regular tube $\mathcal{T}^+$ such that, for every $q > 0$,*

$$\nu\{\Xi_m^K \in \mathcal{O},\ V \notin \mathcal{T}^+\} \le C_{m,q}\gamma^q.$$

This excludes contributions from neighborhoods of all other flat configurations, including those with central holonomies, as well as from nonflat coarse fields.

Throughout, the normalizing constant satisfies $c_n\gamma^{3n^3-1} \le \widehat{Z} \le C_n\gamma^{3n^3-1}$.

Proof. The cases of finitely many small K are covered by the bounds of Section 35.3, so we may take $K_0(m) = m$; any larger choice is also allowed. We first record the Laplace estimates on the coarse lattice (Step 1) and prove the localization (Step 2), then construct the bounded output coordinates and a good event (Steps 3 and 4), prove the expansion of part (1) (Steps 5–7), and finally prove parts (2), (3), and (4) (Steps 8–10).

Step 1: Laplace estimates on the coarse lattice. By the first part of Proposition 33.12, with its exact conditional normalizing constant, we have

$$\mathbb{E}\big[|v|^r \mid y,\ V \text{ in the coarse tube}\big] \le C_r \gamma^{r/2} \qquad (r < \infty). \tag{35.20}$$

To obtain the mass of a patch, we apply the additive Laplace formula of the same lemma with a nonnegative smooth tangential bump h, supported strictly inside the patch, and a normal cutoff equal to one on a smaller ball. Positivity and the bounds on the amplitude and on the Hessian give

$$c_h \gamma^{3n^3-1} \le \widehat{Z}\, \mathbb{E}_{\widehat{\nu}}[h(y)\chi(v)] \le C_h \gamma^{3n^3-1}$$

for all sufficiently small γ, uniformly in K; here the additive error $O_h(\sqrt{\gamma})$ has been absorbed into the positive leading integral, and we used $(2\pi\gamma)^{d_{\mathrm{reg}}/2} = (2\pi\gamma)^{3n^3-1}$. By Theorem 33.10, $\widehat{Z}$ is bounded above and below by constant multiples of the same power γ^{3n^3-1}. Dividing the two bounds, we find that every fixed nonempty open regular subpatch has coarse probability bounded below by a positive constant, uniformly in K and γ. No convergence of the tangential amplitude is used. Integrating (35.20) over the coarse tube proves the first assertion of part (3), both under the normalized restriction to the tube and with any bounded multiplicative factor under ν.

Step 2: localization (part (5)). We work on the compact quotient of the coarse configuration space by gauge transformations fixed at the basepoint. The zero set $\mathcal{F}_n$ of E_0 is the set of flat configurations, as in Section 36. For any fixed $\eta > 0$, compactness and continuity give

$$c_\eta = \inf\{\kappa_n E_0(V) : \operatorname{dist}(V, \mathcal{F}_n) \ge \eta\} > 0,$$

since otherwise a convergent sequence in this closed set would have a flat limit in the set. Since the centered effective interaction is bounded, $nE_{JK,\mathrm{sat}} \ge \kappa_n E_0$, and the product Haar measure has mass one, the lower bound on $\widehat{Z}$ implies

$$\widehat{\nu}\{\operatorname{dist}(V, \mathcal{F}_n) \ge \eta\} \le C_n \gamma^{-(3n^3-1)} e^{-c_\eta/\gamma} \le C_{n,\eta,q}\gamma^q \qquad (q > 0). \tag{35.21}$$

The last bound follows by maximizing $x^{3n^3-1+q}e^{-c_\eta x}$ over $x \ge 1/\gamma_0$.

Let $\mathcal{O}$ be the given compact output tube. The flat holonomies meeting a sufficiently small neighborhood of $\mathcal{O}$ stay away from the central triples and from the boundary of the identity chart. We may therefore choose a strictly larger compact set of regular commuting holonomies in the relative interior of P^{++}, and a coarse regular tube $\mathcal{T}^+$ over it. On the compact complement, within the set of flat configurations, of the flat configurations with holonomies in this larger patch, the distance of the flat holonomies from $\mathcal{O}$ is at least some $a_0 > 0$. By the modulus of Theorem 35.9, there exists $\eta_m > 0$ such that a change of the input by less than $2\eta_m$ changes every flat output by less than

$a_0/2$. For the finitely many steps $j \le m$, the coordinates of the first m steps satisfy deterministically

$$|z_{\le m}| \le C_m \sqrt{\gamma}(1 + |\log \gamma|). \tag{35.22}$$

Indeed each coordinate is a fixed ratio times $\sqrt{\gamma}\, w_{j,r}$, followed by the bounded Hessian normalization on these finite lattices, and $|w_{j,r}| \le p_j$. For small enough γ_m the right side of (35.22) is less than η_m. Decreasing η_m if necessary, we may also assume that a coarse field within distance η_m of a flat configuration with holonomies in the larger patch belongs to $\mathcal{T}^+$ whenever the holonomies of that flat configuration are within $a_0/2$ of $\mathcal{O}$. Now suppose that $\Xi_m^K \in \mathcal{O}$, $V \notin \mathcal{T}^+$, and $\operatorname{dist}(V, \mathcal{F}_n) < \eta_m$, and let V_0 be flat with $\operatorname{dist}(V, V_0) < \eta_m$. The input distance between $(V, z_{\le m})$ and $(V_0, 0)$ is less than $2\eta_m$, so $\operatorname{Hol}(V_0)$ is within $a_0/2$ of $\Xi_m^K \in \mathcal{O}$. By the choice of a_0, the holonomies of V_0 lie in the larger patch, and then $V \in \mathcal{T}^+$, a contradiction. We conclude that an output in $\mathcal{O}$ coming from outside $\mathcal{T}^+$ forces $\operatorname{dist}(V, \mathcal{F}_n) \ge \eta_m$, and (35.21) proves part (5). The flat configurations with central holonomies lie in the excluded part; the argument does not use that small curvature forces trivial holonomy.

Step 3: bounded output coordinates. We fix regular output tubes $\mathcal{O}_1 \Subset \mathcal{O}_2 \Subset \mathcal{O}_3$ with positive margins, such that $\mathcal{O}_1$ contains the flat outputs of the larger coarse patch being used. Let ϕ_{out} be a smooth function equal to one on $\mathcal{O}_2$ and supported in $\mathcal{O}_3$. On $\mathcal{O}_3$ we multiply the local coordinate maps by ϕ_{out}, and we set both products equal to zero elsewhere on $\mathrm{SU}(2)^3$. This gives the bounded Borel maps

$$b_{\mathrm{ext}}(H) = \phi_{\mathrm{out}}(H)\, b(\operatorname{Log} H), \qquad y_{\mathrm{ext}}(H) = \phi_{\mathrm{out}}(H)\, y(\operatorname{Log} H), \tag{35.23}$$

where the right sides are used only on $\mathcal{O}_3$. They agree with the normal and tangential coordinates on $\mathcal{O}_2$, and they are the extensions used in part (1). They do not alter the invariant observables, which were extended by zero.

Step 4: a good event. We consider the restriction of ν to the coarse tube, normalized by its own mass. By the uniform first-derivative bound and the exact flat values of Theorem 35.9, there exists $\varepsilon_m > 0$, inside the input neighborhood of that theorem, such that $|v| + |z_{\le m}| \le 2\varepsilon_m$ implies $\Xi_m^K \in \mathcal{O}_2$, uniformly in K. By (35.22), after decreasing γ_m we have $|z_{\le m}| \le \varepsilon_m$ deterministically. Let $G_m = \{|v| \le \varepsilon_m\}$ inside the coarse tube. Then

$$\mathbb{P}(G_m^c \mid V \text{ in the coarse tube}) \le C_m \gamma^{-(3n^3-1)} e^{-c_m/\gamma}. \tag{35.24}$$

Indeed, the normal phase is at least $c_n|v|^2$ throughout the coarse tube, the amplitude is bounded, and the conditional normalizing constant at each y is bounded below by $c\gamma^{3n^3-1}$ by the coarse Laplace formula; we then integrate over the tangential distribution. The same estimate holds conditionally at each y in the compact subpatch. Since no departure from $\mathcal{O}_2$ occurs on G_m, (35.24) also bounds the probability of such a departure.

Step 5: Taylor expansion on the good event. On G_m we use the local coordinates and write $u = (v, z_{\le m})$. By the uniform $C^{1,1}$ bound and the smoothness of the normal projection, Taylor's formula along the segment su, $0 \le s \le 1$, gives

$$\Big| b(\operatorname{Log} \Xi_m^K) - T_{0,K} v - \sqrt{\gamma} \sum_{j=1}^{m} A_{j,K} w_j \Big| \le C_m \big(|v| + |z_{\le m}| \big)^2. \tag{35.25}$$

The derivatives here are those of the flowed triple $\mathscr{H}_K$ of the fine configuration, since setting the later fluctuation variables to zero does not change the derivative in an earlier variable at the flat refinements. Substituting $v = \sqrt{\gamma} H_K^{-1/2} z_0$ gives the coarse term $\sqrt{\gamma} A_{0,K} z_0$. The normal moments (35.20) and the deterministic bound (35.22) then bound the remainder divided by $\sqrt{\gamma}$, on G_m, by $C_{m,r'} \sqrt{\gamma} (1 + |\log \gamma|)^2$ in $L^{r'}$. Using the first-order bound for the tangential coordinate, we similarly obtain the bound $C_{m,r'} \sqrt{\gamma} (1 + |\log \gamma|)$ for its displacement.

Step 6: the exceptional event. On G_m^c we define $\mathcal{R}_{K,m}$ by subtracting the displayed linear terms from $b_{\mathrm{ext}}(\Xi_m^K) / \sqrt{\gamma}$. Both extended coordinate maps are bounded, the coarse tube has bounded v, and the fluctuation terms are bounded by $C_m(1 + |\log \gamma|)$ there. This remainder is at most $C_m \gamma^{-1/2}$ for small γ, and (35.24) implies, for every fixed $r' < \infty$ and every $q > 0$,

$$\| \mathbf{1}_{G_m^c} \mathcal{R}_{K,m} \|_{L^{r'}} \le C_{m,r',q} \gamma^q, \qquad \| \mathbf{1}_{G_m^c} \big(y_{\mathrm{ext}}(\Xi_m^K) - y \big) \|_{L^{r'}} \le C_{m,r',q} \gamma^q;$$

here we took the r'-th root of the exponential bound and absorbed the fixed negative power of γ. Together with Step 5 this proves both estimates of part (1). Multiplying the r'-th powers by the mass of the coarse tube, and then by the norm of a bounded multiplicative factor, proves the integrated versions. Any other fixed bounded Borel extensions agreeing with the coordinates on $\mathcal{O}_2$ satisfy the same estimates, with their own bound in the constant.

Step 7: recentering. For $j \le m$ the field at the start of the j-th step is a coarse field in B_r satisfying the coordinate-domain conditions. Since the conditional fluctuation kernel and its cutoff are preserved by Theorem 15.12, Theorem 13.10 applies with $t = t_j$. By (35.7),

$$|\bar{w}_j| \le C \sqrt{D_j}\, t_j r \le C_{m,n,M,J,r} \sqrt{\gamma} \qquad (1 \le j \le m).$$

The inequality holds for every value of the earlier variables, hence also in $L^{r'}$ under the restriction to the coarse tube. Using (35.10) and the Cauchy–Schwarz inequality, we obtain

$$\Big\| \sum_{j=1}^{m} A_{j,K} \bar{w}_j \Big\|_{L^{r'}} \le C \Big(\sum_{j=1}^{m} D_j t_j^2 r^2 \Big)^{1/2} \le C_{m,r'} \sqrt{\gamma}. \tag{35.26}$$

The finite sum may grow with m, as allowed. This is the mean under the conditional fluctuation kernel, not under an enclosing product measure. Replacing w_j by $w_j - \bar{w}_j$ changes the scaled remainder by exactly this quantity, which completes the proof of part (1).

Step 8: the moment identities (part (2)). At fixed m all uncentered moments of the normalized fluctuation variables are bounded, since their centered moments were bounded in Lemma 35.8 and their means are $O_m(\sqrt{\gamma})$. Let $Z = Z_{K,m}$, $b' = b_{\mathrm{ext}}(\Xi_m^K)$, and $y' = y_{\mathrm{ext}}(\Xi_m^K)$. On G_m these are the local coordinates, so $X' = y' + b' = \operatorname{Log} \Xi_m^K$ there. By Taylor's formula, the bound on the exceptional event, and (35.26), we have, under the whole restriction to the coarse tube,

$$b'/\sqrt{\gamma} = Z + R, \qquad \|R\|_{L^r} \le C_{m,r}\sqrt{\gamma}(1 + |\log \gamma|)^2.$$

Every fixed moment of Z is bounded, by Lemma 35.8, and the error R has bounded fixed moments for small γ. The inverse covariance Σ_θ^{-1} has a fixed Lipschitz norm on the larger regular tube. Expanding the quadratic form in $Z + R$, and using $\|y' - y\|_{L^{2r}} \le C_{m,r}\sqrt{\gamma}(1 + |\log \gamma|)$ and Hölder's inequality with higher fixed moments of Z and R for each product, we obtain on G_m

$$\frac{q_*(X')}{\gamma} = \frac{1}{2} Z^{\mathsf{T}} \Sigma_\theta(y)^{-1} Z + O_{L^r,m}\big(\sqrt{\gamma}(1 + |\log \gamma|)^2\big).$$

For the square we use $a^2 - b^2 = (a - b)(a + b)$ and Hölder's inequality, which gives the same order with a possibly larger power of the logarithm. On G_m^c, each bounded weighted observable divided by γ^l has expectation at most $C\gamma^{-l}\mathbb{P}(G_m^c)$, which is smaller than any power of γ by (35.24). The corresponding polynomial in Z has a bounded second moment, so its contribution from G_m^c is at most $C_m \mathbb{P}(G_m^c)^{1/2}$; for $l \le 2$ this uses moments of Z only up to order eight. Thus the comparison extends to the weighted expectations, without evaluating a logarithm or the quadratic form at a point where they are not defined.

The normal cutoff $\chi_w(b')$ differs from one only at a fixed positive normal radius. Using Taylor's formula, the coarse Laplace estimates, and the moments of the first m steps, we find $\mathbb{E}[|b'|^r \mathbf{1}_{\{\Xi_m^K \text{ in the larger tube}\}}] \le C_{m,r}\gamma^{r/2}$ for every fixed r. Markov's inequality with $r > 2(q + l)$ bounds the effect of replacing $\chi_w(b')$ by one, even after division by γ^l, by $C_{m,q}\gamma^q$, and part (5) controls the complement of the larger tube. Next we replace the smooth tangential weight $w(y')$ by $w(y)$; the error is bounded by its Lipschitz norm times $|y' - y|$, multiplied by a power of the scaled quadratic form that is bounded in L^2. We then apply Lemma 35.8 to the resulting polynomial of degree $2l$, conditionally on y, and integrate over the tangential distribution of the coarse field. The coefficient fields of this polynomial are smooth on the fixed compact bundle subcharts, hence bounded and Borel,

as required by that lemma. If $Z \sim G_{\Sigma_m^K(y)}$, then $Z^{\mathsf{T}}\Sigma_\theta(y)^{-1}Z/2$ has the law of $G^{\mathsf{T}}CG/2$ with $C = \widetilde{\Sigma}_m^K(y)$ and G standard Gaussian in four dimensions, and diagonalizing the nonnegative symmetric matrix C gives

$$\mathbb{E}\Big(\frac{1}{2}G^{\mathsf{T}}CG\Big) = \frac{1}{2}\operatorname{tr} C, \qquad \mathbb{E}\Big(\frac{1}{2}G^{\mathsf{T}}CG\Big)^2 = \frac{1}{4}\big\{(\operatorname{tr} C)^2 + 2\operatorname{tr} C^2\big\}.$$

Here we used $\mathbb{E}G_i^2 = 1$, $\mathbb{E}G_i^4 = 3$, and, by independence, $\mathbb{E}G_i^2G_j^2 = 1$ for $i \neq j$ (special cases of Isserlis' theorem [112]); a zero eigenvalue simply deletes the corresponding summand. This identifies the polynomials $\mathfrak{m}_l$ of (35.19).

Step 9: return to the output coordinates. By (35.15), Σ_m^K has a uniformly bounded Lipschitz norm at each fixed m. The field Σ_θ and its inverse square root are smooth, with fixed positive spectral bounds, on the larger regular patch by Theorem 33.11, and the binomial series used in the proof of Theorem 35.10 also bounds the derivative of the inverse square root. Then $\widetilde{\Sigma}_m^K$ has a uniform Lipschitz bound at each fixed m, and the tangential test $w(y)\mathfrak{m}_l(\widetilde{\Sigma}_m^K(y))$ can be moved back to y' with error $C_{m,w}\sqrt{\gamma}(1+|\log\gamma|)^{k_m}$. Finally we multiply by the normal cutoff $\zeta(b')$; as before, $1-\zeta(b')$ is supported at a fixed positive normal radius, so this costs $C_{m,q}\gamma^q$, and part (5) controls the complement of the larger tube. The test on the right side is then exactly $w^+(\Xi_m^K)\mathfrak{m}_l(\widetilde{\Sigma}_m^K(y'))$, and the tube coordinates are never evaluated outside the support of w^+. This proves part (2).

Step 10: normal moments for $m = 0$ and the two value ranges of ψ (parts (3) and (4)). For $m = 0$ there are no fluctuation variables. By the exact flat values and the uniform first derivative, we have $|b(\operatorname{Log}\Xi_0^K)| \le C|v|$ in the larger coarse tube on G_0, and (35.20) gives the claimed moment bound on G_0. On its complement inside the larger coarse tube, the normal radius of an output in the given regular tube is bounded and (35.24) is smaller than any power of γ. Outside the coarse tube, part (5) gives the same bound. These three cases prove the second assertion of part (3); the constant depends on $\mathcal{V}$ but, since only $m = 0$ is used, not on m.

For part (4), let $h_0, h_+ \le 1$ be nonnegative smooth tangential bumps, with positive integrals, supported strictly inside the open sets O_0 (where $\psi_0 = 0$) and O_+ (where $\psi_0 \ge 2b_*$), and fix a smaller normal ball on which $\chi = 1$. By Step 1, the coarse probability of each of the two corresponding sets of coarse fields is at least some $a > 0$. These compact supports have a fixed positive margin to the boundaries of O_0 and O_+ and to the boundary of $\{\chi = 1\}$. Markov's inequality, applied to the tangential and normal displacement bounds of part (1), makes the probability of crossing these margins less than $a/2$, after decreasing γ_m. On the first remaining event $\psi(\operatorname{Log}\Xi_m^K) = 0$, and on the second $\psi(\operatorname{Log}\Xi_m^K) \ge 2b_* \ge b_*$. Thus $c_* = a/2$ works, independently of m, K, and γ; only the required threshold γ_m depends on m. This completes the proof. □

35.5 Regression identities, moment comparison, and removal of the conditioning

This subsection collects the regression identities (Lemma 35.12), a comparison estimate for localized moments at nearby triples (Lemma 35.13), the removal of the conditioning together with the passage to the continuum (Lemma 35.14), and lower bounds for fixed nonnegative observables (Lemma 35.15).

Lemma 35.12. *Let P be a probability measure and let A, B be bounded real random variables with $s = \mathbb{E}_P B^2 > 0$ and $v = \operatorname{Var}_P B > 0$. Then*

$$\mathscr{C}(P; A, B) = \frac{\operatorname{Var}_P A - \operatorname{Cov}_P(A,B)^2/v}{s} = \frac{\inf_{\alpha,c\in\mathbb{R}} \mathbb{E}_P(A - \alpha B - c)^2}{s}.$$

If $0 \le B \le 1$, $P\{B = 0\} \ge p_0 > 0$, and $P\{B \ge b_*\} \ge p_1 > 0$, then $s \ge p_1 b_*^2$ and $v \ge p_0 p_1 b_*^2$. Further, put $a = \mathbb{E}_P B$ and define e_1, e_2, e_3 by

$$\mathbb{E}_P A = \gamma(2a + e_1), \qquad \mathbb{E}_P[AB] = \gamma(2s + e_2), \qquad \mathbb{E}_P A^2 = \gamma^2(6s + e_3)$$

for some $\gamma > 0$. Then

$$\frac{\mathscr{C}(P; A, B)}{\gamma^2} = 2 + \frac{e_3 - 4e_2 - e_1^2 - (e_2 - a e_1)^2/v}{s}. \tag{35.27}$$

In particular, if $P = P_\gamma$ depends on γ, the bounds p_0, p_1, and b_* hold uniformly, and $e_1, e_2, e_3 \to 0$ as $\gamma \downarrow 0$, then $\mathscr{C}(P_\gamma; A, B) = 2\gamma^2 + o(\gamma^2)$, even if $\mathbb{E}_{P_\gamma} B$ and $\mathbb{E}_{P_\gamma} B^2$ have no limits.

Proof. We minimize first over c. At a given α the unique minimizer is $c = \mathbb{E}A - \alpha \mathbb{E}B$, and the remaining quadratic is $\operatorname{Var} A - 2\alpha \operatorname{Cov}(A,B) + \alpha^2 v$. Since $v > 0$, its minimizer is $\alpha = \operatorname{Cov}(A,B)/v$, and its minimum is the numerator in the first expression. This proves the regression identity.

For an independent copy B' of B we have $\operatorname{Var} B = \mathbb{E}(B - B')^2/2$. The two events $\{B = 0,\ B' \ge b_*\}$ and $\{B' = 0,\ B \ge b_*\}$ each have probability at least $p_0 p_1$, and $(B - B')^2 \ge b_*^2$ on each of them, which implies $v \ge p_0 p_1 b_*^2$. Integrating B^2 over $\{B \ge b_*\}$ gives $s \ge p_1 b_*^2$.

For (35.27), note that $v = s - a^2$, that $\operatorname{Cov}(A,B)/\gamma = 2v + e_2 - a e_1$, and that $\operatorname{Var} A/\gamma^2 = 6s + e_3 - (2a + e_1)^2$. Subtracting the square of the first expression divided by v from the second, the terms linear in $a e_1$ cancel, and we obtain $2s + e_3 - 4e_2 - e_1^2 - (e_2 - a e_1)^2/v$; dividing by s gives (35.27). Uniform positive lower bounds on s and v, together with $|a| \le 1$, make the correction in (35.27) tend to zero when $e_1, e_2, e_3 \to 0$, without any limit for a or s. □

Lemma 35.13. *Let $\mathcal{U} \Subset \mathcal{U}^+ \Subset \mathcal{U}^{++}$ be the tubes of Definition 35.1, and let $\widetilde{f}$ be a smooth invariant weight supported strictly inside $\mathcal{U}$ (for example ψ, ψ^2, or a localizing weight $\widetilde{w}$).*

Assume that the inverse covariance Σ_θ^{-1} is bounded and locally Lipschitz on $\mathcal{U}^{++}$ (it is in fact smooth there). Put $f_l = \widetilde{f} q_*^l$, with the fixed bounded zero extensions. For two random triples H, H' in a common gauge frame at the basepoint let

$$D = \max_i \|H_i - H_i'\|_{\mathrm{op}}, \qquad d = \min(1, D), \qquad \beta = |b(\operatorname{Log} H')| \mathbf{1}_{\{H' \in \mathcal{U}^+\}}.$$

There exist $C < \infty$ and $0 < \eta_0 < 1$, depending only on the tubes and their margins, on $\|\Sigma_\theta^{-1}\|_\infty + \operatorname{Lip}(\Sigma_\theta^{-1})$ on $\mathcal{U}^{++}$, and on the weight, such that for every $p \geq 1$ and $l = 1, 2$,

$$|\mathbb{E} f_l(H) - \mathbb{E} f_l(H')| \leq C \big[\mathbb{E}(\beta + d)^{4l-2}\big]^{1/2} \big[\mathbb{E} d^2\big]^{1/2} + C \eta_0^{-p} \, \mathbb{E} d^p,$$

where the constant in front of η_0^{-p} does not depend on p. For $l = 0$ the bound is $C \, \mathbb{E} d$. Applied under ν to $H = \mathcal{H}^K$ and $H' = \Xi_m^K$, with $p = 2l + 2 \leq 6$, these bounds give

$$\limsup_{K \to \infty} \gamma^{-l} |\mathbb{E}_\nu f_l(\mathcal{H}^K) - \mathbb{E}_\nu f_l(\Xi_m^K)| \leq C \delta_m^{1/2} + r_m(\gamma), \qquad l = 1, 2,$$

where $r_m(\gamma) \to 0$ as $\gamma \downarrow 0$ for each fixed m, and C does not depend on m.

Proof. We first prove the comparison inequality without any probabilistic assumption on H, H'. In the coordinates $X = y + b$ write $\mathcal{L}(y) = \Sigma_\theta(y)^{-1}$. The boundedness and local Lipschitz continuity of $\mathcal{L}$, and the smoothness of y and b on the tubes, give

$$|q_*(X) - q_*(X')| \leq C\big(|b(X)| + |b(X')|\big)|X - X'|.$$

Indeed, we expand the difference of the two quadratic forms, first changing b with $\mathcal{L}$ fixed and then changing $\mathcal{L}$; the second term is at most $C|b(X')|^2 |y(X) - y(X')|$, which is bounded by the displayed expression since the tube radius is bounded. For $l = 1, 2$, the factorization of a difference of l-th powers and the Lipschitz bound on $\widetilde{f}$ give

$$|f_l(X) - f_l(X')| \leq C\big(|b(X')| + |X - X'|\big)^{2l-1} |X - X'| \tag{35.28}$$

whenever the segment between the two points lies in $\mathcal{U}^{++}$. The derivative of the weight contributes a term of order $|b|^{2l}$, which we absorbed using the fixed upper bound on $|b|$.

We choose $\eta_0 < 1$ so small that any two triples at matrix distance at most η_0, one of which lies in the support of f_l, both lie in $\mathcal{U}^+$ and have their logarithmic segment in $\mathcal{U}^{++}$. Such a choice exists: we cover the compact support by finitely many coordinate balls whose doubled closures lie in $\mathcal{U}^{++}$ and use the positive margins to the complement of $\mathcal{U}^+$. The logarithm and the tube coordinates have bounded derivatives on these balls, so $|X - X'| \leq CD$ there. On $\{D \leq \eta_0\}$, if both values of f_l vanish there is no difference; otherwise (35.28) gives

$$|f_l(H) - f_l(H')| \leq C(\beta + d)^{2l-1} d.$$

On $\{D > \eta_0\}$ the difference is at most $2\|f_l\|_\infty \le 2\|f_l\|_\infty \eta_0^{-p} d^p$. Taking expectations and applying the Cauchy–Schwarz inequality on the first event proves the inequality; the constant in front of η_0^{-p} does not depend on p. For $l = 0$, the fixed smooth zero extension of $\widetilde{f}$ is globally Lipschitz for the bounded distance d, and the same argument gives $C\,\mathbb{E}d$.

We now prove the application, and first bound the moments of β uniformly in m. Let $d_m = \min(1, D_{K,m})$ and $d_0 = \min(1, D_{K,0})$, where $D_{K,m} = \max_i \|\mathcal{H}_i^K - \Xi_{m,i}^K\|_{\mathrm{op}}$ as in Theorem 34.10, and let $e_m = \min(1, \max_i \|\Xi_{m,i}^K - \Xi_{0,i}^K\|_{\mathrm{op}})$. By the triangle inequality, $e_m \le d_m + d_0$. On $\{e_m \le \eta_1\}$, with η_1 fixed sufficiently small, an endpoint $\Xi_m^K \in \mathcal{U}^+$ has Ξ_0^K in a fixed larger regular tube $\mathcal{V} \subset \mathcal{U}^{++}$, and $|b(\operatorname{Log}\Xi_m^K)| \le |b(\operatorname{Log}\Xi_0^K)| + Ce_m$. On $\{e_m > \eta_1\}$, the bounded normal radius is at most $C\eta_1^{-1}e_m$. Combining the two cases, we find, for every fixed $r \le 8$,

$$\mathbb{E}\beta^r \le C_r\,\mathbb{E}\big[|b(\operatorname{Log}\Xi_0^K)|^r \mathbf{1}_{\{\Xi_0^K \in \mathcal{V}\}}\big] + C_r\,\mathbb{E}(d_m + d_0)^r \le C_r\gamma^{r/2}. \tag{35.29}$$

In the last step we used only part (3) of Theorem 35.11 with $m = 0$ and the bounds on high moments in Theorem 34.10. Both are estimates under ν, at the fixed side and in the same gauge frame at the basepoint. The tube $\mathcal{V}$ is chosen before m, and both constants for the distance moments are independent of m, so the constant in (35.29) does not depend on m.

For $l = 1, 2$ we take $r = 4l - 2$, which is two or six. By (35.29) and the moment bound for d_m, we have $\mathbb{E}(\beta + d_m)^{4l-2} \le C\gamma^{2l-1}$. The second-moment bound of Theorem 34.10 gives

$$(\mathbb{E}d_m^2)^{1/2} \le C\sqrt{\gamma}\,\delta_m^{1/2} + C\gamma(1 + |\log\gamma|)^k,$$

where k denotes the exponent written d in that theorem. With $p = 2l + 2$, the exceptional term is at most $C_p\gamma^{l+1}$ by the same theorem. The comparison inequality therefore gives, at every finite $K \ge m$,

$$\gamma^{-l}|\mathbb{E}f_l(\mathcal{H}^K) - \mathbb{E}f_l(\Xi_m^K)| \le C\delta_m^{1/2} + C\sqrt{\gamma}(1 + |\log\gamma|)^k + C\gamma. \tag{35.30}$$

This proves the claim, with $r_m(\gamma) = C\sqrt{\gamma}(1 + |\log\gamma|)^k + C\gamma$. For $l = 2$ the sixth normal moment is used in an essential way. □

Lemma 35.14. *Fix $0 < \gamma \le \gamma_W(n)$, and let $F : \mathrm{SU}(2)^3 \to \mathbb{R}$ be bounded, continuous, and invariant under simultaneous conjugation; F may depend on γ. Write $e = \mu_{N,\gamma}(S_{N,n,\gamma}^c)$, with $N = nB^K$. Then, for every $q > 0$,*

$$|\mathbb{E}_{\mu_{N,\gamma}}F(\mathcal{H}^K) - \mathbb{E}_\nu F(\mathcal{H}^K)| \le 2\|F\|_\infty e \le 2\|F\|_\infty C_{n,q}\gamma^q,$$

uniformly in K, and

$$\lim_{K\to\infty} \mathbb{E}_{\mu_{N,\gamma}}F(\mathcal{H}^K) = \mathbb{E}_{\lambda_\gamma}F(H),$$

where H denotes the coordinate-cycle holonomy triple of $X(\theta L^2)$.

Proof. The value $F(\mathcal{H}^K)$ depends only on the gauge orbit of the fine configuration, since F is invariant, the reconstruction maps produce a gauge-equivalent configuration, and the Wilson flow commutes with lattice gauge transformations. Hence $F(\mathcal{H}^K)$ equals F evaluated at the coordinate-cycle holonomy triple of $\Psi^{(N)}_{\theta L^2}U$, which is a bounded measurable function on the whole configuration space; this is how $F(\mathcal{H}^K)$ is understood under $\mu_{N,\gamma}$. For any bounded F and any event S with $e = \mu(S^c)$ we have

$$\mathbb{E}_\mu F = (1-e)\mathbb{E}_\nu F + e\,\mathbb{E}_\mu(F \mid S^c), \qquad |\mathbb{E}_\mu F - \mathbb{E}_\nu F| \le 2\|F\|_\infty e, \tag{35.31}$$

where the last term of the identity is set to zero when $e = 0$; see also Lemma 5.5. By Corollary 23.11, at the fixed side n we have $e \le C_{n,q}\gamma^q$ for every fixed $q > 0$, uniformly in K. This proves the first assertion.

For the second, Lemma 5.6 writes $F = f \circ \mathfrak{p}$, where $\mathfrak{p}$ is the vector of the seven normalized traces of H_1, H_2, H_3, H_1H_2, H_1H_3, H_2H_3, and $H_1H_2H_3$, and f is continuous on $[-1,1]^7$ with $\|f\|_\infty \le \|F\|_\infty$. These traces are the normalized fundamental Wilson loops of the three coordinate cycles and of their concatenations, which are fixed piecewise C^1 based loops of bounded length. On each lattice of the sequence they are exact lattice loops, which form admissible approximations. By Theorem 29.25, in the form of Corollary 29.26, the joint law of these seven traces under $\mu_{N,\gamma}$, at the flow time θL^2, converges as $K \to \infty$ to their joint law under λ_γ. At fixed γ the corollary may discard finitely many initial terms of the sequence nB^K; this does not affect the limit, and the side n is not changed. Since f is bounded and continuous, the expectations converge. □

Lemma 35.15. *Let $\mathsf{K}_1 \subset \mathsf{P}^{++}$ be a compact invariant set with nonempty relative interior, contained in the relative interior of P^{++}, and let $r_c > 0$ be such that $\mathcal{T}_c = \{y + b : y \in \mathsf{K}_1,\ b \in \mathcal{N}_y,\ |b| \le r_c\} \subset \mathcal{U}^{++}$. Let $\varphi : \mathrm{SU}(2)^3 \to [0,\infty)$ be bounded, invariant under simultaneous conjugation, and Lipschitz for the matrix distance, and assume $\varphi(H) \ge c_1 > 0$ whenever $\operatorname{Log} H \in \mathcal{T}_c$. Then there exist $a, \gamma_1 > 0$ such that, for $0 < \gamma \le \gamma_1$ and $K \ge K_0(0)$,*

$$\mathbb{E}_\nu \varphi(\Xi_0^K) \ge c_1 a, \qquad \mathbb{E}_\nu \varphi(\mathcal{H}^K) \ge c_1 a/2, \qquad \mathbb{E}_{\lambda_\gamma} \varphi(H) \ge c_1 a/4.$$

Proof. Let K_1' be a compact invariant subset of the relative interior of K_1 with nonempty relative interior. At the flat coarse field $V(y,0)$ we have $\operatorname{Log}\Xi_0^K = y$, by the exact flat values of Theorem 35.9. By the uniform first-derivative bound of that theorem with $m = 0$, there exists $\varepsilon' > 0$ such that, for every coarse field $V = V(y,v)$ with $y \in \mathsf{K}_1'$ and $|v| \le \varepsilon'$, the tangential component of $\operatorname{Log}\Xi_0^K$ lies in K_1 and its normal component has norm at most r_c; hence $\operatorname{Log}\Xi_0^K \in \mathcal{T}_c$, uniformly in K. Taking in Step 1 of the proof of Theorem 35.11 a tangential bump supported in K_1' and a normal cutoff supported in $\{|v| \le \varepsilon'\}$, we find that the set $\{V(y,v) : y \in \mathsf{K}_1',\ |v| \le \varepsilon'\}$ has $\widehat{\nu}$-probability at least some $a > 0$, uniformly in K, for all sufficiently small γ. This gives $\mathbb{E}_\nu \varphi(\Xi_0^K) \ge c_1 a$.

Since φ is Lipschitz for the bounded matrix distance, Theorem 34.10 with $m = 0$ gives

$$|\mathbb{E}_\nu \varphi(\mathcal{H}^K) - \mathbb{E}_\nu \varphi(\Xi_0^K)| \le \operatorname{Lip}(\varphi)\,\big(\mathbb{E}_\nu \min(1, D_{K,0})^2\big)^{1/2} \le C\sqrt{\gamma},$$

so $\mathbb{E}_\nu \varphi(\mathcal{H}^K) \geq c_1 a/2$ for small γ, uniformly in K. Finally, by Lemma 35.14 with a fixed $q > 0$, we have $\mathbb{E}_{\mu_{N,\gamma}} \varphi(\mathcal{H}^K) \geq c_1 a/2 - 2C_{n,q}\gamma^q$ for every K, and letting $K \to \infty$ gives $\mathbb{E}_{\lambda_\gamma} \varphi \geq c_1 a/2 - 2C_{n,q}\gamma^q \geq c_1 a/4$ for small γ. □

35.6 Proof of the regression coefficient

Proof of Theorem 35.2. We first check that the observables are admissible continuum observables (Step 1) and prove the lower bounds on the denominators (Step 2). We then prove the normalized moment estimate at finite cutoff (Steps 3 and 4), take the limits in the stated order (Step 5), and conclude with Lemma 35.12 (Step 6).

Step 1: the observables. The inverse covariance Σ_θ^{-1}, the tube coordinates, and the cutoffs are invariant under simultaneous conjugation. The supports of ψ and ψ^2 have positive distance from the boundary of the identity chart, so their zero extensions, and their products with q_* and q_*^2, are bounded and continuous on $\mathrm{SU}(2)^3$; they contain no coupling parameter. The continuous invariant factorization of Lemma 5.6 applies on the whole compact space of triples, including central triples and triples of deficient rank. In particular, these observables are continuous functions of the seven normalized traces, as stated.

Step 2: lower bounds on the denominators. We choose compact invariant sets $\mathsf{K}_0 \subset O_0$ and $\mathsf{K}_+ \subset O_+$ with nonempty relative interiors, and a radius $r_c > 0$ such that $\chi(b) = 1$ whenever $|b| \leq 2r_c$. Let $\rho_0, \rho_+ : \mathrm{SU}(2)^3 \to [0,1]$ be smooth invariant functions, equal to one on the tubes of radius r_c over K_0 and K_+ respectively, with ρ_0 supported in the interior of $\{\psi = 0\}$ and ρ_+ supported inside $\{\psi > b_*\}$. The latter set has room for such a choice because $\psi_0 \geq 2b_*$ on O_+ and $\chi = 1$ on the normal ball of radius $2r_c$. In finite coordinates such functions are obtained from a smooth function of the squared distance in finitely many small balls, by adding these bumps and truncating smoothly to one on their cores. Averaging over simultaneous conjugation with respect to the Haar probability measure makes them invariant; since the relevant sets are invariant, the support and core properties are preserved. Both functions are Lipschitz for the matrix distance. By Lemma 35.15, there exists $a' > 0$ such that $\mathbb{E}_{\lambda_\gamma} \rho_0 \geq a'$ and $\mathbb{E}_{\lambda_\gamma} \rho_+ \geq a'$ for all sufficiently small γ. By the support properties, $\lambda_\gamma\{B_{\mathrm{obs}} = 0\} \geq a'$ and $\lambda_\gamma\{B_{\mathrm{obs}} \geq b_*\} \geq a'$. Since $0 \leq B_{\mathrm{obs}} \leq 1$, Lemma 35.12 implies $\mathbb{E}_{\lambda_\gamma} B_{\mathrm{obs}}^2 \geq a' b_*^2$ and $\mathrm{Var}_{\lambda_\gamma} B_{\mathrm{obs}} \geq (a')^2 b_*^2$, which proves the first assertion.

Step 3: the Gaussian moment polynomials. On any bounded set of nonnegative 4×4 matrices we have

$$|\mathfrak{m}_1(C) - 2| + |\mathfrak{m}_2(C) - 6| \leq C' \|C - I\|.$$

Indeed, $|\mathrm{tr}(C - I)| \leq 4\|C - I\|$, $|\mathrm{tr}\, C^2 - 4| = |\mathrm{tr}((C - I)(C + I))| \leq 4\|C - I\|(\|C\| + 1)$, and $(\mathrm{tr}\, C)^2 - 16 = (\mathrm{tr}\, C - 4)(\mathrm{tr}\, C + 4)$. By (35.16), $0 \leq \Sigma_m^K \leq \Sigma_\theta^N$, and together with

the spectral bounds of Theorem 33.11 this bounds the norms of all $\widetilde{\Sigma}_m^K$ by a constant independent of m. Then (35.14) compares the moment polynomials at finite K directly with $\mathfrak{m}_1(I) = 2$ and $\mathfrak{m}_2(I) = 6$.

Step 4: the normalized moments at finite cutoff. We apply part (2) of Theorem 35.11 with the tangential weights ψ_0 and ψ_0^2 and the normal cutoffs χ and χ^2, so that $\widetilde{w} = \psi$ or ψ^2. On its right side, w^+ and $\widetilde{w}$ differ only at a fixed positive normal radius. The normal moment bounds of Step 8 of its proof, Markov's inequality, and the boundedness of $\mathfrak{m}_l(\widetilde{\Sigma}_m^K)$ show that replacing w^+ by $\widetilde{w}$ changes the expectation by $O_{m,q}(\gamma^q)$ for every fixed q; the polynomial comparison in that theorem is supplied by Lemma 35.8. We take $K_0(m) \geq \max\{m, K_0(0)\}$, as allowed. For $f = \psi$ and $f = \psi^2$ and $l = 1, 2$, we compare $\gamma^{-l}\mathbb{E}_\nu[f q_*^l(\mathcal{H}^K)]$ with $\gamma^{-l}\mathbb{E}_\nu[f q_*^l(\Xi_m^K)]$ by (35.30), then with $\mathbb{E}_\nu[f(\Xi_m^K)\mathfrak{m}_l(\widetilde{\Sigma}_m^K(y'))]$ by part (2), then with $\mathfrak{m}_l(I)\mathbb{E}_\nu f(\Xi_m^K)$ by Step 3 and (35.14), and finally with $\mathfrak{m}_l(I)\mathbb{E}_\nu f(\mathcal{H}^K)$ by the case $l = 0$ of Lemma 35.13, which costs $C\,\mathbb{E}d_m \leq C\sqrt{\gamma}$. We obtain

$$\begin{aligned} &\bigl|\gamma^{-l}\mathbb{E}_\nu[f q_*^l(\mathcal{H}^K)] - \mathfrak{m}_l(I)\mathbb{E}_\nu[f(\mathcal{H}^K)]\bigr| \\ &\qquad \leq C\bigl\{\delta_m^{1/2} + \delta_m + (nB^K)^{-2}\bigr\} + e_m(\gamma), \qquad K \geq K_0(m), \end{aligned} \tag{35.32}$$

where $e_m(\gamma) \to 0$ as $\gamma \downarrow 0$ for each fixed m; one may take for e_m a finite sum of terms $C_m\sqrt{\gamma}(1 + |\log\gamma|)^{k_m}$, $C\sqrt{\gamma}(1 + |\log\gamma|)^k$, and $C_m\gamma$. The constants in front of $\delta_m^{1/2}$, δ_m, and the lattice error do not depend on m.

Step 5: the limits. We apply Lemma 35.14 to each bounded product $f q_*^l$ and to f, before dividing by γ^l. For a fixed $q > 2$, the cost of replacing ν by $\mu_{N,\gamma}$ is $O(\gamma^{q-l}) = o(1)$ after division by γ^l, for every $l \leq 2$. Then (35.32) holds for $\mu_{N,\gamma}$, with this additional error. At each fixed γ, Lemma 35.14 gives the limits as $K \to \infty$ of these expectations under $\mu_{N,\gamma}$, which are the corresponding expectations under λ_γ. When $K \to \infty$, the lattice error disappears, without any division by γ. Next we let $\gamma \downarrow 0$ at the fixed m, which gives

$$\limsup_{\gamma\downarrow 0}\bigl|\gamma^{-l}\mathbb{E}_{\lambda_\gamma}[f q_*^l] - \mathfrak{m}_l(I)\mathbb{E}_{\lambda_\gamma} f\bigr| \leq C\bigl(\delta_m^{1/2} + \delta_m\bigr).$$

Letting $m \to \infty$, we obtain the two moment identities. The side n and the sequence nB^K are fixed throughout; only finitely many initial terms of the sequence may be discarded in the inner limit $K \to \infty$, as allowed by Corollary 29.26.

Step 6: the statistic. With $A_{\mathrm{obs}} = \psi q_*$ and $B_{\mathrm{obs}} = \psi$, the three errors of Lemma 35.12 are

$$e_1 = \gamma^{-1}\mathbb{E}[\psi q_*] - 2\mathbb{E}\psi, \qquad e_2 = \gamma^{-1}\mathbb{E}[\psi^2 q_*] - 2\mathbb{E}\psi^2, \qquad e_3 = \gamma^{-2}\mathbb{E}[\psi^2 q_*^2] - 6\mathbb{E}\psi^2,$$

with all expectations under λ_γ. By Step 5 they tend to zero. Combining the lower bounds of Step 2 with (35.27), we obtain $\mathscr{C}_\gamma = 2\gamma^2 + o(\gamma^2)$. Further, Step 5 shows that at each fixed m the upper limits of $|e_1|, |e_2|, |e_3|$ are at most $C(\delta_m^{1/2} + \delta_m)$, and the exact identity

(35.27) then implies the stated bound on $\mathscr{C}_\gamma/\gamma^2 - 2$, with a constant independent of m. The quadratic errors e_1^2 and $(e_2 - ae_1)^2$ are absorbed using that δ_m is bounded in m and that $|a| \le 1$. □

35.7 A weighted chi-square limit with four degrees of freedom

Proof of Theorem 35.3. Only the values of q_* on the support of $\widetilde{w}$ enter, where q_* is the exact nonnegative quadratic form; the extension of q_* has no effect on π_γ. We first prove a finite-scale version of the statement for bounded Lipschitz f (Steps 1–3) and replace the finite-scale triple by the triple of the fine configuration (Step 4). We then prove the lower bound on D_γ (Step 5), pass to the continuum and take the limits (Step 6), and finally extend the result to bounded continuous f and identify the limit law (Step 7).

Step 1: the finite-scale expansion. Fix m, let $K \ge K_0(m) \ge \max\{m, K_0(0)\}$, let γ be below the threshold of Theorem 35.11, and write $H_m = \Xi_m^K$ and $a_f = \mathbb{E} f(|G_4|^2/2)$. We choose a larger coarse regular tube before m: its flat holonomies cover a fixed larger regular patch and are separated from the compact support of $\widetilde{w}$ on the complementary part of the set of flat configurations. The modulus of Theorem 35.9 has an input margin depending on m, which changes the coupling threshold but not this tube. By part (5) of Theorem 35.11, there exists a larger coarse regular tube $\mathcal{T}^+$ such that an output in the support of $\widetilde{w}$ coming from outside $\mathcal{T}^+$ has probability $O_{m,q}(\gamma^q)$ for each fixed $q > 0$. Inside the coarse tube we use the restriction of ν normalized by its own mass, and write y for the tangential coordinate of the coarse field. Part (1) of the same theorem, with its bounded output coordinates, gives

$$b(H_m)/\sqrt{\gamma} = Z_{K,m} + \mathcal{R}_{K,m}, \qquad \|\mathcal{R}_{K,m}\|_{L^r} \le C_{m,r}\sqrt{\gamma}(1 + |\log\gamma|)^2,$$

and $\|y(H_m) - y\|_{L^r} \le C_{m,r}\sqrt{\gamma}(1 + |\log\gamma|)$ for every fixed finite r, where the recentering by the conditional means is included in $\mathcal{R}_{K,m}$. These formulas are local coordinate identities only on the good event G_m of Step 4 of that proof, whose complement has probability $O_{m,q}(\gamma^q)$ for every fixed $q > 0$ by (35.24). By Lemma 35.8, all required moments of $Z_{K,m}$ are bounded at this fixed m.

Step 2: comparison with a Gaussian quadratic form. The ambient inverse covariance $P_{\mathcal{N}_y}\Sigma_\theta(y)^{-1}P_{\mathcal{N}_y}$ is smooth on the larger patch by Theorem 33.11. Expanding the quadratic form and using Hölder's inequality, we obtain on the good event

$$\Big\| \frac{q_*(H_m)}{\gamma} - \frac{1}{2} Z_{K,m}^{\mathsf{T}} \Sigma_\theta(y)^{-1} Z_{K,m} \Big\|_{L^1} \le C_m \sqrt{\gamma}(1 + |\log\gamma|)^{k_m}.$$

Explicitly, the difference is bounded by a constant times $|\mathcal{R}|(|Z| + |\mathcal{R}|) + |y(H_m) - y|(|Z| + |\mathcal{R}|)^2$, and moments of order at most six suffice. Since f is Lipschitz, the same

bound times $\operatorname{Lip} f$ controls the change of $f(q_*(H_m)/\gamma)$. The smooth weight $w(y(H_m))$ can be moved to $w(y)$, and back, with an error of the same order. The normal cutoff χ_w differs from one only at a fixed positive normal radius, so arbitrarily high fixed moments of the normal coordinate of H_m (Step 8 of the proof of Theorem 35.11) make the effect of replacing χ_w by one $O_{m,q}(\gamma^q)$. On the exceptional events we use only that f and the weight are bounded, without taking a logarithm there. These comparisons hold after multiplication by the mass of the coarse tube, which is at most one.

Step 3: the Gaussian value. Conditionally on y, we apply Lemma 35.8 to the bounded Borel function $z \mapsto f(z^{\mathsf T}\Sigma_\theta(y)^{-1}z/2)$. This gives the Gaussian value

$$\kappa_f\big(\widetilde\Sigma_m^K(y)\big) = \mathbb{E} f\Big(\frac{1}{2} G_4^{\mathsf T}\widetilde\Sigma_m^K(y) G_4\Big),$$

with error $C_m\|f\|_\infty\sqrt{\gamma}(1+|\log\gamma|)$. The equality of the laws of the two Gaussian quadratic forms follows by diagonalizing the nonnegative covariance matrix; no inverse of Σ_m^K is used. Coupling the two quadratic forms through the same G_4, we obtain

$$|\kappa_f(C) - a_f| \le \frac{1}{2}\operatorname{Lip} f\, \|C-I\|\, \mathbb{E}|G_4|^2 = 2\operatorname{Lip} f\, \|C-I\|.$$

Integrating against the tangential law of the coarse field and using (35.14), we obtain

$$\big|\mathbb{E}_\nu[\widetilde w(H_m) f(q_*(H_m)/\gamma)] - a_f \mathbb{E}_\nu \widetilde w(H_m)\big| \le C_w\|f\|_{\mathrm{BL}}\big\{\delta_m + (nB^K)^{-2}\big\} + \|f\|_{\mathrm{BL}}\, e_{m,w}(\gamma), \tag{35.33}$$

with $e_{m,w}(\gamma) \to 0$ as $\gamma \downarrow 0$. One may take for $e_{m,w}$ a finite sum of terms $C_{m,w}\sqrt{\gamma}(1+|\log\gamma|)^{k_m}$ and of arbitrarily high fixed powers of γ. The constant C_w does not depend on m: only the bound on the weight and the uniform covariance error enter it.

Step 4: comparison with the triple of the fine configuration. We now replace H_m by $H = \mathcal{H}^K$ in the bounded test $F_\gamma(H) = \widetilde w(H) f(q_*(H)/\gamma)$. This needs a separate estimate, because the Lipschitz constant of $f(q_*/\gamma)$ grows as $\gamma \downarrow 0$. We use the nested tubes of Lemma 35.13 and set

$$d_m = \min\Big(1, \max_i \|H_i - H_{m,i}\|_{\mathrm{op}}\Big), \qquad \beta_m = |b(\operatorname{Log} H_m)|\mathbf{1}_{\{H_m \in \mathcal{U}^+\}}.$$

The normal coordinate is used only on the indicated tube. For a fixed $0 < \eta < 1$, if $d_m \le \eta$ and at least one of the two weights is nonzero, then both triples lie in $\mathcal{U}^+$ and their logarithmic segment lies in $\mathcal{U}^{++}$. On this event the smooth coordinates and the Lipschitz bound on Σ_θ^{-1} give

$$|q_*(H) - q_*(H_m)| \le C(\beta_m + d_m) d_m;$$

indeed we expand the two quadratic forms and use $|b(\operatorname{Log} H)| \le |b(\operatorname{Log} H_m)| + C d_m$. Therefore, on this event,

$$|F_\gamma(H) - F_\gamma(H_m)| \le C_w\|f\|_\infty d_m + C_w \operatorname{Lip} f\, \gamma^{-1}(\beta_m + d_m) d_m.$$

If both weights vanish, the difference is zero. On $\{d_m > \eta\}$ the boundedness of F_γ gives the bound $C_w\|f\|_\infty \eta^{-4} d_m^4$.

We bound the second normal moment with a constant independent of m. We compare H_m with $H_0 = \Xi_0^K$ and let $d_0 = \min(1, \max_i \|H_i - H_{0,i}\|_{\mathrm{op}})$; the truncated distance between H_m and H_0 is at most $d_m + d_0$. When this distance is small and $H_m \in \mathcal{U}^+$, H_0 lies in a fixed larger regular tube $\mathcal{V}$ and $\beta_m \le |b(\operatorname{Log} H_0)| + C(d_m + d_0)$. When the distance exceeds a fixed margin, the boundedness of the normal radius gives $\beta_m \le C(d_m + d_0)$. Combining the two cases, we obtain

$$\mathbb{E}_\nu \beta_m^2 \le C\,\mathbb{E}_\nu\big[|b(\operatorname{Log} H_0)|^2 \mathbf{1}_{\{H_0 \in \mathcal{V}\}}\big] + C\,\mathbb{E}_\nu (d_m + d_0)^2 \le C\gamma,$$

where we used part (3) of Theorem 35.11 with $m = 0$ and the moment bounds of Theorem 34.10, which hold for all m with the same constants. The tube $\mathcal{V}$ is fixed before m. By the Cauchy–Schwarz inequality and Theorem 34.10, we have, uniformly for $K \ge K_0(m)$,

$$|\mathbb{E}_\nu F_\gamma(H) - \mathbb{E}_\nu F_\gamma(H_m)| \le C_w \|f\|_{\mathrm{BL}} \big\{\delta_m^{1/2} + \sqrt{\gamma}(1 + |\log\gamma|)^k + \gamma^2\big\}. \tag{35.34}$$

Indeed $(\mathbb{E}(\beta_m + d_m)^2)^{1/2} \le C\sqrt{\gamma}$ and $(\mathbb{E} d_m^2)^{1/2} \le C\sqrt{\gamma}\,\delta_m^{1/2} + C\gamma(1 + |\log\gamma|)^k$, so the factor γ^{-1} is compensated by the size of the quadratic form; the fourth moment on the far event is at most $C\gamma^2$. For the weight alone, its global Lipschitz continuity gives the simpler bound $|\mathbb{E}\widetilde{w}(H) - \mathbb{E}\widetilde{w}(H_m)| \le C_w\sqrt{\gamma}$.

Step 5: the lower bound on D_γ. Since w is continuous, nonnegative, and not identically zero, there exist a compact invariant set K_1 with nonempty relative interior in the relative interior of P and $c_1 > 0$ with $w \ge c_1$ on K_1; let $r_c > 0$ be such that $\chi_w = 1$ on $\{|b| \le r_c\}$. Then $\widetilde{w} \ge c_1$ on the corresponding tube $\mathcal{T}_c$, and $\widetilde{w}$ is smooth, invariant, and Lipschitz for the matrix distance. By Lemma 35.15, $\mathbb{E}_\nu \widetilde{w}(H) \ge c_w'$ uniformly in K and $D_\gamma = \mathbb{E}_{\lambda_\gamma}\widetilde{w} \ge c_w > 0$ for all sufficiently small γ.

Step 6: the continuum and the limits. For each fixed $\gamma > 0$, F_γ is a bounded continuous invariant function on the compact space of triples, with its fixed zero extension, and its supremum $\|\widetilde{w}\|_\infty \|f\|_\infty$ does not depend on γ. By Lemma 35.14, the expectations of $F_\gamma(\mathcal{H}^K)$ and of $\widetilde{w}(\mathcal{H}^K)$ under ν and under $\mu_{N,\gamma}$ differ by at most $C_{w,q}\|f\|_\infty \gamma^q$ for any fixed $q > 0$, and the expectations under $\mu_{N,\gamma}$ converge to the expectations under λ_γ as $K \to \infty$. This uses only the supremum of the test, never its Lipschitz constant, so no negative power of γ appears. Combining (35.33) and (35.34) with the bound for the weight alone, letting $K \to \infty$ at fixed γ and m, and dividing by $D_\gamma \ge c_w$, we obtain the quantitative bound in the statement, after absorbing the terms from Step 4 and from the conditioning into $e_{m,w}$. The lattice error vanishes in this first limit. The estimates at finite cutoff were needed only for $K \ge K_0(m)$, which suffices for this limit. Letting $\gamma \downarrow 0$ at fixed m, and then $m \to \infty$, we obtain $\int f\, d\pi_\gamma \to \mathbb{E} f(|G_4|^2/2)$ for every bounded Lipschitz f.

Step 7: bounded continuous tests and the limit law. We extend the convergence to bounded continuous f by tightness, without using convergence of moments. Let η_R be zero on $[0, R]$, linear on $[R, R+1]$, and one on $[R+1, \infty)$. It is bounded and Lipschitz, so the convergence already proved gives

$$\limsup_{\gamma \downarrow 0} \pi_\gamma([R+1, \infty)) \le \mathbb{E}\eta_R(|G_4|^2/2) \le \mathbb{P}\{|G_4|^2/2 > R\} \longrightarrow 0 \qquad (R \to \infty).$$

On each compact interval a bounded continuous f has uniformly accurate piecewise linear approximations, which we extend by constants outside the interval; they are bounded Lipschitz functions. The two tail probabilities bound the error outside the interval by a fixed multiple of $\|f\|_\infty$. Increasing first the interval and then decreasing the approximation error, we obtain the convergence for f. Finally, each of $(G_1^2 + G_2^2)/2$ and $(G_3^2 + G_4^2)/2$ has density $e^{-u}\mathbf{1}_{\{u \ge 0\}}$, by polar coordinates in the plane. They are independent, and their convolution has density $ue^{-u}\mathbf{1}_{\{u \ge 0\}}$, which identifies the law of $|G_4|^2/2$ and completes the proof. □

35.8 Gaussian approximation on the regular normal bundle

Proof of Theorem 35.4. We first verify the geometric and measurability statements (Step 1) and extend a Lipschitz test to a larger bundle (Step 2). We then prove the quantitative bound for bounded Lipschitz F at finite cutoff, first for the finite-scale triple (Steps 3–5) and then for the triple of the fine configuration (Step 6), and pass to the continuum (Step 7). Finally we extend the result to bounded continuous F (Step 8).

Step 1: geometry of the quotient. All vector comparisons below use the Euclidean embedding of the normal spaces in $\mathbb{R}^9$; no global frame is introduced. On a finite smooth orthonormal bundle atlas, Σ_θ and its inverse square root are smooth with bounded derivatives, by Theorems 33.11 and 35.10, and they are equivariant under simultaneous conjugation, as are the normal coordinates. For $g \in \mathrm{SU}(2)$ the isometry $\mathrm{Ad}(g) : \mathcal{N}_y \to \mathcal{N}_{\mathrm{Ad}(g)y}$ therefore carries Γ_y to $\Gamma_{\mathrm{Ad}(g)y}$, and the invariance of F gives $\overline{F}(\mathrm{Ad}(g)y) = \overline{F}(y)$. The quotient of the compact invariant patch P' is compact and metrizable, for example by

$$d_{\mathrm{orb}}([y], [y']) = \min_{g \in \mathrm{SU}(2)} |y - \mathrm{Ad}(g)y'|.$$

Since the group is compact, the minimum is attained and zero distance identifies exactly one orbit; the isometric action gives the triangle inequality. Its topology is the quotient topology, since the continuous bijection from the compact quotient to this metric space is a homeomorphism. On the compact support of $\widetilde{w}$, the tangential projection followed by the quotient map is continuous and invariant. By Lemma 5.6, the seven traces separate the classes of simultaneous conjugacy; their map on this compact support is a continuous

surjection onto its Hausdorff image, hence a quotient map, and the tangential class factors continuously through this image. In particular $[y_\gamma]$ is a Borel function on the support of $\widetilde{w}$; elsewhere we may assign any fixed point of the quotient, since the weight vanishes there. Thus ρ_γ is a probability measure on the Borel quotient, and the identity $D_\gamma^{-1}\mathbb{E}[\widetilde{w}\,\overline{F}(y_\gamma)] = \int \overline{F}\,d\rho_\gamma$ holds and does not depend on the choice of representatives. For the regularity of the fiber integral, let $E_y : \mathbb{R}^4 \to \mathcal{N}_y$ be a smooth orthonormal frame in one chart and write $\overline{F}(y) = \mathbb{E}F(y, E_y G_4)$. The bounded derivative of the frame gives

$$|\overline{F}(y) - \overline{F}(y')| \le C \operatorname{Lip} F\,(1 + \mathbb{E}|G_4|)|y - y'|,$$

and a finite cover with positive interior margins gives the same bound on the compact patch. Hence $\overline{F}$ is bounded Lipschitz with $\|\overline{F}\|_{\mathrm{BL}} \le C\|F\|_{\mathrm{BL}}$. The same formula and dominated convergence show that $\overline{F}$ is continuous when F is only continuous.

Step 2: extension of a Lipschitz test. Let F be bounded Lipschitz. In the proof the test is evaluated at the tangential coordinate y of the coarse field and at triples where the weight may vanish, and these tangential coordinates may lie outside P'. We therefore first extend F. Let $\widehat{F}(x) = \inf_s\{F(s) + \operatorname{Lip} F\,|x - s|\}$, the infimum over s in the normal bundle over P', be the McShane extension to $\mathbb{R}^9 \times \mathbb{R}^9$; it has the same Lipschitz constant. Truncating it at $\pm\|F\|_\infty$ preserves the Lipschitz constant and gives the bound $\|F\|_\infty$. Averaging the result with respect to the Haar probability measure over the diagonal action $(y, z) \mapsto (\mathrm{Ad}(g)y, \mathrm{Ad}(g)z)$, which acts by isometries of $\mathbb{R}^9 \times \mathbb{R}^9$, preserves the bound and the Lipschitz constant and gives an invariant function. Since F is invariant and the bundle over P' is invariant, the averaged function agrees with F there. We denote this extension, restricted to the normal bundle over P^{++}, again by F, and define $\overline{F}$ by the same formula on P^{++}; Step 1 applies on P^{++} as well. Since $\widetilde{w}$ vanishes unless the tangential coordinate lies in P', the quantities in the theorem are unchanged.

Step 3: the finite-scale expansion. We work under ν, with $H = \mathcal{H}^K$ and $H_m = \Xi_m^K$, the triple of the finite-scale reconstruction from the first m steps on the same sample. All estimates are for $K \ge K_0(m)$, as allowed by Theorem 35.11. Under the restriction of ν to its larger coarse regular tube, normalized by its own mass, let y be the tangential coordinate of the coarse field. That theorem and Lemma 35.8 give

$$\gamma^{-1/2} b(H_m) = Z_{K,m} + \mathcal{R}_{K,m}, \qquad \|\mathcal{R}_{K,m}\|_{L^r} \le C_{m,r}\sqrt{\gamma}(1 + |\log\gamma|)^2,$$

$$\|y(H_m) - y\|_{L^r} \le C_{m,r}\sqrt{\gamma}(1 + |\log\gamma|), \qquad Z_{K,m} = A_{0,K} z_0 + \sum_{j=1}^{m} A_{j,K}(w_j - \bar{w}_j),$$

where $\bar{w}_j$ is the conditional mean of w_j under the conditional fluctuation kernel and the error of the recentering is included in $\mathcal{R}_{K,m}$. All fixed moments of $Z_{K,m}$ are bounded uniformly in K at this m. These are local coordinate identities only on the output tube,

with the bounded extensions of part (1) of Theorem 35.11. By part (5) of that theorem, outputs in the support of the weight coming from outside the larger coarse tube have probability at most $C_{m,q}\gamma^q$ for every fixed $q > 0$; inside, the exceptional event (35.24) has the same bound. Bounded tests on these exceptional events therefore contribute only $C_{m,q}\|F\|_\infty\gamma^q$.

Step 4: comparison of the normalized normal vectors. On the good event, using the bounded derivatives of the inverse square root, Hölder's inequality, and the preceding moments, we obtain

$$\mathbb{E}\big|\gamma^{-1/2}\Sigma_\theta(y(H_m))^{-1/2}b(H_m) - \Sigma_\theta(y)^{-1/2}Z_{K,m}\big| \le C_m\sqrt{\gamma}(1+|\log\gamma|)^{k_m};$$

indeed the difference is bounded by $C|\mathcal{R}_{K,m}| + C|y(H_m)-y||Z_{K,m}|$. Since F is Lipschitz in both arguments, $F(y(H_m),z(H_m))$ may be replaced by $F(y,\Sigma_\theta(y)^{-1/2}Z_{K,m})$ with an error $\operatorname{Lip}F$ times this bound plus $\operatorname{Lip}F\,\mathbb{E}|y(H_m)-y|$. Replacing $w(y(H_m))$ by $w(y)$ gives an error of the same type. The normal cutoff χ_w differs from one only at a fixed positive distance from zero, and arbitrarily high fixed normal moments from the same theorem bound the effect of replacing it by one by $C_{m,q}\gamma^q$.

Step 5: the Gaussian value. Conditionally on y, we apply Lemma 35.8 to the function $v \mapsto F(y,\Sigma_\theta(y)^{-1/2}v)$. Since it is a jointly Borel bounded function of the whole vector, the lemma applies without any radial restriction, and the Gaussian value is $\mathbb{E}F(y,(\widetilde{\Sigma}_m^K(y))^{1/2}G_y)$ with $G_y \sim \Gamma_y$. For every nonnegative self-adjoint C we have

$$\|C^{1/2}-I\|_{\mathrm{op}} \le \|C-I\|_{\mathrm{op}}, \qquad |\mathbb{E}F(y,C^{1/2}G_y)-\overline{F}(y)| \le 2\operatorname{Lip}F\,\|C-I\|_{\mathrm{op}}.$$

The first inequality follows on each eigenvalue from $|\sqrt{r}-1| = |r-1|/(\sqrt{r}+1)$, including $r=0$; the second uses $\mathbb{E}|G_y| \le (\mathbb{E}|G_y|^2)^{1/2} = 2$. Moving $\overline{F}(y)$ back to $\overline{F}(y(H_m))$ with the Lipschitz bound of Step 1 and the weight back to $\widetilde{w}(H_m)$, and using the covariance error (35.14), we obtain

$$\begin{aligned}\Big|\mathbb{E}_\nu\big\{\widetilde{w}(H_m)\big[F(y(H_m),z(H_m))-\overline{F}(y(H_m))\big]\big\}\Big| \\ \le C_w\|F\|_{\mathrm{BL}}\big\{\delta_m + (nB^K)^{-2}\big\} + \|F\|_{\mathrm{BL}}\,e^1_{m,w}(\gamma),\end{aligned} \tag{35.35}$$

where $z(H') = \gamma^{-1/2}\Sigma_\theta(y(H'))^{-1/2}b(H')$ and $e^1_{m,w}(\gamma) \to 0$ as $\gamma \downarrow 0$ at fixed m. Multiplying by the mass of the coarse tube, which is at most one, justifies the use of the normalized conditional estimates. The tangential integration in this step is always against the law of the coarse field, and the constant in front of the covariance error does not depend on m.

Step 6: comparison with the triple of the fine configuration. We replace H_m by H on the same sample. Let $d_m = \min(1,\max_i\|H_i - H_{m,i}\|_{\mathrm{op}})$, and fix nested regular output

tubes with positive margins. There exists $\eta > 0$, independent of m, such that if $d_m \le \eta$ and at least one of the two weights is nonzero, both triples lie in the larger identity chart. On that event the normal coordinate, the tangential coordinate, and the map $H' \mapsto \Sigma_\theta(y(H'))^{-1/2} b(H')$ have bounded derivatives, as one sees by differentiating the product on the fixed bounded tube. Hence, for $J_\gamma(H') = \widetilde{w}(H') F(y(H'), z(H'))$,

$$|J_\gamma(H) - J_\gamma(H_m)| \le C_w \|F\|_{\mathrm{BL}} (1 + \gamma^{-1/2}) d_m.$$

If both weights vanish, the difference is zero; on $\{d_m > \eta\}$ we use the bound $2\|\widetilde{w}\|_\infty \|F\|_\infty$. By Theorem 34.10,

$$\gamma^{-1/2} \mathbb{E}_\nu d_m \le C\delta_m^{1/2} + C\sqrt{\gamma}(1 + |\log \gamma|)^k, \qquad \nu\{d_m > \eta\} \le C_\eta \gamma^2.$$

The same argument for $\widetilde{w}(H')\overline{F}(y(H'))$ involves no factor $\gamma^{-1/2}$. Combining these bounds with (35.35), we obtain the same estimate for H in place of H_m, with an additional term $C_w \|F\|_{\mathrm{BL}} \delta_m^{1/2}$ and an additional error at fixed m that tends to zero with γ.

Step 7: the continuum and the limits. For each fixed $\gamma > 0$, both tests J_γ and $\widetilde{w}\,\overline{F}(y(\cdot))$ are bounded continuous invariant functions on $\mathrm{SU}(2)^3$, with the stated zero extensions. By Lemma 35.14, the expectations under ν and $\mu_{N,\gamma}$ differ by at most $C_{w,q}\|F\|_{\mathrm{BL}}\gamma^q$ for any fixed $q > 0$, and the expectations under $\mu_{N,\gamma}$ converge to those under λ_γ as $K \to \infty$. This uses only the supremum of the tests, not their Lipschitz constants, which depend on γ. Letting $K \to \infty$ at fixed γ and m and dividing by $D_\gamma \ge c_w$ (Theorem 35.3), we obtain (35.3). Letting $\gamma \downarrow 0$ at fixed m, and then $m \to \infty$, proves (35.2) for bounded Lipschitz F.

Step 8: bounded continuous tests. Let F be bounded and continuous. On the support of the weight we have $|z_\gamma|^2/2 = q_*/\gamma$, so Theorem 35.3 shows that the localized probabilities of $\{|z_\gamma| > R\}$ satisfy $\limsup_{\gamma\downarrow 0} \pi_\gamma((R^2/2, \infty)) \to 0$ as $R \to \infty$. For the comparison integral, the inner probability $\Gamma_y\{|z| > R\} = \mathbb{P}\{|G_4| > R\}$ does not depend on y or on the representative, and integrating it against ρ_γ gives the same tail bound. The set $\{(y, z) : y \in \mathsf{P}',\ |z| \le R\}$ is compact, and a continuous function on it admits uniformly accurate bounded Lipschitz approximations. To construct them, we take a sufficiently fine finite net, form the upper and lower cones of a sufficiently large finite slope through the values on the net, and truncate at the supremum bound. The uniform continuity of F gives the approximation as the net is refined and the slope is increased, and these cone functions are defined on the whole ambient space. Averaging them over simultaneous conjugations with respect to the Haar probability measure makes them invariant, preserves their bound and their Lipschitz constant, and preserves the approximation on this invariant compact set. We apply the bounded Lipschitz case to each approximant; the two tail probabilities control the errors outside the compact set. Letting first the approximation error tend to zero and then $R \to \infty$, we obtain (35.2). □

35.9 Comparison probability measures

This subsection evaluates the observables of Definition 35.1 under the four comparison probability measures of Definition 4.13: the Abelian Maxwell measure with Haar cycle holonomies (item (1) there, constructed in Lemma 33.14), Gaussian holonomies with independent Haar factors (item (2)), Gaussian holonomies with Gaussian constant modes (item (3)), and the conditional normal Gaussian measure (item (4)). These measures are different constructions, and their hypotheses are part of their definitions. The comparisons show how to read the conclusion of Theorem 35.2. The conditional normal Gaussian measure has the same coefficient $2\gamma^2$. The two holonomy models without a non-Abelian flat background give a vanishing statistic or a statistic of order one, and the Gaussian holonomies with Gaussian constant modes give the regular patch an exponentially small mass.

For the third measure we use Gaussian concentration. Its classical antecedents are the Gaussian isoperimetric inequalities of Borell [30] and of Sudakov and Tsirelson [148], and the sample-function formulation of Cirel'son, Ibragimov, and Sudakov [60]; we use the formulation of Adler and Taylor [3].

Lemma 35.16. *Let $d \geq 1$, let G be a standard Gaussian vector in $\mathbb{R}^d$, and let $F : \mathbb{R}^d \to \mathbb{R}$ be Lipschitz with constant ℓ for the Euclidean distance. Then for every $\lambda \in \mathbb{R}$,*

$$\log \mathbb{E} e^{\lambda (F(G) - \mathbb{E}F(G))} \leq \lambda^2 \ell^2 / 2.$$

Let $\mathcal{T}$ be a nonempty compact metric space and $(Z_t)_{t \in \mathcal{T}}$ a centered real Gaussian process, whose finite-dimensional covariances may be degenerate, with a separable realization having almost surely continuous paths, and assume $\sigma_Z^2 = \sup_{t \in \mathcal{T}} \mathbb{E} Z_t^2 < \infty$. For any fixed countable dense set $\mathcal{T}_0 \subset \mathcal{T}$, the random variable $S_Z = \sup_{t \in \mathcal{T}} Z_t = \sup_{t \in \mathcal{T}_0} Z_t$ is measurable, almost surely finite, and integrable. If $\sigma_Z^2 > 0$, then, writing $m_Z = \mathbb{E} S_Z$,

$$\log \mathbb{E} e^{\lambda (S_Z - m_Z)} \leq \lambda^2 \sigma_Z^2 / 2 \quad (\lambda \in \mathbb{R}), \qquad \mathbb{P}\{S_Z - m_Z \geq u\} \leq e^{-u^2/(2\sigma_Z^2)} \quad (u > 0).$$

If $\sigma_Z^2 = 0$, the process and its supremum vanish almost surely. In particular this applies to $\mathcal{T} = \mathbb{T}_L^3 \times \{1,2,3\} \times S^2$ and $Z_{x,i,v} = \langle v, G_i(x) \rangle$ for a continuous centered Gaussian field $G = (G_i)$ with this realization; its supremum is $\max_i \sup_x |G_i(x)|$. The only constants are the displayed Lipschitz constant and supremum variance; no dimension, cardinality of the index set, or parameter of the Yang–Mills measure enters.

Proof. We use two statements of Adler and Taylor. By [3, Theorem 2.1.1, p. 50, (2.1.5)], the supremum of an almost surely bounded centered Gaussian process has finite mean and satisfies an upper tail bound. By [3, Lemma 2.1.5, p. 54, (2.1.13)], with the boundedness assumption added in the authors' correction list (entry 54-6), we have $\mathbb{E} e^{t h(G)} \leq e^{t^2/2}$ for $t > 0$, every bounded C^2 function h with $\mathrm{Lip}(h) \leq 1$ and $\mathbb{E} h(G) = 0$, and a vector G of

independent standard real Gaussian variables. The reference to Lemma 2.1.4 specifies this law of G.

The case $\lambda = 0$ is immediate, and if $\ell = 0$ then F is constant. Suppose $\ell > 0$ and $\lambda \neq 0$. Let $F_R = \max(-R, \min(F, R))$ and let $F_{R,\varepsilon}$ be its convolution with a nonnegative smooth probability kernel supported in a ball of radius ε. Then $F_{R,\varepsilon}$ is bounded and smooth with bounded derivatives, $\operatorname{Lip}(F_{R,\varepsilon}) \le \ell$, and $|F_{R,\varepsilon} - F_R| \le \ell\varepsilon$. Applying the corrected lemma to $h = \pm(F_{R,\varepsilon} - \mathbb{E}F_{R,\varepsilon}(G))/\ell$, with $t = |\lambda|\ell$ and the sign of λ, gives the asserted exponential moment bound for $F_{R,\varepsilon}$. At fixed R, uniform convergence as $\varepsilon \downarrow 0$ gives the bound for F_R; the centered functions differ by at most $2\ell\varepsilon$. Next $F_R \to F$ pointwise as $R \to \infty$ and $|F_R| \le |F|$. The bound $|F(g)| \le |F(0)| + \ell|g|$ implies integrability of $F(G)$ and every $e^{c|F(G)|}$, since $c\ell|g| \le |g|^2/4 + c^2\ell^2$. In particular,

$$e^{\lambda(F_R(G) - \mathbb{E}F_R(G))} \le e^{|\lambda|(|F(G)| + \mathbb{E}|F(G)|)},$$

an integrable bound independent of R. Dominated convergence for the expectations and centered exponentials proves the first assertion.

For the process, we set all values equal to zero on the exceptional null set where the paths are not continuous; this does not change the finite-dimensional laws. Continuity on the compact metric space identifies S_Z with the supremum over $\mathcal{T}_0$ and makes it measurable and almost surely finite. These properties, the centered Gaussian finite-dimensional laws, and separability are the hypotheses of the cited theorem, which gives a finite mean. Since $S_Z \ge Z_{t_1}$ for any fixed t_1, the negative part of S_Z is bounded by $|Z_{t_1}|$, so S_Z is integrable. We enumerate $\mathcal{T}_0 = \{t_1, t_2, \dots\}$, repeating points if it is finite, and let $M_N = \max_{i \le N} Z_{t_i}$. Let C_N be the positive semidefinite covariance of $(Z_{t_i})_{i \le N}$, take a square root $C_N^{1/2}$, and denote its rows by v_i. Then $(Z_{t_i})_{i \le N}$ has the law of $(v_i \cdot G)_{i \le N}$, since both characteristic functions equal $\exp(-\xi^{\mathsf{T}} C_N \xi/2)$. Since $|v_i|^2 = (C_N)_{ii} \le \sigma_Z^2$, the map $g \mapsto \max_i v_i \cdot g$ is σ_Z-Lipschitz, and the first assertion gives its centered exponential moment bound uniformly in N; no inverse covariance is used, so singular covariances are included. Since $M_N - Z_{t_1} \uparrow S_Z - Z_{t_1} \ge 0$, we have $\mathbb{E}M_N \to m_Z$ by monotone convergence, and Fatou's lemma yields, for each $\lambda \in \mathbb{R}$,

$$\mathbb{E}e^{\lambda(S_Z - m_Z)} \le \liminf_{N \to \infty} \mathbb{E}e^{\lambda(M_N - \mathbb{E}M_N)} \le e^{\lambda^2\sigma_Z^2/2}.$$

If $\sigma_Z > 0$, Markov's inequality with $\lambda = u/\sigma_Z^2$ gives the stated upper tail. If $\sigma_Z = 0$, all coordinates on $\mathcal{T}_0$ vanish on one event of probability one, and continuity extends this to every index. Finally, the directional index space $\mathbb{T}_L^3 \times \{1,2,3\} \times S^2$ is compact, and $\sup_{|v|=1} \langle v, G_i(x) \rangle = |G_i(x)|$. □

Lemma 35.17. *Let ψ, q_*, A_{obs}, and B_{obs} be as in Definition 35.1, evaluated at the coordinate-cycle holonomy triple H at the fixed observation time, under each of the following probability measures of Definition 4.13.*

1. *Under the Abelian Maxwell measure with Haar cycle holonomies, all three holonomies commute,* $A_{\mathrm{obs}} = 0$*, the statistic vanishes exactly,* $\mathscr{C}_{\mathrm{Ab}} = 0$*, and* $\mathbb{E}B_{\mathrm{obs}}^2$*,* $\operatorname{Var} B_{\mathrm{obs}} \geq c_{\mathrm{Ab}} > 0$*, independently of the coupling.*
2. *Under Gaussian holonomies with independent Haar factors, the triple* H *has the law* $H^{\otimes 3}$ *for every coupling, and its statistic is the fixed number* $\mathscr{C}(H^{\otimes 3}; A_{\mathrm{obs}}, B_{\mathrm{obs}}) > 0$*. More precisely, let* K_1 *be a compact tangential subset of the regular patch* P *with positive relative volume and* $\psi_0 \geq b_* > 0$ *on* K_1*, let* $r_c > 0$ *with* $\chi(b) = 1$ *whenever* $|b| \leq r_c$*, and put* $\mathcal{T}_c = \{y + b : y \in \mathsf{K}_1,\ b \in \mathcal{N}_y,\ |b| \leq r_c\}$*, a set contained in the tube* $\mathcal{U}$ *on which* q_* *is the exact quadratic form. If* P *is a probability measure on* $\mathrm{SU}(2)^3$ *with* $\operatorname{Var}_P B_{\mathrm{obs}} > 0$ *whose law of* $X = \operatorname{Log} H$ *dominates* $c_0\, d^9X$ *on* $\mathcal{T}_c$*, then* $\mathscr{C}(P; A_{\mathrm{obs}}, B_{\mathrm{obs}}) \geq c_0\kappa_{\mathrm{c}} > 0$*, where* κ_{c} *depends only on* $\mathcal{T}_c$*, the Jacobian of the tube coordinates,* Σ_θ^{-1}*, and the cutoffs.*
3. *Under Gaussian holonomies with Gaussian constant modes, assume the realization of Definition 4.13(3): with* $\mathsf{S}_t a$ *the smoothed field at the observation time, the centered scalar Gaussian process* $\langle v, (\mathsf{S}_t a)_i(x)/\sqrt{\gamma}\rangle$*, indexed by* $(x, i, v) \in \mathbb{T}_L^3 \times \{1,2,3\} \times S^2$*, has a separable realization with continuous paths and*

$$\sigma_*^2 = \sup_{x,i,|v|=1} \operatorname{Var}\langle v, (\mathsf{S}_t a)_i(x)/\sqrt{\gamma}\rangle < \infty.$$

Put $Z_* = \sup_{x,i,|v|=1}\langle v, (\mathsf{S}_t a)_i(x)/\sqrt{\gamma}\rangle$ *and* $m_* = \mathbb{E}Z_*$*. Then* $m_* < \infty$ *and, by Lemma 35.16,* $\mathbb{P}(Z_* - m_* > u) \leq e^{-u^2/(2\sigma_*^2)}$ *for* $u > 0$ *if* $\sigma_* > 0$*. Let* $r_* = \inf_{\operatorname{supp}\psi}|\operatorname{Log} H| > 0$ *and* $a_* = r_*/(\sqrt{3}L)$*. If* $\sqrt{\gamma}m_* \leq a_*/2$ *and* $\sigma_* > 0$*, then*

$$\mathbb{P}\{\operatorname{Log} H \in \operatorname{supp}\psi\} \leq \exp\Big\{-\frac{(a_* - \sqrt{\gamma}m_*)^2}{2\gamma\sigma_*^2}\Big\} \leq e^{-a_*^2/(8\gamma\sigma_*^2)},$$

and if $\sigma_* = 0$ *the regular patch has mass zero. In particular* $\mathbb{E}\psi = O(e^{-c/\gamma})$*. The constants may depend on the fixed covariance and smoothing of this measure, as well as on the fixed data.*
4. *Under the conditional normal Gaussian measure, a fixed smooth positive probability density on the regular patch, charging* O_0 *and* O_+*, is followed, given* y*, by the normalized Gaussian law* $b \sim N(0, \gamma\Sigma_\theta(y))$ *on* $\mathcal{N}_y$ *and by the map* $X = y + b$*; a fixed tube cutoff equal to one near* $b = 0$*, followed by normalization, changes all moments below only by* $O(e^{-c/\gamma})$*. This measure has the moment identities of Theorem 35.2, with errors* $O(e^{-c/\gamma})$*, and* $\mathscr{C} = 2\gamma^2 + O(e^{-c'/\gamma})$*.*

Proof. Item (1). In the embedded Abelian theory every value of the connection lies in the same one-dimensional subalgebra, so path ordering reduces to exponentiation of the integral and the three cycle matrices commute. Their logarithms in the identity chart lie in $\mathcal{M}$, so their normal coordinate is zero and $q_* = 0$ on the tube; off the chart the observables vanish by definition. Thus $A_{\mathrm{obs}} = 0$ everywhere for this measure. Conditionally on the

field of the Abelian Maxwell measure, the three cycle angles are translates of the three independent uniformly distributed phases on $\mathbb{R}/4\pi\mathbb{Z}$, and their joint law is therefore the Haar probability measure on this three-dimensional torus, independently of the coupling (Lemma 33.14). The invariant open sets O_0 and O_+ contain smaller open sets of angles of positive Haar measure, and the invariance of ψ_0 makes these probabilities independent of the color axis of the embedded subgroup. At $b = 0$ the normal cutoff equals one. If $a_0, a_+ > 0$ are the probabilities of these two sets of angles, then $\mathbb{P}\{B_{\mathrm{obs}} = 0\} \geq a_0$ and $\mathbb{P}\{B_{\mathrm{obs}} \geq b_*\} \geq a_+$, and Lemma 35.12 implies $\mathbb{E}B_{\mathrm{obs}}^2 \geq a_+ b_*^2$ and $\operatorname{Var} B_{\mathrm{obs}} \geq a_0 a_+ b_*^2$. This proves item (1).

Item (2): the law of the triple. We condition on the Gaussian field. Each factor $\mathrm{Hol}_i(\mathsf{S}_t a)$ is then deterministic, right multiplication of the Haar distributed U_i^0 by it preserves the Haar measure, and the three U_i^0 remain conditionally independent. For a bounded product test $\prod_i f_i(H_i)$ the conditional expectation is therefore $\prod_i \int f_i \, dH$, independently of the field. Taking indicators of rectangles, we find that the triple has the law $H^{\otimes 3}$ at every coupling.

Item (2): the lower bound. On $\mathcal{T}_c$ the density of d^9X in the tube coordinates, $d^9X = J(y,b)\, d\mathrm{vol}(y)\, db$, has a positive lower bound J_c. For $y \in \mathsf{K}_1$ we define

$$\overline{q}_y = \frac{1}{|B_{r_c}^4|} \int_{|b| \leq r_c} q_*(y+b)\, db, \qquad V_c(y) = \int_{|b| \leq r_c} \big(q_*(y+b) - \overline{q}_y\big)^2 \, db,$$

where $B_{r_c}^4$ is the ball of radius r_c in $\mathcal{N}_y$. The positive definite quadratic form $q_*(y + \cdot)$ is not constant on this ball, so $V_c(y) > 0$. Since its coefficients vary continuously and the ball is fixed in any orthonormal bundle trivialization, V_c is continuous on K_1 and has a positive minimum by compactness. On $\mathcal{T}_c$ we have $B_{\mathrm{obs}} = \psi_0(y) \geq b_*$ and $A_{\mathrm{obs}} = \psi_0(y) q_*$. For all real α and c, subtracting the normal average shows

$$\int_{|b| \leq r_c} \big(\psi_0(y)(q_*(y+b) - \alpha) - c\big)^2 \, db \geq \psi_0(y)^2 V_c(y).$$

If the law of X under P dominates $c_0\, d^9X$ on $\mathcal{T}_c$, the infimum in Lemma 35.12 is therefore at least $c_0 \kappa_{\mathrm{c}}$, where one choice is

$$\kappa_{\mathrm{c}} = J_c b_*^2 \int_{\mathsf{K}_1} V_c(y)\, d\mathrm{vol}(y) > 0.$$

Since $\mathbb{E}_P B_{\mathrm{obs}}^2 \leq 1$, the same lower bound holds for the statistic, whenever its denominators are positive, as assumed. In the identity chart the density of $H^{\otimes 3}$ is $(16\pi^2)^{-3} \prod_{i=1}^3 \operatorname{sinc}^2(|x_i|/2)$ by (4.2), which is smooth and strictly positive on $\mathcal{T}_c$ for any choice of K_1 as above, for instance a compact subset of O_+ with positive relative volume. The open sets of triples over O_0 and O_+ near $b = 0$ have positive Haar measure, so $\operatorname{Var} B_{\mathrm{obs}} > 0$ and $\mathbb{E}B_{\mathrm{obs}}^2 > 0$ under $H^{\otimes 3}$, and the lower bound just proved shows that the statistic of $H^{\otimes 3}$ is a strictly positive number. This proves item (2).

Item (3). We consider the scalar process $f_{x,i,v} = \langle v, (\mathsf{S}_t a)_i(x)/\sqrt{\gamma}\rangle$ on the nonempty compact metric space $\mathbb{T}^3_L \times \{1,2,3\} \times S^2$. Since the smoothing is linear and fixed, every finite vector of this process is centered Gaussian, possibly with singular covariance. Its continuous separable realization and the finiteness of σ_*^2 are the hypotheses imposed in the statement. By Lemma 35.16, we obtain measurability, almost sure finiteness, $m_* < \infty$, and the displayed tail bound above the mean; the supremum variance is $\sup \operatorname{Var} f_{x,i,v} = \sigma_*^2$ and the supremum is $Z_* = \max_i \sup_x |(\mathsf{S}_t a)_i(x)|/\sqrt{\gamma}$. The covariance before smoothing is γC with C fixed, so the law of the normalized field, m_*, and σ_*^2 do not depend on γ.

We check the deterministic bound on the holonomies. Along a coordinate cycle ℓ_i, the transport equation $H' = H(\mathsf{S}_t a)_i$ has speed $|(\mathsf{S}_t a)_i|$ for the invariant metric with the norm $|\cdot|$ on $\mathfrak{su}(2)$. The distance of its endpoint from the identity is at most the length of this path, which is at most $L \sup_{x,j} |(\mathsf{S}_t a)_j(x)|$, and on the identity chart this distance is $|\operatorname{Log} H_i|$. Taking the Euclidean norm of the three components, we obtain

$$|\operatorname{Log} H| \le \sqrt{3} L \sup_{x,i} |(\mathsf{S}_t a)_i(x)| = \sqrt{3} L \sqrt{\gamma}\, Z_*,$$

where the equality uses the supremum over all unit vectors v, which includes both signs. Thus a triple with $\operatorname{Log} H \in \operatorname{supp} \psi$ forces $Z_* \ge a_*/\sqrt{\gamma}$. If $\sqrt{\gamma} m_* \le a_*/2$, this threshold lies strictly above the mean, and the tail bound of Lemma 35.16 with $u = a_*/\sqrt{\gamma} - m_* > 0$ gives both displayed exponential bounds; then $\mathbb{E}\psi \le \mathbb{P}\{\operatorname{Log} H \in \operatorname{supp} \psi\}$. If $\sigma_*^2 = 0$, the zero-variance clause of Lemma 35.16 shows that the directional process and Z_* vanish almost surely; the field vanishes, the holonomies are the identity, which lies outside the regular patch, and the patch has mass zero.

Item (4). In an orthonormal frame of the normal space let G be a standard Gaussian vector in four dimensions, independent of y, and let $b = \sqrt{\gamma}\Sigma_\theta(y)^{1/2} G$. The frame may change between charts, but the conditional law and the following quadratic form on the normal bundle are intrinsic. We define, on the whole normal bundle over the patch,

$$q_{\mathrm{coord}}(y,b) = \frac{1}{2} b^{\mathsf{T}} \Sigma_\theta(y)^{-1} b = \gamma Q_0, \qquad Q_0 = |G|^2/2. \tag{35.36}$$

We choose $b_{\mathrm{t}} > 0$ so that $\{|b| < b_{\mathrm{t}}\}$ lies in a fixed smaller normal tube, where the tube coordinates are unique and the normal cutoff of ψ equals one. Only on this event do we identify $q_*(y+b) = q_{\mathrm{coord}}(y,b)$ and $\psi(y+b) = \psi_0(y)$; outside it, q_* and ψ denote their fixed bounded extensions, not the unbounded quadratic form q_{coord}. Gaussian integration by parts in one dimension gives $\mathbb{E}G_i^2 = 1$ and $\mathbb{E}G_i^4 = 3$, and expanding the square and using independence yields

$$\mathbb{E}Q_0 = 2, \qquad \mathbb{E}Q_0^2 = 6, \qquad \operatorname{Var} Q_0 = 2.$$

The compact patch has spectral bounds $cI \le \Sigma_\theta(y) \le CI$, by Theorem 33.11. We fix $b_1 > 0$ smaller than b_{t} and than every radius on which a tube cutoff equals one. All

departures from the preceding local identities, or from these cutoffs being one, occur on $\{|b| \geq b_1\}$, which requires $|G| \geq b_1/\sqrt{C\gamma}$. For every fixed r, the Gaussian polynomial tail on this event is at most $C_r e^{-c/\gamma}$: the function $|G|^r e^{-|G|^2/8}$ is bounded, and the remaining Gaussian density integrates to a finite constant after extracting $e^{-b_1^2/(8C\gamma)}$. These bounds are uniform in y. For $k = 1, 2$ and $j = 0, 1, 2$, the difference between $\psi(y+b)^k q_*(y+b)^j$ and $\psi_0(y)^k q_{\mathrm{coord}}(y,b)^j$ vanishes on $\{|b| < b_1\}$; on its complement the first is bounded by a fixed constant and the second by $C\gamma^j |G|^{2j}$. The polynomial tail bound therefore makes the expectation of the difference exponentially small, uniformly in y. Inserting the fixed tube cutoff also changes these moments by exponentially small errors, and its total mass is $1 + O(e^{-c/\gamma})$, so dividing by this mass preserves the errors; any polynomial factor in γ^{-1} is absorbed by decreasing c.

Up to these errors, $B_{\mathrm{obs}} = \psi_0(y)$ is independent of Q_0. The positive tangential density charges O_0 and O_+, and together with the normal ball near $b = 0$ this gives fixed positive lower bounds on $\mathbb{E}B_{\mathrm{obs}}^2$ and $\operatorname{Var} B_{\mathrm{obs}}$ for small γ, by Lemma 35.12. For $f = \psi$ and $f = \psi^2$ we obtain

$$\mathbb{E}[f q_*] = 2\gamma \mathbb{E} f + O(e^{-c/\gamma}), \qquad \mathbb{E}[f q_*^2] = 6\gamma^2 \mathbb{E} f + O(e^{-c/\gamma}).$$

The identity (35.27) of Lemma 35.12 now implies $\mathscr{C} = 2\gamma^2 + O(e^{-c'/\gamma})$ for a smaller $c' > 0$. □

35.10 Proof of the theorem on regular commuting triples

Proof of Theorem 2.10. Let L, M, θ, and $n \in 4\mathbb{N}$ be as in Theorem 2.10, fix J and the construction parameters as in Section 35.1, and choose $a \geq 0$ so large that $n' = nB^a$ satisfies the minimum-side conditions of Section 35.1, including $2\pi/n' < r_{\mathrm{flat}}/4$. Since $[n']_M = [n]_M$, the measure $\lambda_\gamma = \lambda_{L,\gamma,[n]_M}$ of Theorem 2.10 is the measure of Section 35.1 for the side n' (Corollary 29.26 and Theorem 29.28), so the results of this section apply with n' in place of n. The function ψ of Theorem 2.10, with a sufficiently small tube, is a function as in Definition 35.1(2). If necessary, we replace its normal cutoff by the average over simultaneous conjugation, which does not change ψ because ψ and its tangential factor are invariant. The tangential factor ψ_0 vanishes on a nonempty open set and is positive on another, hence at least $2b_*$ on a smaller nonempty open set for some $b_* > 0$; these sets may be taken invariant since ψ_0 is invariant. On the tube, q_* is the quadratic form of Theorem 2.10. Part (1) of Theorem 2.10 is Theorem 35.2. Part (2) is Theorem 35.3, since w and χ_w satisfy the invariance and support conditions of Definition 35.1(4); these invariant normal cutoffs, like the normal cutoff χ of ψ, need not be radial. Part (3) is Theorem 35.4, applied to the restriction of F to the normal bundle over a compact invariant regular patch containing the support of w in its relative interior. The constants depend on L, M, n, θ, and the test functions, but not on γ, and in each case the continuum limit is taken first, at fixed γ. □

SECTION 36

Quartic asymptotics near central holonomies

This section describes the continuum measures λ_γ near the eight central triples $(\pm I, \pm I, \pm I)$ as $\gamma \to 0$, and proves Theorem 2.11. We observe the holonomies $H = (H_1, H_2, H_3)$ around the three coordinate cycles, based at the origin, at a fixed flow time $t = \theta L^2$. Near the identity we write their logarithms as $X \in \mathfrak{su}(2)^3 \simeq \mathbb{R}^9$. Near the trivial flat connection, the Hessian of the Wilson action vanishes in the nine constant directions, and the leading term in these directions is the constant-mode quartic form

$$Q(Y) = \frac{1}{2} \sum_{i<j} |y_i \times y_j|^2, \qquad Y = (y_1, y_2, y_3) \in \mathbb{R}^9,$$

where the cross product corresponds to the Lie bracket of $\mathfrak{su}(2)$. We study central windows of radius $r_\gamma = \gamma^{1/4}$ and show that compactly supported tests of X/r_γ have leading expectations proportional to their integrals against the quartic reference measure $e^{-Q(Y)}\, dY$. This measure has infinite total mass, and all statements concern compactly supported tests. A continuous, nonnegative, nonzero, compactly supported invariant test has expectation comparable to r_γ. Ratios of expectations converge to ratios of integrals against $e^{-Q(Y)}\, dY$, with an error $O(\gamma^{1/4})$ for Lipschitz tests, and the dilation statistic tends to zero. We also treat the eight central triples, finitely many flow times, and holonomy paths on a compact time interval, and we compute the dilation statistic for four comparison measures.

The block averaging constraint and the effective classical action come from Sections 6, 9, and 10, and the flat refinements, the reconstruction maps, and the disintegration of the conditioned Wilson measure from Sections 14 and 15. The coordinates near the trivial flat connection, the transverse Hessian, and the order of the normalization constant come from Section 33, and the regularity of the flowed zero-fluctuation reconstruction and the comparison of flowed holonomies from Sections 25, 34, and 35. Finally, we use the bound on the small-field failure probability from Section 23 and the continuum limit at fixed coupling from Section 29. The covariance of Theorem 33.11 enters only in the last comparison measure. The results of this section are not used in later sections; they prove Theorem 2.11 and the further statements about central triples described after it in Section 2.

Section 36.1 fixes the setting and explains the scaling. The main steps are the exact quartic term of the effective classical action (Section 36.2), the comparison of flowed

holonomies (Section 36.3), and the integration over the transverse modes (Section 36.5). The passage to the continuum measure and the further results occupy Sections 36.6 to 36.9, and Section 36.10 deduces Theorem 2.11.

The separation of constant modes, with a quartic commutator interaction, from the nonconstant modes on a torus is an established idea in finite-volume Yang–Mills theory; see Lüscher [127] and Coste, González-Arroyo, Jurkiewicz, and Korthals Altes [62]. For a direct comparison in four-dimensional perturbation theory in finite volume, see Fodor, Holland, Kuti, Nógrádi, and Wong [91, Section 2, (2.1)–(2.7)], who separate the constant modes, treat their quartic interaction separately, and integrate the nonconstant modes. What we add is the exact coefficient Q/n for the constrained minimizers of our block averaging constraint at every finite depth, with bounds uniform in the depth, and a uniform comparison on windows of size $\gamma^{1/4}$. Up to normalization, Q is the action of the bosonic reduced SU(2) Yang–Mills matrix integral with three matrices, whose divergence is known: see Krauth, Nicolai, and Staudacher [122, (24)], Krauth and Staudacher [121, (2)], and, for a rigorous treatment, Austing and Wheater [7, Section 3 and Appendix A]. The integration over the transverse modes is a Laplace argument with degenerate directions (see Wong [155] for background); the main work is to verify its hypotheses uniformly. The center symmetry of Lemma 36.11 is the standard center symmetry of periodic lattice gauge theory, which goes back to 't Hooft [149].

36.1 Setting and notation

We fix the comparison side n and all parameters of the construction before the coupling varies. Below, K counts RG steps, and the underlying classical depth is JK. The quantity a_{map} below is the bound on the derivatives of the zero-fluctuation reconstruction maps fixed in Definition 34.1.

Definition 36.1. Fix $L > 0$, $\theta > 0$, an odd integer $M \geq 3$, an integer $J \geq 1$ with $B = M^J$, and the remaining parameters of the construction, such that $a_{\mathrm{map}}\sqrt{B} \leq 32/49$. Fix $n_* \in 4\mathbb{N}$ and a comparison side $n = n_* B^a$ on the sequence $(n_* B^K)_{K\geq 0}$, large enough for the lower bounds on the coarse side in Corollaries 23.11 and 29.26 and Definition 34.1, and in particular for (36.1) below. These choices are made before γ varies in $(0, \gamma_0]$, where $0 < \gamma_0 \leq 1$ is a fixed ceiling. For $K \geq 0$ set

$$N = nB^K, \qquad g^2 = \frac{\gamma}{n}, \qquad \nu = \nu_{N,n,\gamma}, \qquad \widehat{\nu} = (T_M^{JK})_{\#}\nu, \qquad r_\gamma = \gamma^{1/4},$$

and let Q be the quartic form on $\mathbb{R}^9$ displayed at the beginning of this section.

1. The stopped measure $\widehat{\nu}$ is the law of the coarse configuration $V = T_M^{JK} U$ on Λ_n when U has law ν. It has density

$$d\widehat{\nu} = \widehat{Z}^{-1} \mathbf{1}_{D_r} e^{-E_{JK,\mathrm{sat}}/g^2 - \overline{R}_{K,\gamma}}\, dH_n, \qquad \overline{R}_{K,\gamma} = R_{K,\gamma} - R_{K,\gamma}(I),$$

where $\widehat{Z}$ is the normalization constant, $R_{K,\gamma}$ is the effective interaction, and $E_{JK,\mathrm{sat}}$ is the gauge-invariant extension of the effective classical action E_{JK} from B_r to D_r of Theorem 11.6, that is, $E_{JK,\mathrm{sat}}(U) = E_{JK}(U^k)$ whenever $U^k \in B_r$. In particular $E_{JK,\mathrm{sat}} = E_{JK}$ on B_r.

2. Near the trivial orbit modulo based gauge transformations (gauge transformations equal to the identity at the origin) we use the coordinates of Theorem 33.8,

$$V(X,s) = e^{X/n+s}, \qquad X \in \mathbb{R}^9, \qquad d_0^* s = 0, \qquad \sum_x s_i(x) = 0,$$

with $d_{\mathrm{st}} = \dim s = 6n^3 - 6$, where X/n denotes the constant configuration and d_0^* is the lattice divergence on Λ_n. We write $J_n(X,s)\,dX\,ds$ for the image of the product Haar measure in the based quotient, and set

$$F_K(X,s) = E_{JK}(V(X,s)), \qquad f_K(X) = F_K(X,0), \qquad A_K(X) = D_s^2 F_K(X,0).$$

We write $\overline{R}_{K,\gamma}(X,s)$ for $\overline{R}_{K,\gamma}(V(X,s))$.

3. Let $\mathcal{H}^K = (\mathcal{H}_i^K)_{i=1}^3$ be the holonomies, around the three coordinate cycles based at the origin, of the fine configuration flowed by the Wilson flow $\Psi_{\theta L^2}^{(N)}$, where the fine configuration is represented through the reconstruction maps of Theorem 15.12. Let $\mathcal{H}_0^K(V)$ be the same triple for the flowed zero-fluctuation reconstruction of V (the map Ξ_0^K of Definition 34.1), in the same gauge frame at the basepoint. Let $\mathcal{H}_n(V) = \mathrm{Hol}(V)$ be the triple of coordinate-cycle holonomies of V itself, without flow.

4. Fix a neighborhood $\mathcal{V}$ of (I,I,I) with compact closure in $(\mathrm{SU}(2) \setminus \{-I\})^3$, on which Log denotes the componentwise principal logarithm. For a bounded Borel function $\varphi : \mathbb{R}^9 \to \mathbb{R}$ with compact support, define

$$\mathcal{I}_{\gamma,\varphi}(H) = \begin{cases} \varphi(\mathrm{Log}\, H / r_\gamma), & H \in \mathcal{V}, \\ 0, & H \notin \mathcal{V}. \end{cases}$$

5. A radial cutoff is a function $\chi \in C_c^\infty([0,\infty))$ that is nonnegative, not identically zero, and constant near zero. For a radial cutoff χ we write $\mathcal{I}_{\gamma,\chi(|\cdot|)}$ for the observable of the test $Y \mapsto \chi(|Y|)$, and we set

$$W_\chi(Y) = (4Q(Y) - 9)\chi(|Y|) - |Y|\chi'(|Y|), \qquad \mathcal{S}_{\gamma,P}(\chi) = \frac{\mathbb{E}_P \mathcal{I}_{\gamma,W_\chi}}{\mathbb{E}_P \mathcal{I}_{\gamma,\chi(|\cdot|)}}$$

for a probability P under which the denominator is positive.

6. For a probability P of a random vector $X \in \mathbb{R}^9$ we use instead $\mathcal{I}_{\gamma,\varphi}^{\mathrm{coord}}(X) = \mathbf{1}_{\{X \in \mathrm{Log}\,\mathcal{V}\}} \varphi(X/r_\gamma)$, and define $\mathcal{S}_{\gamma,P}(\chi)$ with $\mathcal{I}^{\mathrm{coord}}$ in place of $\mathcal{I}$.

We call $\mathcal{S}_{\gamma,P}(\chi)$ the dilation statistic; the name refers to the dilation integration-by-parts identity $\int W_\chi\, e^{-Q}\, dY = 0$ of Lemma 36.4. For each fixed bound on the support of φ and all sufficiently small γ, the map $Y \mapsto r_\gamma Y$ sends the support of $Y \mapsto \varphi(Y)$ into a compact subset of $\operatorname{Log}\mathcal{V}$. Then $\mathcal{I}_{\gamma,\varphi}$ is a continuous function on $\mathrm{SU}(2)^3$ for continuous φ, and the indicator in $\mathcal{I}^{\mathrm{coord}}_{\gamma,\varphi}$ equals one on the support of $\varphi(\cdot/r_\gamma)$. The observables are defined by extension by zero because we never use a logarithm outside $\mathcal{V}$.

We apply Theorem 33.8 at depth JK; in the depth notation of that theorem, $F_K = F_{JK}$, $A_K = A_{JK}$, and $d_{\mathrm{st}} = d_n$. The coordinates $V(X,s)$ are defined on a fixed neighborhood $\{|X| < \rho_n,\ |s| < s_n\}$ whose image lies in $B_r \subset D_r$, and the density J_n is smooth and strictly positive. The gauge directions along a based spanning tree integrate to one, while the conjugation at the root remains in the measure and is not divided out. The theorem also gives

$$D_s F_K(X,0) = 0, \qquad a_n I \le A_K(X) \le C_n I,$$

where the Hessian lower bound $a_n > 0$ is a fixed constant (in this section a_n does not denote the mesh L/n). The first derivative of $\overline{R}_{K,\gamma}$ remains in the density. The measure $\widehat{\nu}$ is the stopped measure of Definition 4.4 at side n and depth JK. Since no coarser restriction remains at the side n, it is the law of V under ν by Theorem 14.8(9).

Constants. Unless stated otherwise, constants $C, c, C_n, c_n, \dots$ in this section may depend on n, L, θ, M, J, the remaining parameters, γ_0, the charts, the neighborhoods, and the gauge frames fixed in this section, and the test functions, but not on K, N, the number of preceding averaging steps, or $\gamma \in (0, \gamma_0]$. This is the dependence described in item (6) of Definition 4.14. Additional dependence is indicated by subscripts. All estimates are on the periodic torus of side L.

Margins. Fix a radius $r_{\mathrm{flat}} < r$ below the margins of the classical, block-averaging, and gauge domains of the construction. The lower bound on n in Definition 36.1 includes

$$\frac{2\pi}{n} < \frac{r_{\mathrm{flat}}}{4}. \tag{36.1}$$

By Lemma 14.9, every flat configuration on Λ_n is gauge equivalent to constant commuting links $e^{H_i/n}$ with commuting $H_i \in \mathfrak{su}(2)$, $|H_i| \le 2\pi$. Its flat refinements to side nM^ℓ have links $e^{H_i/(nM^\ell)}$, and $|H_i|/(nM^\ell) \le 2\pi/n < r_{\mathrm{flat}}/4$ for every $\ell \ge 0$. The flat refinements, their vanishing conditional constrained minimizers, and their vanishing normalized fluctuation variables therefore lie in all coordinate domains of the construction with the same margins at every depth. This holds near each of the eight central triples.

We also fix nested coordinate balls $\mathcal{C} \Subset \mathcal{C}^+$ in the chart of Theorem 33.8, with

$$\frac{\rho_{\mathrm{c}}^+}{n} + s_{\mathrm{c}}^+ < \frac{1}{2}\min(r, r_{\mathrm{flat}}), \qquad \mathcal{C}^+ = \{|X| < \rho_{\mathrm{c}}^+,\ |s| < s_{\mathrm{c}}^+\}, \tag{36.2}$$

where the radii may be reduced, and such that the closure of $\mathcal{C}^+$ lies in the chart. Since $\max_{x,i}|X_i/n + s_i(x)| \le |X|/n + |s|$, the bound (36.2) gives a fixed chart of link logarithms on which the derivative bounds for $\overline{R}_{K,\gamma}$ in Lemma 33.6 hold. On $\{s = 0\}$, it also places the commuting constant configurations in the domains above. The coordinate map extends analytically past the closure of $\mathcal{C}^+$, and by compactness its derivatives of each fixed order are bounded there. These choices concern only the coordinates used for integration; the conditioned Wilson measure and the restriction to D_r in $\widehat{v}$ are unchanged.

Heuristics. In the coordinates $V(X,s)$, the stopped measure has density proportional to $e^{-F_K(X,s)/g^2}$ times the smooth positive factor $e^{-\overline{R}_{K,\gamma}} J_n$. By Theorem 36.2 below, $f_K(X) = Q(X)/n + O(|X|^5)$, and by Theorem 33.8, $F_K(X,s) = f_K(X) + (1/2)s^{\mathsf{T}} A_K(X) s + O(|s|^3)$. Since $ng^2 = \gamma = r_\gamma^4$, the substitution

$$X = r_\gamma Y, \qquad s = gz, \qquad g = \frac{r_\gamma^2}{\sqrt{n}},$$

gives

$$\frac{F_K(X,s)}{g^2} = Q(Y) + \frac{1}{2} z^{\mathsf{T}} A_K(0) z + (\text{an error of order } r_\gamma \text{ after integration}).$$

The Jacobian of the substitution is $r_\gamma^9 g^{d_{\mathrm{st}}}$. By Theorem 33.10, the normalization constant is of order $g^{d_{\mathrm{st}}+4}$, where the extra power g^4 comes from a neighborhood of the cone of commuting triples, along which Q vanishes. Since $r_\gamma^9/g^4 = n^2 r_\gamma$, the expectation of a compactly supported test of X/r_γ is of order r_γ. More precisely, for a bounded test φ supported in $\{|Y| \le R\}$ and either output map of Theorem 36.6, its expectation is $r_\gamma \kappa_{K,\gamma} \{ \int \varphi(Y) e^{-Q(Y)}\, dY + O_{n,R}(\|\varphi\|_\infty r_\gamma)\}$, where $\kappa_{K,\gamma}$ is positive and bounded above and below. The factor $\kappa_{K,\gamma}$ does not depend on the test and cancels in ratios, so we never need its limit. The measure $e^{-Q(Y)}\, dY$ has infinite mass because Q vanishes on the five-dimensional cone of commuting triples and grows only quadratically in the four normal directions, with a coefficient proportional to the square of the distance from the origin (Lemma 36.4). After rescaling, most of the mass near the cone lies at commuting triples far from the central triple. In the unscaled variables these triples give the dominant contribution to the normalization constant, but tests supported on the scale r_γ do not see them. This is why only compactly supported tests appear.

To pass from the coarse configuration to the flowed holonomies of the fine configuration, we compare $\mathcal{H}^K$ with the deterministic triple $\mathcal{H}_0^K(V)$. The matrix difference is of order $\sqrt{\gamma} = r_\gamma^2$, while the window $\{|\operatorname{Log} \mathcal{H}_0^K(V)| \le R r_\gamma\}$ has probability of order r_γ. An average estimate of the difference does not suffice, since its contribution could be large relative to the small probability of the window. Instead, we use an estimate conditional on the coarse configuration V (Theorem 34.11). Suppose that the window is measurable

with respect to V and has probability $O(r_\gamma)$, and that the conditional expected difference is $O(r_\gamma^2)$ uniformly in V. Then the expected difference on the window is $O(r_\gamma^3)$, which is $O(r_\gamma^2)$ relative to the window. This is the mechanism behind the rate $\gamma^{1/4}$.

Finally, we distinguish three quotients. The integration over V takes place in the quotient by based gauge transformations, so that the constant coordinates $X \in \mathbb{R}^9$ include the simultaneous conjugation at the basepoint, which is kept in the nine-dimensional integral. Observables of the continuum measure are invariant under simultaneous conjugation of the triple, and at several flow times they are invariant under an independent conjugation at each time. On a time interval, the observable is a path in the quotient $\mathfrak{su}(2)^3 / \operatorname{Ad}\mathrm{SU}(2)$; no gauge frame common to different times is needed.

36.2 The quartic term of the effective classical action

The following theorem identifies the fourth Taylor polynomial of the effective classical action on constant configurations. Here E_d is the effective classical action at depth d on the lattice of side n, that is, the value of the constrained minimizer of Theorem 10.6 (the background field, following Bałaban [16]), with $E_0 = S_W$.

Theorem 36.2. *For every side n as in Definition 36.1 there exist $\rho_0(n) > 0$ and $C_n < \infty$ such that, for every depth $d \geq 0$, the function $f_d(X) = E_d(e^{X/n})$ satisfies*

$$D^j f_d(0) = 0 \quad (0 \leq j \leq 3), \qquad \frac{1}{4!} D^4 f_d(0)[X, X, X, X] = \frac{Q(X)}{n},$$

and

$$\left| E_d(e^{X/n}) - \frac{Q(X)}{n} \right| \leq C_n |X|^5 \qquad (|X| < \rho_0(n)). \tag{36.3}$$

The constants depend only on n, M, and the domains and derivative bounds of Theorem 10.11; they do not depend on d or on the coupling. In particular this applies to f_K of Definition 36.1, with $d = JK$.

Moreover, for every fixed d and X there exist constant fine links $e^{a_i(u)}$, analytic in u for $|u| < u_{d,X}$, such that

$$a_i(u) = uM^{-d} x_i / n + O_{d,X}(u^2), \qquad T_M^d(e^{a(u)}) = e^{uX/n},$$

and these links lie in the domain of the variational comparison of Theorem 9.7 at depth d. The radius $u_{d,X}$ need not be uniform in d.

We identify the fourth Taylor polynomial exactly, at each finite depth, by comparing the minimizer with an exactly constrained trial configuration. The proof uses two different tools. To identify the Taylor coefficients at a fixed depth d, we use an inverse of the block averaging constraint on constant configurations whose radius of definition may shrink

as d grows. This is harmless, because Taylor coefficients at the origin are determined by arbitrarily small neighborhoods. For the uniformity of the remainder in d, we use instead the bounds on the fifth derivative of E_d from Theorem 10.11, which are uniform in the depth. We also distinguish two constraints: the block averaging constraint $T_M^d U = e^\theta$ itself, and the gauge-modified constraint satisfied by the fields in the projected Landau gauge slice of Theorem 9.9. The trial configurations and the representative of the minimizer constructed in Step 2 satisfy the former, and their transforms into the slice in Step 1 satisfy the latter. The gauge transformation used in Step 5 need not preserve either constraint; we use it only to compute the action, which it leaves unchanged.

Proof. All variational comparisons use real targets, fields, and parameters; holomorphic extensions supply analytic representatives and Taylor bounds.

Step 1: the variational comparison. We set $\varepsilon_d = M^{-d}$ and measure lengths in units of the lattice of side n, so that the fine lattice has side n/ε_d and the action is

$$S_{\varepsilon_d}(U) = \frac{4}{\varepsilon_d} \sum_p q(U_p). \tag{36.4}$$

We take the minimizer and its value from Theorem 10.6, in the notation of Definition 10.1. We write Ξ_d for the constraint coordinates $\mathsf{P}_d^{\mathrm{cl}}$ and H_d for the minimizing linear extension H_d, as in Theorem 9.7. The critical point is $v_d^*(\theta) \in \mathcal{V}_d$, the minimizing field is $A_d(\theta) = \Xi_d(v_d^*(\theta) + H_d\theta)$, and

$$E_d(e^\theta) = S_{\varepsilon_d}(e^{\varepsilon_d A_d(\theta)}). \tag{36.5}$$

Fix $0 < r_{\mathrm{ph}} < r_0$ within the common margins, where r_0 and C_* are the constants of Theorem 9.7. By the bound on v_d^* in Theorem 10.6, there exists a constant $C_{\min}$, which includes the conversion from first differences to the curl, such that

$$\|v_d^*(\theta)\|_\infty + \|\mathrm{d}_{\varepsilon_d} v_d^*(\theta)\|_\infty \le C_{\min}\|\theta\|_\infty^2.$$

Let $\tau > 0$ be a target radius with

$$\tau < \min\{r_\theta/2,\ r_{\mathrm{ph}}/(2C_*)\}, \qquad C_{\min}\tau^2 < r_{\mathrm{ph}}/4, \tag{36.6}$$

where r_θ is the radius of Theorem 10.6. For $\|\theta\|_\infty < \tau$ the critical point then lies strictly inside the convex domain of potentials and curls of Theorem 9.7, which verifies the critical point hypothesis of that theorem.

Next we describe the trial configurations, which are needed only in a small neighborhood that may depend on d. Let $U = e^{\varepsilon_d A}$ satisfy $T_M^d U = e^\theta$ with $\|\theta\|_\infty < \tau$, $\|A\|_{\mathsf{X}} = \|A\|_\infty + \|\mathrm{div}_{\varepsilon_d} A\|_\infty < r_{\mathsf{X}}$, and small curl. We apply Theorem 9.9 with prescribed coarse gauge datum zero. The transformed field has vanishing projected divergence and gauge-modified target exactly e^θ. It has the same action, and its potential A' and its curl

tend to zero with those of A. The transformed field need not satisfy the block averaging constraint $T_M^d U = e^\theta$ itself; for this reason, Step 2 constructs a separate representative of the minimizer that does.

To check that A' lies in the chart of Theorem 9.7, we write the constraint coordinates as $\Xi_d(w) = w - H_d \mathscr{D}_d(w)$, with $\mathscr{D}_d(0) = D\mathscr{D}_d(0) = 0$; here the argument w is a fine field, not a vector of normalized fluctuation variables. Since H_d is a fixed linear map on this finite lattice, the first-derivative estimate of Theorem 10.11 makes $w \mapsto A' + H_d \mathscr{D}_d(w)$ a contraction on a sufficiently small ball, which implies that Ξ_d is locally invertible at A'. By the defining identities of the constraint coordinates, the gauge-modified constraint of $\Xi_d(w)$ is the linear target, and the correction $H_d \mathscr{D}_d(w)$ has vanishing projected divergence. Hence the inverse parameter has the form $w = a + H_d\theta$ with $a \in \mathcal{V}_d$, and on this finite lattice the norm of a in potential and curl tends to zero with (A', θ). In particular, a sufficiently small trial configuration satisfies

$$\|a\|_\infty + \|\mathrm{d}_{\varepsilon_d} a\|_\infty < r_{\mathrm{ph}}/2. \tag{36.7}$$

By (36.6) and (36.7), the trial parameter and the critical point lie in the same convex domain with target e^θ, and so does the segment joining them. Since the transformation into the slice preserves the action, the convexity inequality of Theorem 9.7, together with the minimum of Theorem 10.6, implies that

$$E_d(e^\theta) \le S_{\varepsilon_d}(U). \tag{36.8}$$

The smallness required in this step may depend on d and on the direction of the trial configuration.

Step 2: an analytic representative of the minimizer. The field $A_d(\theta)$ is holomorphic, and its value is (36.5). It satisfies the gauge-modified constraint of the projected Landau slice, and its accumulated gauge transformation is a finite composition of the analytic gauge maps of that slice. We take the logarithm of this gauge transformation at the vertices of the coarse lattice, extend it by any fixed linear extension to all fine vertices, and exponentiate. The result is an analytic periodic fine gauge transformation with the prescribed values at the coarse vertices. Since T_M is gauge covariant, applying this transformation changes the target of the block averaging constraint to e^θ, and it leaves (36.4) unchanged. We obtain an analytic configuration $U_*(\theta)$ with

$$U_*(0) = I, \qquad T_M^d U_*(\theta) = e^\theta, \qquad S_{\varepsilon_d}(U_*(\theta)) = E_d(e^\theta).$$

Only analyticity at the fixed depth d is used: even if the derivative bounds of this extension grow with d, it tends to the identity as $\theta \to 0$ at fixed d.

Step 3: an exactly constrained trial and the upper bound. Fix d and X. On constant configurations, the map $G_d(a) = \operatorname{Log} T_M^d(e^a)$ is analytic near zero and $DG_d(0) = \varepsilon_d^{-1} I_9$. Indeed, the derivative at the identity of the formula of Definition 6.1 is the average of the integrals of a over the block paths. On a constant configuration each of these paths has integral Ma_i, and d iterations give $M^d a_i$. To invert G_d without a radius uniform in d, we solve

$$a = \varepsilon_d u \frac{X}{n} - \varepsilon_d \{ G_d(a) - \varepsilon_d^{-1} a \}.$$

Since the derivative of the term in braces vanishes at zero, the right side is a contraction with factor at most $1/2$ on a small fixed complex ball. For small $|u|$, it also maps the ball into itself. The iterates converge uniformly on a smaller complex disc in u, and the limit is analytic in u and real for real u. A fixed point satisfies $G_d(a) = uX/n$, and we obtain

$$a_i(u) = u\varepsilon_d x_i/n + O_{d,X}(u^2), \qquad T_M^d(e^{a(u)}) = e^{uX/n}. \tag{36.9}$$

The potential $a(u)/\varepsilon_d$ is constant, has vanishing divergence and curl, and tends to zero as $u \to 0$. We reduce $u_{d,X}$ until $\|uX/n\|_\infty < \tau$, the input bound of the projected Landau slice holds, and the trial parameter satisfies (36.7). By (36.6), the critical point for the same target lies in the same convex chart, and (36.8) applies to $e^{a(u)}$. The logarithm of a plaquette of the constant configuration $e^{a(u)}$ in the (i,j) plane is $u^2[\varepsilon_d x_i/n, \varepsilon_d x_j/n] + O_{d,X}(u^3)$. Using $q(e^v) = |v|^2/8 + O(|v|^4)$ and the fact that there are $(n/\varepsilon_d)^3$ plaquettes in each plane, we obtain

$$\begin{aligned} E_d(e^{uX/n}) &\le \frac{4}{\varepsilon_d}\Big(\frac{n}{\varepsilon_d}\Big)^3 \frac{u^4}{8} \sum_{i<j} |[\varepsilon_d x_i/n, \varepsilon_d x_j/n]|^2 + O_{d,X}(u^5) \\ &= \frac{u^4}{n} Q(X) + O_{d,X}(u^5). \end{aligned} \tag{36.10}$$

Step 4: the first-order term of the minimizer. We write the link logarithms of $U_*(uX/n)$ from Step 2 as $ua + O(u^2)$, where a is a cochain on the fine torus. By Step 2, its action equals $E_d(e^{uX/n})$, which is nonnegative and, by (36.10), of order u^4. The coefficient of u^2 in its action therefore vanishes. This coefficient is

$$\frac{1}{2\varepsilon_d} \sum_x \sum_{i<j} |(\mathrm{d}a)_{ij}(x)|^2,$$

where d denotes the unscaled cochain differential on the fine torus. We conclude that $\mathrm{d}a = 0$.

We record the periodic decomposition of a closed cochain. A closed cochain has the same integral over every translate of a coordinate cycle, because the difference of two such cycles is a sum of plaquette boundaries. We subtract the constant c_i equal to this integral divided by n/ε_d. The resulting cochain is closed and has vanishing integrals over

the coordinate cycles. Its integrals over all closed paths vanish: neighboring coordinate steps can be exchanged using plaquette boundaries, adjacent inverse steps cancel, and a remaining closed path reduces to a combination of the three coordinate cycles. Hence its integral from a fixed vertex to a vertex x does not depend on the path. Applying this to a and writing $\phi(x)$ for the integral of the modified cochain from the fixed vertex to x, we have

$$a_i(x) = c_i + \phi(x + \varepsilon_d e_i) - \phi(x). \tag{36.11}$$

Each statement holds separately in each real component of $\mathfrak{su}(2)$.

At the identity, the derivative of the block averaging map is the average of the integrals over the block paths. For a closed cochain, a translated path with endpoint connectors and the reference path differ by a contractible closed path and have equal integrals. It follows that d averaging steps send the constant part of (36.11) to $\varepsilon_d^{-1} c_i$, and the gradient to the gradient of the restriction of ϕ to the coarse lattice. The linearization of the constraint $T_M^d U_*(uX/n) = e^{uX/n}$ states that this image equals x_i/n on every coarse link in direction i. When we average over all coarse links in direction i, the gradient terms cancel by periodicity, and we obtain

$$c_i = \varepsilon_d x_i / n. \tag{36.12}$$

Step 5: the lower bound. The periodic fine gauge transformation $e^{u\phi(x)}$, with ϕ normalized to vanish at the root, removes the gradient in (36.11) to first order, and it preserves the action. In this gauge the link logarithms are $uc + u^2 b + O(u^3)$ for some cochain b, and the plaquette logarithms are

$$u^2 \big\{ (\mathrm{d}b)_{ij}(x) + [c_i, c_j] \big\} + O(u^3).$$

For each $i < j$, we have $\sum_x (\mathrm{d}b)_{ij}(x) = 0$ by periodicity, and therefore

$$\sum_x |(\mathrm{d}b)_{ij}(x) + [c_i, c_j]|^2 = \sum_x |(\mathrm{d}b)_{ij}(x)|^2 + \Big(\frac{n}{\varepsilon_d}\Big)^3 |[c_i, c_j]|^2.$$

Using (36.12) and $q(e^v) = |v|^2/8 + O(|v|^4)$, we find that the coefficient of u^4 in $E_d(e^{uX/n})$ is at least

$$\frac{1}{2\varepsilon_d} \Big(\frac{n}{\varepsilon_d}\Big)^3 \sum_{i<j} |[\varepsilon_d x_i/n, \varepsilon_d x_j/n]|^2 = \frac{Q(X)}{n}.$$

Together with (36.10), this proves that the fourth Taylor coefficient of $u \mapsto E_d(e^{uX/n})$ equals $Q(X)/n$ for every direction X. The vanishing of the lower coefficients also follows from $0 \le f_d(uX) \le C_{d,X} u^4$ for both signs of small real u. By analyticity and polarization, we obtain the stated identities for the multilinear derivatives, so the fourth Taylor polynomial of f_d at zero is Q/n at every finite depth. We make no claim about the fifth Taylor polynomial.

Step 6: the uniform remainder. Fix the side n. On a common smaller ball, we restrict the bound of Theorem 10.11 on the derivatives of order five of $\theta \mapsto E_d(e^\theta)$ to the linear substitution $\theta_{x,i} = X_i/n$. At the fixed side n there are finitely many coordinates $\theta_{x,i}$. Summing the tensor entries and including the factors $1/n$, we obtain

$$\sup_{d\geq 0} \sup_{|X|<\rho_0(n)} \|D^5 f_d(X)\| \leq C_n.$$

The ball and the bound do not depend on the radii $u_{d,X}$ of the trial configurations. Since the Taylor polynomial of order four of f_d at zero is Q/n by Step 5, Taylor's formula on the segment from 0 to X gives

$$f_d(X) - \frac{Q(X)}{n} = \frac{1}{4!}\int_0^1 (1-t)^4 D^5 f_d(tX)[X,X,X,X,X]\,dt.$$

The absolute value of the right side is at most $C_n|X|^5/5!$, which proves (36.3). □

36.3 Holonomies near the trivial flat configuration

This section proves two facts about the flowed holonomies. The first is deterministic. In the central coordinates, the logarithm of the flowed zero-fluctuation holonomy triple equals X up to errors of order $|X|^2 + |s|$. Further, a configuration that is close to the set of flat configurations and whose zero-fluctuation holonomies are close to the identity lies close to the trivial flat configuration. The second fact is probabilistic: under the conditioned Wilson measure, the flowed holonomies of the configuration differ from those of its zero-fluctuation reconstruction by $O(\sqrt{\gamma})$ in mean square. Let $\mathcal{F}_n$ denote the set of flat configurations on Λ_n, regarded in the quotient by based gauge transformations.

Theorem 36.3. *After a fixed reduction of the central coordinate neighborhood and of $\mathcal{V}$, the map $Z_K(X,s) = \operatorname{Log} \mathcal{H}_0^K(V(X,s))$ is defined on that neighborhood for every K, and*

$$\sup_K \|Z_K\|_{C^{1,1}} \leq C_n, \qquad |Z_K(X,s) - X| \leq C_n(|X|^2 + |s|), \qquad |Z_K(X,s)| \geq \tfrac{3}{4}|X| - C_n|s|,$$

$$\|D_X Z_K(X,s) - I\|_{\mathrm{op}} \leq C_n(|X| + |s|).$$

The maps $\mathcal{H}_0^K$ are equicontinuous, in a fixed finite family of smooth charts of the based quotient, on a neighborhood of $\mathcal{F}_n$, and $\mathcal{H}_0^K = \mathcal{H}_n$ on $\mathcal{F}_n$ for every finite K. Fix a continuous distance d on the based quotient. For every open neighborhood $\mathcal{U}$ of the trivial based orbit there exists $\delta_{\mathcal{U}} > 0$, independent of K and γ, such that

$$d(V,\mathcal{F}_n) \leq \delta_{\mathcal{U}} \quad \text{and} \quad \Big(\sum_{i=1}^{3} \rho_G(\mathcal{H}_{0,i}^K(V))^2\Big)^{1/2} \leq \delta_{\mathcal{U}} \qquad \text{imply} \qquad V \in \mathcal{U}.$$

The constant $\delta_{\mathcal{U}}$ may depend on d and $\mathcal{U}$.

Let $D_K = \max_i \|\mathcal{H}_i^K - \mathcal{H}_{0,i}^K(V)\|_{\mathrm{op}}$. Then, uniformly in K and $0 < \gamma \le \gamma_0$,

$$\mathbb{E}_\nu \min(1, D_K)^2 \le C_n \gamma.$$

For every neighborhood $\mathcal{V}'$ with compact closure in $\mathcal{V}$,

$$\mathbb{E}_\nu \Big[\mathbf{1}_{\{\mathcal{H}^K, \mathcal{H}_0^K(V) \in \mathcal{V}'\}} \min\big(1, |\operatorname{Log} \mathcal{H}^K - \operatorname{Log} \mathcal{H}_0^K(V)|\big)^2 \Big] \le C_{n,\mathcal{V}'} \gamma.$$

The estimates on D_K are averages over the whole conditioned Wilson measure; they are not conditioned on the configuration being near a central triple.

Proof. Steps 1–3 prove the deterministic statements, and Step 4 the probabilistic ones.

Step 1: deterministic regularity. We apply Theorem 35.9 with $m = 0$ to the parameters and the side n of Definition 36.1. With $m = 0$ there are no fluctuation variables among the inputs. The input is the coarse configuration alone, and the map of that theorem is $\Xi_0^K = \mathcal{H}_0^K$, with the same gauge frame at the basepoint and the same flow time. The part of Theorem 35.9 concerning a neighborhood of all flat configurations applies, because (36.1) places every commuting constant representative strictly inside the classical, block-averaging, and gauge margins, as checked in Section 36.1. We obtain a neighborhood of the trivial flat configuration on which $\sup_K \|\mathcal{H}_0^K\|_{C^{1,1}} \le C_n$, a modulus of continuity of $\mathcal{H}_0^K$ near $\mathcal{F}_n$ that is common to all K, and the identity

$$\mathcal{H}_0^K(V_0) = \mathrm{Hol}(V_0) \qquad (V_0 \in \mathcal{F}_n) \tag{36.13}$$

at every finite K. Independently, Lemma 14.9 explains (36.13): the zero-fluctuation refinements of a flat configuration are flat refinements, and the Wilson flow is stationary on flat configurations. These are identities of matrices; the conjugation at the basepoint has not been divided out. The neighborhoods and the modulus are those of the deterministic theorem, on its finite cover of charts, and they do not depend on K or γ. In particular, they are not chosen using the small-field event.

Step 2: the logarithm. At $V = I$ the output is (I, I, I). By the common modulus, for any prescribed smaller neighborhood of the identity in $\mathcal{V}$, there exists a neighborhood of the input whose outputs lie in it. The logarithm and its first two derivatives are bounded on the closure of that neighborhood. Composing with the maps of Step 1, we obtain $\sup_K \|Z_K\|_{C^{1,1}} \le C_n$. Let $b_K(X, s) = Z_K(X, s) - X$. If $s = 0$ and the three components of X are parallel, the links of $V(X, 0)$ commute, the configuration is flat, and (36.13) implies that $b_K(X, 0) = 0$. Each of the nine coordinate directions of $\mathbb{R}^9$ is of this form, and these directions span $\mathbb{R}^9$. Differentiating along them, we find

$$b_K(0, 0) = 0, \qquad D_X b_K(0, 0) = 0.$$

Integrating the Lipschitz bound on $D_X b_K$ along $v \mapsto (vX, 0)$, we obtain $|b_K(X,0)| \le C_n|X|^2$, and the bound on the derivative in s gives $|b_K(X,s) - b_K(X,0)| \le C_n|s|$. The Lipschitz bound on the derivative also implies $\|D_X Z_K(X,s) - I\| \le C_n(|X| + |s|)$. We reduce the radius in X so that $C_n|X| \le 1/4$. Then, by the triangle inequality, $|Z_K(X,s)| \ge |X| - C_n|X|^2 - C_n|s| \ge (3/4)|X| - C_n|s|$. The same reduction works for every K and every coupling.

Step 3: localization near the trivial flat configuration. The based quotient is compact, since it is the quotient of a finite product of copies of $\mathrm{SU}(2)$ by a compact group, and $\mathcal{F}_n$ is a closed subset. On a flat configuration, the transport along a path is unchanged by elementary plaquette moves and depends only on the homotopy class of the path. Then, on the universal covering lattice, the transports from the root define a periodic gauge transformation to the trivial configuration if and only if all three cycle holonomies are the identity. Thus the trivial orbit is the only flat based orbit whose cycle triple is (I, I, I); this is the based version of Lemma 14.9.

Let $\mathcal{U}$ be given, and let $\mathcal{U}_1$ be an open set containing the trivial orbit with $\overline{\mathcal{U}_1} \subset \mathcal{U}$. Suppose first that $\mathcal{F}_n \setminus \mathcal{U}_1$ is nonempty. Since it is compact and contains no flat configuration with identity cycle triple,

$$m = \min_{V_0 \in \mathcal{F}_n \setminus \mathcal{U}_1} \Big(\sum_i \rho_G(\mathrm{Hol}_i(V_0))^2 \Big)^{1/2} > 0.$$

By the common modulus of Step 1, (36.13), and the continuity of ρ_G, there exists $\delta_1 > 0$ such that, for every K, if V_0 is flat and $d(V, V_0) < \delta_1$, then the quantities $(\sum_i \rho_G(\mathcal{H}^K_{0,i}(V))^2)^{1/2}$ and $(\sum_i \rho_G(\mathrm{Hol}_i(V_0))^2)^{1/2}$ differ by less than $m/2$. Let $\delta_2 > 0$ be smaller than the distance from $\overline{\mathcal{U}_1}$ to the complement of $\mathcal{U}$, and let $\delta_{\mathcal{U}}$ be smaller than $\delta_1/2$, $\delta_2/2$, $m/4$, and the radius of the charts of Step 1. Suppose that V satisfies the two hypotheses, and let $V_0 \in \mathcal{F}_n$ be a closest flat point, which exists by compactness. Then the cycle radius of V_0, that is, the second of the two quantities above, is less than $\delta_{\mathcal{U}} + m/2 < m$. Hence $V_0 \notin \mathcal{F}_n \setminus \mathcal{U}_1$, that is, $V_0 \in \mathcal{U}_1$, and since $d(V, V_0) < \delta_2$, we have $V \in \mathcal{U}$. If $\mathcal{F}_n \setminus \mathcal{U}_1$ is empty, then $\mathcal{F}_n$ has positive distance from the complement of $\mathcal{U}$, and the first hypothesis alone implies the conclusion. This argument includes all flat configurations, in particular those near the other seven central triples.

Step 4: the probabilistic estimates. We apply Theorem 34.10 with $m = 0$ and $p = 2$. Its comparison triple is $\mathcal{H}^K_0(V)$, and its probability measure is the whole conditioned Wilson measure ν. By the moment bound of that theorem, we have

$$\mathbb{E}_\nu \min(1, D_K)^2 \le C_n \gamma.$$

This uses the condition $a_{\mathrm{map}}\sqrt{B} \le 32/49$ imposed in Definition 36.1. That theorem includes the conditional means, the matrices at the basepoint, and all flat configurations.

Finally, Log is Lipschitz, as a map of the three matrices, on the compact closure of $\mathcal{V}'$. To obtain a single constant for all pairs, we cover the closure by finitely many neighborhoods on which Log has bounded derivatives. Pairs closer than a Lebesgue number of this cover satisfy the derivative estimate in one of these neighborhoods. For the remaining pairs, we use the boundedness of Log and the positive lower bound on their distance. We obtain

$$\min\bigl(1, |\operatorname{Log} H - \operatorname{Log} H'|\bigr) \le C_{\mathcal{V}'} \min\bigl(1, \max_i \|H_i - H_i'\|_{\mathrm{op}}\bigr) \qquad (H, H' \in \mathcal{V}').$$

Squaring, restricting to the event in the statement, and using the bound on $\mathbb{E}_\nu \min(1, D_K)^2$, we obtain the last estimate. All reductions used fixed neighborhoods, the fixed side, and the bounds of the cited theorems, so the constants have the stated dependence. □

36.4 The quartic reference measure

We write m_Q for the quartic reference measure $dm_Q(Y) = e^{-Q(Y)}\, d^9Y$ on $\mathbb{R}^9$. The following lemma records its basic properties. The divergence of its total mass is known in the matrix-integral literature cited at the beginning of this section; we give a direct proof in the coordinates of Lemma 33.2.

Lemma 36.4. *The measure m_Q is locally finite and has infinite total mass. For every $\chi \in C_c^\infty([0,\infty))$ that is constant near zero and every $\lambda > 0$,*

$$\int \chi(\lambda|Y|)\, dm_Q(Y) = \lambda^{-9} \int \chi(|Y|) e^{-\lambda^{-4} Q(Y)}\, d^9Y,$$

and

$$\int \bigl\{(4Q(Y) - 9)\chi(|Y|) - |Y|\chi'(|Y|)\bigr\}\, dm_Q(Y) = 0.$$

If $\chi \ge 0$ and χ is not identically zero, then $\int \chi(|Y|)\, dm_Q(Y)$ is finite and strictly positive.

We call the second identity the dilation integration-by-parts identity. It states that $\int W_\chi\, dm_Q = 0$ for every radial cutoff χ, and it uses only the compact support of the test; no normalization of m_Q is involved.

Proof. Since $Q \ge 0$ is a polynomial, $0 < e^{-Q} \le 1$ everywhere, which proves local finiteness.

Infinite mass. We use Lemma 33.2, with its homogeneous cone, its injective normal tube, and its bound on the Jacobian, at every radius. We write the commuting triples as $y_i = \rho a_i u$ with $\rho \ge 1$ and $a, u \in S^2$, where (a, u) and $(-a, -u)$ give the same triple, and we set $\zeta_i = a_i u$. The normal space at ζ is

$$\mathcal{B}_{a,u} = \Bigl\{ b = (b_1, b_2, b_3) : b_i \perp u,\ \sum_i a_i b_i = 0 \Bigr\}, \qquad \dim \mathcal{B}_{a,u} = 4.$$

We claim that

$$Q(\zeta + b) = \tfrac{1}{2}|b|^2 + Q(b) \qquad (b \in \mathcal{B}_{a,u}). \tag{36.14}$$

Indeed, $(\zeta_i + b_i) \times (\zeta_j + b_j) = u \times (a_i b_j - a_j b_i) + b_i \times b_j$. The first term lies in $u^\perp$, while $b_i \times b_j$ is parallel to u because $b_i, b_j \perp u$. The two terms are therefore orthogonal. Since $|u \times w| = |w|$ for $w \perp u$, and

$$\sum_{i<j} |a_i b_j - a_j b_i|^2 = |a|^2 \sum_i |b_i|^2 - \Big|\sum_i a_i b_i\Big|^2 = |b|^2,$$

we obtain (36.14). The same computation with $y = \rho\zeta$ gives $Q(y + b) = \rho^2|b|^2/2 + Q(b)$.

Let $\eta > 0$ be smaller than the relative radius of the tube in Lemma 33.2 and so small that the Jacobian of the tube is at least $1/2$ when $|b|/\rho \le \eta$. We restrict to $|b| \le \eta/\rho$. For $\rho \ge 1$, this set lies in the tube, and $|b|/\rho \le \eta$. Since

$$Q(b) \le \frac{1}{2} \sum_{i<j} |b_i|^2 |b_j|^2 \le \frac{1}{4} |b|^4,$$

we have $Q(y + b) \le \eta^2/2 + \eta^4/4$, which we denote by C_η, on this whole unbounded tube. By Lemma 33.2, the volume of the cone is $(1/2)\rho^4 \, d\rho \, d\Omega_a \, d\Omega_u$, where the factor $1/2$ accounts for the double parametrization, and the tube is injective in the point y of the cone. The normal ball has volume $v_4 \eta^4 \rho^{-4}$, where v_4 is the volume of the unit ball in $\mathbb{R}^4$. For every $T > 1$, we obtain

$$\int_{\mathbb{R}^9} e^{-Q(X)} \, dX \ge \frac{1}{4} e^{-C_\eta} (4\pi)^2 v_4 \eta^4 \int_1^T \rho^4 \rho^{-4} \, d\rho = c_\eta (T - 1).$$

Letting $T \to \infty$ proves that the total mass is infinite. All radii and constants in this argument are absolute.

Scaling, the dilation integration-by-parts identity, and positivity. The change of variables $Z = \lambda Y$, together with $Q(Z/\lambda) = \lambda^{-4} Q(Z)$, gives the scaling formula. For λ in a compact neighborhood of 1, the integrands and their derivatives in λ are supported in a common compact set and have a common integrable bound. We may therefore differentiate at $\lambda = 1$, which gives the dilation integration-by-parts identity. Equivalently, by the homogeneity relation $Y \cdot \nabla Q = 4Q$, we have

$$\operatorname{div}\big\{ Y \chi(|Y|) e^{-Q(Y)} \big\} = \big\{ 9\chi(|Y|) + |Y| \chi'(|Y|) - 4Q(Y) \chi(|Y|) \big\} e^{-Q(Y)}.$$

The vector field on the left is smooth at zero because χ is constant there, and it vanishes outside a compact set. The integral of each of its coordinate derivatives over a box containing its support is zero, which proves the dilation integration-by-parts identity with the stated sign. Finally, a nonnegative smooth radial test that is not identically zero is positive on an interval of radii, which corresponds to a subset of $\mathbb{R}^9$ of positive volume. Since the density e^{-Q} is positive, the integral is positive, and it is finite by compact support. □

Remark 36.5. For $F_Q(\rho) = m_Q\{|Y| \le \rho\}$ and $f_Q = F_Q'$ we have, as $\rho \downarrow 0$,

$$f_Q(\rho) = \frac{32\pi^4}{105}\rho^8\big[1 + O(\rho^4)\big], \qquad F_Q(\rho) = \frac{32\pi^4}{945}\rho^9\big[1 + O(\rho^4)\big],$$

with absolute constants for the Euclidean norm and the normalization of Q used here. Indeed, polar coordinates give

$$f_Q(\rho) = \rho^8 \int_{S^8} e^{-\rho^4 Q(\omega)}\, d\omega. \tag{36.15}$$

Since Q is bounded on S^8, the exponential is $1 + O(\rho^4)$ uniformly. The area of S^8 is $2\pi^{9/2}/\Gamma(9/2) = 32\pi^4/105$, by $\Gamma(1/2) = \sqrt{\pi}$ and $\Gamma(v+1) = v\Gamma(v)$. Integrating the density from zero gives the asymptotics of F_Q. These formulas are not used below.

36.5 Integration over the transverse modes

The next theorem, our main integration result, computes the expectation, under the stopped measure, of a compactly supported test of the rescaled logarithm of either the unflowed coarse holonomy triple $\mathcal{H}_n(V)$ or the flowed zero-fluctuation holonomy triple $\mathcal{H}_0^K(V)$.

Theorem 36.6. *For every $R < \infty$ there exist $C_{n,R} < \infty$ and $\gamma_R > 0$ such that, for every bounded Borel function φ supported in $\{|Y| \le R\}$, every $K \ge 0$, and every $0 < \gamma \le \gamma_R$, both $T = \mathcal{H}_n(V)$ and $T = \mathcal{H}_0^K(V)$ satisfy*

$$\mathbb{E}_{\widehat{\nu}}\mathcal{I}_{\gamma,\varphi}(T) = r_\gamma \kappa_{K,\gamma}\Big\{\int \varphi\, dm_Q + \mathcal{E}_{K,\gamma,T,\varphi}\Big\}, \qquad |\mathcal{E}_{K,\gamma,T,\varphi}| \le C_{n,R}\|\varphi\|_\infty r_\gamma,$$

where the factor $\kappa_{K,\gamma}$ is the same for both maps and all tests, namely

$$\kappa_{K,\gamma} = (2\pi)^{d_{\mathrm{st}}/2} n^2 \frac{e^{-\overline{R}_{K,\gamma}(0,0)} J_n(0,0)}{\sqrt{\det A_K(0)}}\, \frac{g^{d_{\mathrm{st}}+4}}{\widehat{Z}}, \qquad 0 < c_n \le \kappa_{K,\gamma} \le C_n.$$

Here $\widehat{Z}$ is the normalization constant of $\widehat{\nu}$ in Definition 36.1, and $c_n g^{d_{\mathrm{st}}+4} \le \widehat{Z} \le C_n g^{d_{\mathrm{st}}+4}$.

Further, for $T_K(X,s) = \mathrm{Log}\, T(V(X,s))$ and both maps, the change of variables $Z = T_K(X,s)$ is invertible on a fixed smaller ball of outputs, and its inverse $X = H_K(Z,s)$ satisfies

$$|H_K(Z,s) - Z| \le C_n(|Z|^2 + |s|), \qquad |\det D_Z H_K(Z,s) - 1| \le C_n(|Z| + |s|).$$

The error bound depends on φ only through $\|\varphi\|_\infty$, and no modulus of continuity of φ enters. It accounts for the density factor $e^{-\overline{R}_{K,\gamma}} J_n$, including the first derivatives of $\overline{R}_{K,\gamma}$, for the Gaussian determinant of the transverse modes, and for the contributions of configurations away from the trivial flat configuration. We do not assert that $\kappa_{K,\gamma}$ has a limit. Since $\kappa_{K,\gamma}$ depends only on the stopped measure, it does not depend on the flow time at which $\mathcal{H}_0^K$ is observed.

Proof. Throughout the proof we write $D = d_{\mathrm{st}}$ and $\epsilon = r_\gamma$, and we set

$$a_{K,\gamma}(X,s) = e^{-\overline{R}_{K,\gamma}(X,s)} J_n(X,s), \qquad a^0_{K,\gamma} = a_{K,\gamma}(0,0).$$

Steps 1–3 localize to the central coordinates and invert the output map, Step 4 rescales so that the test becomes exactly $\varphi(Y)$, and Steps 5–6 compare the density with its Gaussian–quartic model and integrate.

Step 1: bounds on the density. We apply Theorem 33.8 to the stopped measure at depth JK, with the side, the parameters, and the upper bound γ_0 on the coupling from Definition 36.1. The chart $\mathcal{C}^+$ of (36.2) is a fixed chart of link logarithms, independent of the depth and the coupling. On it, Lemma 33.6, with $d = JK$ and link logarithms $X/n + s$, together with the residual value bound (P3) in Section 33.2, gives

$$\sup_{K,\,0<\gamma\le\gamma_0} \sup_{\mathcal{C}^+} \big(|\overline{R}_{K,\gamma}| + \|D_{X,s}\overline{R}_{K,\gamma}\|\big) \le C_n.$$

The smooth positive density J_n has positive upper and lower bounds and bounded first derivatives on the closure of a slightly smaller chart that still contains $\overline{\mathcal{C}}$, and we replace $\mathcal{C}^+$ by this chart. The identity

$$D_{X,s} a_{K,\gamma} = e^{-\overline{R}_{K,\gamma}} \big(D_{X,s} J_n - J_n D_{X,s}\overline{R}_{K,\gamma}\big)$$

then gives, on this fixed chart,

$$0 < c_n \le a_{K,\gamma}(X,s) \le C_n, \qquad \|D_{X,s} a_{K,\gamma}(X,s)\| \le C_n. \tag{36.16}$$

This uses the first derivatives of the centered effective interaction in both X and s. Together with the uniform classical derivative bounds of Theorem 10.11, Theorem 33.8 also gives

$$\begin{aligned} c_n I \le A_K(X) \le C_n I, \qquad \|A_K(X) - A_K(0)\| \le C_n|X|, \\ F_K(X,s) = f_K(X) + \tfrac{1}{2} s^{\mathsf{T}} A_K(X) s + O_n(|s|^3), \qquad F_K(X,s) \ge f_K(X) + c_n|s|^2. \end{aligned} \tag{36.17}$$

The density in Theorem 33.8 at depth JK is the stopped measure of Definition 36.1, so its normalization constant is $\widehat{Z}$. By Theorem 33.10, after reducing the upper bound on the coupling if necessary, we have

$$c_n g^{D+4} \le \widehat{Z} \le C_n g^{D+4}. \tag{36.18}$$

Step 2: reduction to a neighborhood of the trivial flat configuration. Fix a neighborhood $\mathcal{U}$ of the trivial based orbit whose closure lies in the coordinate chart of (36.17). By Theorem 36.3, applied to the map $\mathcal{H}^K_0$, there exists $\delta > 0$ such that a configuration within distance δ of $\mathcal{F}_n$ whose cycle radius $(\sum_i \rho_G(\mathcal{H}^K_{0,i}(V))^2)^{1/2}$ is at most δ lies in $\mathcal{U}$. For the map $\mathcal{H}_n = \mathrm{Hol}$, the same statement follows from the argument of Step 3 of that proof,

with the continuous map Hol in place of $\mathcal{H}_0^K$. On the complement of $\{d(V,\mathcal{F}_n)\le\delta\}$, we have $E_0\ge c_{n,\delta}>0$ by the compactness of the configuration space and $E_0^{-1}(0)=\mathcal{F}_n$. The lower bound $E_{JK,\mathrm{sat}}\ge\kappa E_0$ on D_r and the bound $|\overline{R}_{K,\gamma}|\le C_n$ on D_r, properties (P1) and (P3) in Section 33.2, together with (36.18), give

$$\widehat{\nu}\{d(V,\mathcal{F}_n)>\delta\}\le C_n g^{-(D+4)}e^{-c_n/g^2}. \tag{36.19}$$

Since the product Haar measure has total mass one, no volume factor depending on K appears in this bound. Suppose that $R\epsilon<\delta$ and that the image of $\{|Y|\le R\}$ under $Y\mapsto\epsilon Y$ lies in $\operatorname{Log}\mathcal{V}$. If $\mathcal{I}_{\gamma,\varphi}(T)\neq 0$, then $|\operatorname{Log}T|\le R\epsilon$, and the cycle radius is at most $R\epsilon<\delta$, since $\rho_G(H_i)\le|\operatorname{Log}H_i|$. Every contribution to either observable from $V\notin\mathcal{U}$ is therefore bounded by (36.19). The flat configurations near the other seven central triples, and all other flat configurations, still contribute to $\widehat{Z}$.

Step 3: the output coordinates. For $T=\mathcal{H}_0^K$, Theorem 36.3 gives

$$|T_K(X,s)-X|\le C_n(|X|^2+|s|),\qquad \|D_XT_K(X,s)-I\|\le C_n(|X|+|s|). \tag{36.20}$$

For $T=\mathrm{Hol}$, each cycle holonomy is a product of n link matrices of $V(X,s)$, which are analytic functions of (X,s) at the fixed side n, and at $s=0$ the i-th holonomy is exactly e^{x_i}. Then $T_K(X,0)=X$ and $D_XT_K(X,0)=I$. Since these finite products and Log have bounded derivatives, (36.20) holds for this map as well, with constants independent of K.

Fix a convex ball $\{|X|\le\rho\}$ and a ball in s on which $\|D_XT_K-I\|\le 1/4$ for both maps. We set $b_K=T_K-X$ and restrict $|s|$ further so that $|b_K(0,s)|\le\rho/8$. For $|Z|<\rho/4$, the map $X\mapsto Z-b_K(X,s)$ sends the closed ball of radius $\rho/2$ into itself, since $|Z-b_K(X,s)|\le|Z|+|b_K(0,s)|+|X|/4\le\rho/2$, and it is a contraction with factor at most $1/4$. Its iterates converge to a unique fixed point $X=H_K(Z,s)$, which solves $T_K(X,s)=Z$. The inequality

$$|T_K(X,s)-T_K(X',s)|\ge\tfrac{3}{4}|X-X'|$$

on the larger convex ball excludes any other preimage there. Differentiating the fixed point equation, or taking difference quotients and using the uniformly convergent Neumann series for $(I+D_Xb_K)^{-1}$, we obtain

$$D_ZH_K=\big(I+D_Xb_K(H_K,s)\big)^{-1}.$$

The fixed point equation first gives $|H_K|\le|Z|+|b_K(0,s)|+|H_K|/4$, which implies $|H_K|\le C_n(|Z|+|s|)$, and then

$$|H_K(Z,s)-Z|\le C_n(|Z|^2+|s|),\qquad |\det D_ZH_K(Z,s)-1|\le C_n(|Z|+|s|). \tag{36.21}$$

For the determinant, we expand about I_9 and use the bound on D_Xb_K; the determinant is positive since D_ZH_K stays close to I_9. This proves the second part of the theorem. We may

take the neighborhood $\mathcal{U}$ of Step 2 inside this domain, so that points outside it whose output lies in the compact window are controlled by (36.19). Inside $\mathcal{U}$, after a further fixed reduction of ρ, (36.20) implies the lower bound $|T_K(X,s)| \geq (3/4)|X| - C_n|s|$ for both maps. Because of its term in s, we use it together with the tail bound of Step 4.

Step 4: the transverse tail and the change of variables. Since $f_K \geq 0$, (36.17) and the bounds on the density factor give

$$\widehat{\nu}\big(\{|s| > \epsilon\} \cap \{V \text{ in the central coordinates}\}\big) \leq C_n g^{-4} e^{-c_n \epsilon^2/g^2} = C_n g^{-4} e^{-c_n'/\sqrt{\gamma}}. \tag{36.22}$$

To see this, we split $e^{-c_n|s|^2/g^2}$ into two equal factors and bound one of them by $e^{-c_n\epsilon^2/(2g^2)}$ on $\{|s| > \epsilon\}$. Integrating the other over $\mathbb{R}^D$ gives $C_n g^D$. The X-integral is over a bounded set, and we divide by (36.18). In the last equality, we used $\epsilon^2/g^2 = n/\sqrt{\gamma}$. Both (36.19) and (36.22) are smaller than every fixed power of ϵ: with $v = 1/\sqrt{\gamma}$, each is a fixed power of v times e^{-cv} or e^{-cv^2}.

On $\{|s| \leq \epsilon\}$, an output with $|T_K| \leq R\epsilon$ satisfies $|X| \leq C_{n,R}\epsilon$ by the lower bound of Step 3. For γ_R small, this lies in the domain of the inverse. Conversely, the inverse is defined for all $|Z| \leq R\epsilon$ and $|s| \leq \epsilon$, and the bound $|H_K| \leq C_{n,R}\epsilon$ places its values in $\mathcal{U}$ for γ_R small. The part of the unnormalized integral of the observable over $\mathcal{U} \cap \{|s| \leq \epsilon\}$ is therefore transformed exactly by

$$Z = \epsilon Y, \qquad s = gz, \qquad X = H_K(\epsilon Y, gz), \qquad dX\, ds = \epsilon^9 g^D \det D_Z H_K(\epsilon Y, gz)\, dY\, dz. \tag{36.23}$$

In these variables the test is exactly $\varphi(Y)$, and no regularity of φ is needed. The variable z ranges over the ball $\{|z| \leq \epsilon/g\}$, and the test restricts Y to $\{|Y| \leq R\}$. Since $g = \epsilon^2/\sqrt{n}$, (36.21) gives on this domain

$$\Big|\frac{X}{\epsilon} - Y\Big| \leq C_{n,R}\epsilon(1+|z|), \qquad |\det D_Z H_K - 1| \leq C_{n,R}\epsilon(1+|z|), \qquad \frac{|X|}{\epsilon} \leq C_{n,R}. \tag{36.24}$$

The last bound uses $|s| \leq \epsilon$, so it holds on the whole truncated ball in z, even when $|z|$ is large.

Step 5: comparison of the density. By Theorem 36.2 and $ng^2 = \epsilon^4$, we have $f_K(X)/g^2 = Q(X/\epsilon) + O(|X|^5/g^2)$, and therefore

$$\Big|\frac{f_K(X)}{g^2} - Q(X/\epsilon)\Big| \leq C_n \frac{|X|^5}{g^2} \leq C_{n,R}\epsilon.$$

Since X/ϵ and Y lie in a fixed ball, on which Q has bounded first derivatives, the first bound in (36.24) gives

$$\Big|\frac{f_K(X)}{g^2} - Q(Y)\Big| \leq C_{n,R}\epsilon(1+|z|). \tag{36.25}$$

This uses only $|X| \le C_{n,R}\epsilon$, which holds on the whole truncated domain. In particular, it bounds the absolute error on the compact rescaled window, including the directions of commuting triples, where Q vanishes. The expansion in (36.17) gives

$$\Big|\frac{F_K(X, gz) - f_K(X)}{g^2} - \frac{1}{2} z^{\mathsf{T}} A_K(0) z\Big| \le C_{n,R}\big(\epsilon|z|^2 + g|z|^3\big), \tag{36.26}$$

where we used $\|A_K(X) - A_K(0)\| \le C_n|X| \le C_{n,R}\epsilon$ and the cubic remainder in $s = gz$. We also use the elementary inequality

$$|e^{-A} - e^{-B}| \le |A - B|\big(e^{-A} + e^{-B}\big) \qquad (A, B \in \mathbb{R}), \tag{36.27}$$

which holds because the integral of the derivative of $t \mapsto e^{-t}$ between A and B is at most $|A - B| \max(e^{-A}, e^{-B})$.

Let $P_K(Y, z) = F_K(H_K(\epsilon Y, gz), gz)/g^2$ and $P_K^0(Y, z) = Q(Y) + z^{\mathsf{T}} A_K(0) z/2$. Both are at least $c_n|z|^2$, by $f_K \ge 0$, $Q \ge 0$, and the lower bounds in (36.17). Combining (36.25) and (36.26), and using $g \le C_n\epsilon^2 \le C_n\epsilon$, we find

$$|P_K - P_K^0| \le C_{n,R}\epsilon\big(1 + |z| + |z|^2 + |z|^3\big).$$

By (36.27), $|e^{-P_K} - e^{-P_K^0}|$ is at most $C_{n,R}\epsilon$ times a fixed polynomial in $|z|$ times $e^{-c_n|z|^2}$, which is integrable over $\mathbb{R}^D$ uniformly in K and γ; the phase error itself need not be uniformly small on the whole truncated ball in z. For the density factor and the Jacobian, we write $b_{K,\gamma}(Y, z) = a_{K,\gamma}(X, gz) \det D_Z H_K(\epsilon Y, gz)$ with $X = H_K(\epsilon Y, gz)$. By (36.16) and (36.24), these quantities are bounded on our domain and

$$|b_{K,\gamma}(Y, z) - a_{K,\gamma}^0| \le C_{n,R}\epsilon(1 + |z|).$$

Splitting the difference as $(b_{K,\gamma} - a_{K,\gamma}^0)e^{-P_K} + a_{K,\gamma}^0(e^{-P_K} - e^{-P_K^0})$ and using that $t \mapsto (1 + t + t^2 + t^3)e^{-c_n t^2/2}/(1 + t)$ is bounded on $[0, \infty)$, we obtain

$$\Big|b_{K,\gamma}(Y, z)e^{-P_K(Y,z)} - a_{K,\gamma}^0 e^{-P_K^0(Y,z)}\Big| \le C_{n,R}\epsilon(1 + |z|)e^{-c_n'|z|^2} \qquad (|Y| \le R,\ |z| \le \epsilon/g), \tag{36.28}$$

with $c_n' = c_n/2$.

Step 6: integration and the common factor. The Gaussian integral of $a_{K,\gamma}^0 e^{-P_K^0}$ over $\{|z| > \epsilon/g\}$ is exponentially small, since $\epsilon/g = \sqrt{n}/\epsilon \to \infty$. Integrating (36.28) first in z and then over $\{|Y| \le R\}$, we obtain

$$\widehat{Z}\,\mathbb{E}_{\widehat{\nu}}\mathcal{I}_{\gamma,\varphi}(T) = g^D\epsilon^9\Big\{a_{K,\gamma}^0\frac{(2\pi)^{D/2}}{\sqrt{\det A_K(0)}}\int \varphi(Y)e^{-Q(Y)}\,dY + O_{n,R}\big(\|\varphi\|_\infty\epsilon\big)\Big\}. \tag{36.29}$$

The contributions discarded in Steps 2 and 4 satisfy the same bound after reducing γ_R: after normalization by $\widehat{Z}$ they are $O_{n,R}(\|\varphi\|_\infty\epsilon^2)$, while the prefactor of the claimed expansion is bounded above and below by fixed multiples of ϵ.

Finally, since $\epsilon^4 = \gamma = ng^2$, we have the identity

$$\frac{g^D \epsilon^9}{\widehat{Z}} = \epsilon n^2 \frac{g^{D+4}}{\widehat{Z}}.$$

Thus the coefficient of $\int \varphi \, dm_Q$ in (36.29), divided by $\widehat{Z}$, is exactly $\epsilon \kappa_{K,\gamma}$. The bounds $c_n \le \kappa_{K,\gamma} \le C_n$ follow from (36.18), $c_n \le a^0_{K,\gamma} \le C_n$, and $c_n I \le A_K(0) \le C_n I$ in the fixed dimension D. Dividing by $\epsilon \kappa_{K,\gamma}$, we obtain the stated bound on $\mathcal{E}_{K,\gamma,T,\varphi}$. The leading term involves only $a^0_{K,\gamma}$ and $A_K(0)$, which are the same for both maps; the factor is therefore the same for both maps and every test. Every reduction used a radius or an upper bound on the coupling depending only on the fixed data and R. □

36.6 Passage to the continuum measure

We now pass from the stopped measure to the conditioned Wilson measure, then to the Wilson measure, and finally to the continuum measure. The order of limits is as follows: at each fixed γ we let $K \to \infty$ with the comparison side n fixed, and only afterwards do we let $\gamma \to 0$. Throughout, $\lambda_\gamma = \lambda_{L,\gamma,[n_*]_M}$ denotes the continuum measure for the sequence of sides $(n_* B^K)_{K \ge 0}$ (Theorem 29.25 and Corollary 29.26). Since $n = n_* B^a$, the classes $[n]_M$ and $[n_*]_M$ coincide. We observe the holonomies of a trajectory around the three coordinate cycles based at the origin, at the time $t = \theta L^2$. Under λ_γ this triple is defined up to simultaneous conjugation, and we use invariant tests.

Theorem 36.7. *Fix the data of Definition 36.1 before varying γ. For every continuous compactly supported function $\varphi : \mathbb{R}^9 \to \mathbb{R}$ that is invariant under simultaneous conjugation and every radial cutoff χ,*

$$\lim_{\gamma \downarrow 0} \frac{\mathbb{E}_{\lambda_\gamma} \mathcal{I}_{\gamma,\varphi}}{\mathbb{E}_{\lambda_\gamma} \mathcal{I}_{\gamma,\chi(|\cdot|)}} = \frac{\int \varphi \, dm_Q}{\int \chi(|Y|) \, dm_Q(Y)}.$$

For every such φ that is nonnegative and not identically zero, there exist $0 < c_\varphi \le C_\varphi < \infty$ and $\gamma_\varphi > 0$ such that

$$c_\varphi r_\gamma \le \mathbb{E}_{\lambda_\gamma} \mathcal{I}_{\gamma,\varphi} \le C_\varphi r_\gamma \qquad (0 < \gamma \le \gamma_\varphi).$$

In particular the denominator above is positive for small γ, and

$$\lim_{\gamma \downarrow 0} \mathcal{S}_{\gamma,\lambda_\gamma}(\chi) = 0.$$

Further, for any two smooth compactly supported functions χ_1, χ_2 on $[0,\infty)$ that are not identically zero, with $A_i = \mathcal{I}_{\gamma,\chi_i(|\cdot|)}$,

$$\frac{\mathrm{Var}_{\lambda_\gamma}(A_1)}{\mathrm{Var}_{\lambda_\gamma}(A_2)} \longrightarrow \frac{\int \chi_1(|Y|)^2 \, dm_Q(Y)}{\int \chi_2(|Y|)^2 \, dm_Q(Y)} \qquad (\gamma \downarrow 0).$$

The tests χ_1, χ_2 in the variance statement need not be nonnegative. The loops and the flow time are fixed, while the window shrinks with γ. Each expectation under λ_γ is the limit, as $K \to \infty$ at fixed γ, of the expectation of the corresponding observable of the flowed lattice holonomies under the Wilson measure $\mu_{nB^K,\gamma}$. By Corollary 23.11, the small-field failure probability satisfies $\sup_K \mu_{nB^K,\gamma}(S^c_{nB^K,n,\gamma}) = O_{n,q}(\gamma^q)$ for every fixed $q > 0$, which is $o(r_\gamma)$.

Proof. For a compactly supported bounded test, we write $m(\varphi) = \int \varphi \, dm_Q$, and we set $\epsilon = r_\gamma$. Until Step 4, where we pass to the continuum measure, we work at finite K, uniformly in K.

Step 1: comparison under the conditioned Wilson measure. Let the support of φ lie in the ball of radius R, and let $0 < \eta \le 1$. For $\eta\epsilon < 1$, Markov's inequality and the bound on $\mathbb{E}_\nu \min(1, D_K)^2$ in Theorem 36.3 give

$$\nu\{D_K > \eta\epsilon\} \le C_n \eta^{-2} \frac{\gamma}{\epsilon^2} = C_n \eta^{-2} \gamma^{1/2}. \tag{36.30}$$

On the complementary event, if either of $\mathcal{I}_{\gamma,\varphi}(\mathcal{H}^K)$ and $\mathcal{I}_{\gamma,\varphi}(\mathcal{H}^K_0(V))$ is nonzero, the corresponding triple is within distance $C_R\epsilon$ of (I, I, I) as a triple of matrices, and the other triple is within an additional distance $\eta\epsilon$. For γ small, both triples therefore lie in a fixed smaller neighborhood of the identity, independently of K. Since Log is Lipschitz there, their rescaled logarithms differ by at most $C_n\eta$, and the rescaled logarithm of $\mathcal{H}^K_0(V)$ lies in the ball of radius $R + C_n$.

Let

$$\omega_\varphi(v) = \sup\bigl\{|\varphi(Y) - \varphi(Y')| : |Y - Y'| \le v\bigr\},$$

which tends to zero as $v \downarrow 0$ since φ is uniformly continuous. Theorem 36.6, applied to the indicator function of the ball of radius $R + C_n$, shows that the event that the rescaled logarithm of $\mathcal{H}^K_0(V)$ lies in this ball has $\widehat{\nu}$-probability at most $C_{n,R}\epsilon$. Since $\mathcal{H}^K_0(V)$ depends only on V, and the law of V under ν is $\widehat{\nu}$, we obtain

$$\Bigl|\mathbb{E}_\nu \mathcal{I}_{\gamma,\varphi}(\mathcal{H}^K) - \mathbb{E}_{\widehat{\nu}} \mathcal{I}_{\gamma,\varphi}(\mathcal{H}^K_0)\Bigr| \le C_{n,R}\epsilon\, \omega_\varphi(C_n\eta) + C_n \|\varphi\|_\infty \eta^{-2}\gamma^{1/2}. \tag{36.31}$$

Here the first term bounds the difference on $\{D_K \le \eta\epsilon\}$, and the second term bounds it on the event in (36.30). After division by ϵ, the right side tends to zero if we first let $\gamma \downarrow 0$ at fixed η and then let $\eta \downarrow 0$, uniformly in K. The factor ϵ in front of the modulus of continuity is essential; it comes from the small probability of the window, and uniform continuity alone would not give it.

Step 2: removing the conditioning. Let $e_{K,\gamma} = \mu_{nB^K,\gamma}(S^c_{nB^K,n,\gamma})$. At our fixed side n, we have $e_{K,\gamma} \le C_{n,q}\gamma^q$ for every fixed $q > 0$, uniformly in K, by Corollary 23.11. For any bounded observable F, conditioning on the small-field event gives

$$\mathbb{E}_\mu F = (1 - e_{K,\gamma})\mathbb{E}_\nu F + e_{K,\gamma}\mathbb{E}_{\mu(\cdot|S^c)} F, \qquad |\mathbb{E}_\mu F - \mathbb{E}_\nu F| \le 2\|F\|_\infty e_{K,\gamma},$$

where $\mu = \mu_{nB^K,\gamma}$; if $e_{K,\gamma} = 0$ the inequality holds without the second conditional expectation. For $q > 1/4$, this error is $o(\epsilon)$ uniformly in K. Combining this with (36.31) and Theorem 36.6, we obtain, for each fixed continuous compactly supported test,

$$\mathbb{E}_{\mu_{nB^K,\gamma}} \mathcal{I}_{\gamma,\varphi}(\mathcal{H}^K) = \epsilon \kappa_{K,\gamma} m(\varphi) + \epsilon \delta^{\varphi}_{K,\gamma}, \qquad \sup_K |\delta^{\varphi}_{K,\gamma}| \longrightarrow 0 \quad (\gamma \downarrow 0). \tag{36.32}$$

The signed error $\delta^{\varphi}_{K,\gamma}$ converges by the explicit bound with two parameters above. Given a tolerance, we first choose η to control the term with the modulus of continuity, and then γ to control the remaining terms. No choice of the comparison side or of the parameters depends on γ.

Step 3: bounds and ratios at finite K. If $\varphi \geq 0$ is continuous and not identically zero, it is positive on a nonempty open ball, and since e^{-Q} is positive everywhere, $m(\varphi) > 0$. By the bounds on $\kappa_{K,\gamma}$ in Theorem 36.6 and (36.32), there exist constants $0 < c_\varphi \leq C_\varphi$ with

$$c_\varphi \epsilon \leq \mathbb{E}_{\mu_{nB^K,\gamma}} \mathcal{I}_{\gamma,\varphi}(\mathcal{H}^K) \leq C_\varphi \epsilon \tag{36.33}$$

for all K and all sufficiently small γ. For a general φ and the fixed radial cutoff χ, let $b = m(\varphi)/m(\chi(|\cdot|))$. We apply (36.32) to $\varphi - b\chi(|\cdot|)$, using $\mathcal{I}_{\gamma,\varphi - b\chi(|\cdot|)} = \mathcal{I}_{\gamma,\varphi} - b\mathcal{I}_{\gamma,\chi(|\cdot|)}$. The leading term vanishes, and the expectation of this observable is $o(\epsilon)$ uniformly in K. Since (36.33) gives a lower bound $c\epsilon$ for the denominator, uniformly in K, the ratio of the expectations under the Wilson measure tends to b as $\gamma \downarrow 0$, uniformly in K.

Step 4: passage to the continuum measure. We fix γ and identify the limit as $K \to \infty$. For small γ, the support of the observable lies strictly inside the logarithmic chart, and $\mathcal{I}_{\gamma,\varphi}$, extended by zero, is a continuous function of the triple. It is invariant under simultaneous conjugation: the logarithm is conjugation covariant in its chart, φ is invariant, and a fixed conjugation-invariant neighborhood of the identity contained in $\mathcal{V}$ contains the shrinking support for small γ. This holds even if $\mathcal{V}$ itself is not conjugation invariant. By Lemma 5.6, $\mathcal{I}_{\gamma,\varphi}$ is therefore a continuous function of the normalized traces of H_1, H_2, H_3, H_1H_2, H_1H_3, H_2H_3, and $H_1H_2H_3$, and convergence in law of these seven traces implies convergence of the expectation of $\mathcal{I}_{\gamma,\varphi}$. The seven traces are characters, divided by two, of the holonomies of loops obtained by concatenating the three based coordinate cycles, observed at the same time. These loops and their lattice versions are covered by Theorem 29.25.

To apply that theorem at a given γ, we may have to drop finitely many terms of the sequence $n_* B^K$. By Corollary 29.26, the shortened sequence has the same tail and hence the same limit of the joint law of the flowed loops at fixed coupling, and neither the comparison side in (36.32) nor its constants change.

We now let $K \to \infty$ at fixed γ. The bounds (36.33) pass to the limit, and the expectation of the observable of $\varphi - b\chi(|\cdot|)$ remains $o(\epsilon)$, since that bound was uniform in K. Dividing

by the limiting denominator and then letting $\gamma \downarrow 0$, we obtain the ratio limit and the two-sided bounds for λ_γ.

Step 5: the dilation statistic and the variances. The function W_χ is continuous, compactly supported, and invariant, and $m(W_\chi) = 0$ by Lemma 36.4. Applying the ratio limit to W_χ, we obtain $\mathcal{S}_{\gamma,\lambda_\gamma}(\chi) \to 0$.

For the variances, let $m_i = m(\chi_i(|\cdot|)^2) > 0$ and $b = m_1/m_2$. Since $A_i^2 = \mathcal{I}_{\gamma,\chi_i(|\cdot|)^2}$, (36.32) applied to $\chi_1(|\cdot|)^2 - b\chi_2(|\cdot|)^2$ shows that $\mathbb{E}A_1^2 - b\mathbb{E}A_2^2 = o(\epsilon)$ under the Wilson measure, uniformly in K. By the same formula, each mean $\mathbb{E}A_i$ is $O(\epsilon)$, and subtracting the squared means changes this difference by $O(\epsilon^2)$. Further, since $\mathbb{E}A_2^2 \geq c\epsilon m_2$ and $(\mathbb{E}A_2)^2 = O(\epsilon^2)$, we have $\operatorname{Var} A_2 \geq c'\epsilon$ for small γ, uniformly in K. We conclude that $\operatorname{Var} A_1 / \operatorname{Var} A_2 - b \to 0$ uniformly in K. At fixed γ, the first and second moments pass to λ_γ by the identification of Step 4, and the ratio of the variances tends to b. □

36.7 Rates, central triples, and several times

This section strengthens Theorem 36.7 in three directions: a rate $\gamma^{1/4}$ for Lipschitz tests, the extension to the eight central triples, and joint statements at finitely many flow times.

Definition 36.8. For a bounded Borel function φ on $\mathbb{R}^9$ with compact support we write $m(\varphi) = \int_{\mathbb{R}^9} \varphi(Y) e^{-Q(Y)}\, d^9Y$. For a bounded function f on $(\mathbb{R}^9)^\ell$, $\ell \geq 1$, we write

$$\|f\|_{\mathrm{BL}} = \|f\|_\infty + \operatorname{Lip} f, \qquad \|(Y^{(1)}, \dots, Y^{(\ell)})\|_{\max} = \max_{1 \leq j \leq \ell} |Y^{(j)}|,$$

where $\operatorname{Lip} f$ is the global Lipschitz constant with respect to the metric of $\|\cdot\|_{\max}$; for $\ell = 1$ this is the Euclidean metric on $\mathbb{R}^9$. We write B_R for the closed Euclidean ball of radius R about the origin in $\mathbb{R}^9$. The coupling-dependent scale is always written r_γ; the radius r in the domains B_r and D_r of configurations keeps its fixed meaning from Definition 36.1.

The norm $\|f\|_{\mathrm{BL}}$ is a sum. Its unit ball is contained in the set of functions with $\|f\|_\infty \leq 1$ and $\operatorname{Lip} f \leq 1$ that defines the bounded-Lipschitz distance d_{BL} used in Lemma 28.9, and it contains that set scaled by $1/2$. The distance dual to $\|f\|_{\mathrm{BL}}$ is therefore equivalent to d_{BL}, within a factor two, but not identical to it.

Rates for compactly supported Lipschitz tests

The next lemma is the quantitative version of Step 1 of the proof of Theorem 36.7. It uses the comparison of holonomies conditional on the coarse configuration, Theorem 34.11. For a coarse configuration v represented in B_r, let $\mathbb{Q}_v^K$ be the conditional law of the normalized fluctuation variables of all K renormalization group steps given $V = v$, that is, the product of the conditional fluctuation kernels of Lemma 15.10. By that lemma, ν disintegrates as $\nu(d\,\cdot) = \int \mathbb{Q}_v^K(d\,\cdot)\, \widehat{\nu}(dv)$.

Lemma 36.9. *For every $R < \infty$ there exist $C_R, \gamma_R > 0$, independent of K and of the test, such that every globally Lipschitz function $\varphi : \mathbb{R}^9 \to \mathbb{R}$ supported in B_R satisfies*

$$\left|\mathbb{E}_\nu \mathcal{I}_{\gamma,\varphi}(\mathcal{H}^K) - \mathbb{E}_{\widehat{\nu}} \mathcal{I}_{\gamma,\varphi}(\mathcal{H}_0^K)\right| \le C_R \|\varphi\|_{\mathrm{BL}} r_\gamma^2 \tag{36.34}$$

for all K and $0 < \gamma \le \gamma_R$.

The proof is the mechanism described in Section 36.1: an event determined by V of probability $O(r_\gamma)$, a conditional matrix difference $O(r_\gamma^2)$, and a loss r_γ^{-1} from the rescaling of the logarithm.

Proof. Let $d = \min(1, \max_i \|\mathcal{H}_i^K - \mathcal{H}_{0,i}^K(v)\|_{\mathrm{op}})$. By Theorem 34.11, applied with $\tau = T = \theta L^2$ and $p = 1, 2$, we have, for every coarse configuration v in the support of $\widehat{\nu}$ and every K,

$$\mathbb{E}_{\mathbb{Q}_v^K} d \le C r_\gamma^2, \qquad \mathbb{E}_{\mathbb{Q}_v^K} d^2 \le C r_\gamma^4,$$

for γ below the upper bound on the coupling in that theorem. On the event $\{d \le r_\gamma\}$, with $r_\gamma < 1$, if either observable is nonzero, then both triples lie in a fixed compact subset of the logarithmic chart, and their rescaled logarithms differ by at most Cd/r_γ. In this case, the zero-fluctuation triple also lies in the event

$$E_{R'} = \{\mathcal{H}_0^K(v) \in \mathcal{V},\ |\mathrm{Log}\, \mathcal{H}_0^K(v)| \le R' r_\gamma\},$$

where R' and the upper bound on γ depend only on R and the chart. The event $E_{R'}$ is determined by v. Theorem 36.6, applied to the indicator function of $B_{R'}$, implies that $\widehat{\nu}(E_{R'}) \le C_R r_\gamma$. By the disintegration of Lemma 15.10,

$$\mathbb{E}_\nu[d \mathbf{1}_{E_{R'}}] = \int_{E_{R'}} \mathbb{E}_{\mathbb{Q}_v^K} d \, \widehat{\nu}(dv) \le C r_\gamma^2 \widehat{\nu}(E_{R'}) \le C_R r_\gamma^3.$$

The contribution of $\{d \le r_\gamma\}$ to the left side of (36.34) is therefore at most $C \,\mathrm{Lip}\, \varphi \, r_\gamma^{-1} \mathbb{E}_\nu[d \mathbf{1}_{E_{R'}}] \le C_R (\mathrm{Lip}\, \varphi) r_\gamma^2$. On $\{d > r_\gamma\}$ we use the bound $2\|\varphi\|_\infty$ and

$$\nu(d > r_\gamma) \le r_\gamma^{-2} \mathbb{E}_\nu d^2 = r_\gamma^{-2} \int \mathbb{E}_{\mathbb{Q}_v^K} d^2 \, \widehat{\nu}(dv) \le C r_\gamma^2.$$

This proves (36.34). □

Theorem 36.10. *Fix the data and the measures λ_γ of Theorem 36.7, and a radial cutoff χ, and set $b_\chi = \int \chi(|Y|)\, dm_{\mathrm{Q}}(Y) > 0$. For every $R < \infty$ there exist $C_{R,\chi}, \gamma_{R,\chi} > 0$ such that every globally Lipschitz function φ supported in B_R and invariant under simultaneous conjugation satisfies*

$$\left|\frac{\mathbb{E}_{\lambda_\gamma} \mathcal{I}_{\gamma,\varphi}}{\mathbb{E}_{\lambda_\gamma} \mathcal{I}_{\gamma,\chi(|\cdot|)}} - \frac{\int \varphi \, dm_{\mathrm{Q}}}{b_\chi}\right| \le C_{R,\chi} \big(\|\varphi\|_\infty + \mathrm{Lip}\, \varphi\big) \gamma^{1/4} \qquad (0 < \gamma \le \gamma_{R,\chi}),$$

and the denominator is at least $c_\chi r_\gamma$. The same bounds hold for the expectations of $\mathcal{I}_{\gamma,\varphi}(\mathcal{H}^K)$ and $\mathcal{I}_{\gamma,\chi(|\cdot|)}(\mathcal{H}^K)$ under the Wilson measures $\mu_{nB^K,\gamma}$, uniformly in K. In particular $|\mathcal{S}_{\gamma,\lambda_\gamma}(\chi)| \le C_\chi \gamma^{1/4}$. For any two fixed smooth compactly supported functions χ_1, χ_2 on $[0,\infty)$ that are not identically zero, the ratio of variances in Theorem 36.7 differs from $m(\chi_1(|\cdot|)^2)/m(\chi_2(|\cdot|)^2)$ by at most $C_{\chi_1,\chi_2}\gamma^{1/4}$, and the denominator $\operatorname{Var} A_2$ *is at least $c_{\chi_2} r_\gamma$; this holds for λ_γ and, uniformly in K, for $\mu_{nB^K,\gamma}$.*

Proof. We write $m(\varphi) = \int \varphi \, dm_Q$ and, in this proof only,

$$A_K(\varphi) = \mathbb{E}_{\mu_{nB^K,\gamma}} \mathcal{I}_{\gamma,\varphi}(\mathcal{H}^K).$$

We combine Lemma 36.9, Theorem 36.6, and the bound of Corollary 23.11 with the exponent $q = 1$. Since $\gamma = r_\gamma^4$, the error from removing the conditioning is at most $2\|\varphi\|_\infty C_{n,1}\gamma = 2C_{n,1}\|\varphi\|_\infty r_\gamma^4$, and we obtain

$$A_K(\varphi) = r_\gamma \kappa_{K,\gamma} m(\varphi) + O_R\big(\|\varphi\|_{\mathrm{BL}} r_\gamma^2\big). \tag{36.35}$$

Applying (36.35) to $\chi(|\cdot|)$, which is globally Lipschitz, and using $\kappa_{K,\gamma} \ge c_n$, we find $A_K(\chi(|\cdot|)) \ge c_\chi r_\gamma$ for small γ. When we subtract $m(\varphi)A_K(\chi(|\cdot|))/b_\chi$ from $A_K(\varphi)$, the leading terms cancel at finite K. Since $|m(\varphi)| \le m(\mathbf{1}_{B_R})\|\varphi\|_\infty$, the difference is $O_{R,\chi}(\|\varphi\|_{\mathrm{BL}} r_\gamma^2)$. Dividing by $A_K(\chi(|\cdot|)) \ge c_\chi r_\gamma$ proves the assertion at finite cutoff, with one upper bound on γ for the whole class of tests.

At fixed γ, these observables are continuous functions of the triple, supported strictly inside the logarithmic chart, and invariant under simultaneous conjugation. By Lemma 5.6, they factor continuously through the seven traces, which are traces of holonomies of concatenations of the three based cycles. We apply Theorem 29.25 and Corollary 29.26 to the combination $A_K(\varphi) - m(\varphi)A_K(\chi(|\cdot|))/b_\chi$ and to the denominator; the comparison side remains valid on the sequence $n_* B^K$, as in Step 4 of the proof of Theorem 36.7. Letting $K \to \infty$ at fixed γ proves the assertion for λ_γ.

The function W_χ is globally Lipschitz with a fixed support, and $m(W_\chi) = 0$ by Lemma 36.4. The ratio bound then gives the bound on the dilation statistic. For the variances, the argument is the same before and after the limit $K \to \infty$. The two means are $O(r_\gamma)$, and their squares are $O(r_\gamma^2)$. Applying (36.35) to the Lipschitz function $\chi_1(|\cdot|)^2 - b\chi_2(|\cdot|)^2$, we obtain

$$\mathbb{E}A_1^2 - b\mathbb{E}A_2^2 = O(r_\gamma^2), \qquad b = \frac{m(\chi_1(|\cdot|)^2)}{m(\chi_2(|\cdot|)^2)} > 0.$$

The second moment $\mathbb{E}A_2^2$ is at least $c r_\gamma$ by (36.35) and the lower bound on $\kappa_{K,\gamma}$. Subtracting the squared mean preserves a lower bound $c' r_\gamma$ for small γ. Subtracting the squared means in the combination above and dividing by this lower bound proves the rate for the variances. □

The eight central triples

The next lemma is the center symmetry of the periodic lattice Wilson measure [149], with a verification that it commutes with the Wilson flow. Here $\mu_{N,\gamma}$ is the Wilson measure of Definition 4.1, and the winding number $w_i(\ell) \in \mathbb{Z}$ of a closed lattice loop ℓ is the signed number of its crossings of the hyperplane $\{x_i = N - 1/2\}$ in lattice units.

Lemma 36.11. *Let $z = (z_1, z_2, z_3) \in \{I, -I\}^3$. There exists a central link configuration c^z, with all plaquette products equal to I and coordinate-cycle products equal to z_i, such that the map $\Gamma_z U = (c^z_e U_e)_e$ preserves $\mu_{N,\gamma}$ and commutes with the Wilson flow at every time. For every based closed lattice loop ℓ,*

$$\mathrm{Hol}_\ell\big(\Psi_t^{(N)}(\Gamma_z U)\big) = \Big(\prod_{i=1}^{3} z_i^{w_i(\ell)}\Big)\,\mathrm{Hol}_\ell\big(\Psi_t^{(N)} U\big).$$

In particular, for any finite list of times, the vector of coordinate-cycle holonomies of the flowed configuration has the same law under $\mu_{N,\gamma}$ after the i-th holonomy is multiplied by z_i at every listed time. These are exact identities for every $N \geq 4$ and $\gamma > 0$; they do not concern the small-field event.

Proof. We represent the vertices by $x \in \{0, \dots, N-1\}^3$ and define, on the positive link from x in direction i,

$$c^z_{x,i} = \begin{cases} z_i, & x_i = N-1, \\ I, & x_i \neq N-1, \end{cases} \qquad c^z_{\bar e} = (c^z_e)^{-1}.$$

In an (i,j) plaquette, the two links in direction i carry the same factor, because a displacement in direction j does not change x_i, and similarly for the two links in direction j. Since the factors are central, they cancel against the oppositely oriented factors. Hence every plaquette product of c^z is I, including the plaquettes that cross a periodic seam. A positive coordinate cycle in direction i crosses the seam in its direction once, and its product is z_i. For a general closed loop, the signed number of crossings of the i-th seam is $w_i(\ell)$. Since the factors are central, they can be moved past every link matrix, and the product of all factors is $\prod_i z_i^{w_i(\ell)}$.

The map Γ_z is a smooth involution of the configuration space, and the product Haar measure is invariant under it, since Haar measure is invariant under multiplication by a fixed element (Lemma 5.1). Every plaquette matrix is unchanged, and so are every $q(U_p)$, the Wilson action, and the normalization constant. This proves that $\mu_{N,\gamma}$ is invariant.

We use the product of the bi-invariant Riemannian metrics, as in the definition of the Wilson flow. Since multiplication by a fixed central element is an isometry, so is Γ_z. Let $S(U) = \sum_p q(U_p)$, so that $S \circ \Gamma_z = S$. For every tangent vector v at U,

$$\langle \nabla S(\Gamma_z U), D\Gamma_z v\rangle_{\Gamma_z U} = dS_{\Gamma_z U}(D\Gamma_z v) = dS_U(v) = \langle D\Gamma_z \nabla S(U), D\Gamma_z v\rangle_{\Gamma_z U},$$

which implies $\nabla S(\Gamma_z U) = D\Gamma_z \nabla S(U)$. The smooth vector field $-\nabla S$ on the compact configuration space has a unique global flow, and Γ_z maps its trajectories to trajectories. This proves commutation at every lattice time, and hence at every physical time $4t/a_N^2$. The identity for the holonomies follows from the identity for the products of the factors. Integrating any bounded Borel function of the finite vector of holonomies, we obtain the identity in law. □

Theorem 36.12. *Choose $\mathcal{V}$ in Definition 36.1 invariant under simultaneous conjugation. For $z \in \{I, -I\}^3$ let $\mathcal{V}_z = z\mathcal{V}$, and set*

$$\mathcal{I}^z_{\gamma,\varphi}(H) = \begin{cases} \varphi\big((\mathrm{Log}(z_i^{-1} H_i))_{i=1}^3 / r_\gamma\big), & H \in \mathcal{V}_z, \\ 0, & H \notin \mathcal{V}_z, \end{cases}$$

so that $\mathcal{I}^{(I,I,I)}_{\gamma,\varphi} = \mathcal{I}_{\gamma,\varphi}$. For every $\gamma > 0$, every positive observation time, and every bounded Borel compactly supported test φ invariant under simultaneous conjugation,

$$\mathbb{E}_{\lambda_\gamma} \mathcal{I}^z_{\gamma,\varphi} = \mathbb{E}_{\lambda_\gamma} \mathcal{I}_{\gamma,\varphi}.$$

The corresponding identity holds under $\mu_{nB^K,\gamma}$ for the flowed lattice holonomies at every finite K, for every bounded Borel compactly supported test. Consequently the ratio limits, the two-sided bounds, the limits of the ratios of variances, and the limit of the dilation statistic in Theorem 36.7, and the rates of Theorem 36.10, hold at each of the eight central triples, with expectations equal to those at (I, I, I) and with constants and ceilings on γ independent of z.

Proof. Let H denote the triple of flowed coordinate-cycle holonomies. At finite cutoff, Lemma 36.11 shows that H and $z^{-1}H$ have the same law. By definition, $\mathcal{I}^z_{\gamma,\varphi}(H) = \mathcal{I}_{\gamma,\varphi}(z^{-1}H)$ pointwise, including on the complements of the charts, since $H \in z\mathcal{V}$ if and only if $z^{-1}H \in \mathcal{V}$. This proves the identity at finite cutoff, without any assumption of regularity or invariance on the test.

For the continuum measure, let F be any continuous function on $\mathrm{SU}(2)^3$ invariant under simultaneous conjugation. Since z is central, $F(z^{-1}\cdot)$ is also continuous and invariant, and both factor continuously through the seven traces by Lemma 5.6. Passing the identity $\mathbb{E}F(H) = \mathbb{E}F(z^{-1}H)$ at finite cutoff to the limit at every fixed $\gamma > 0$ by Theorems 29.28 and 30.6, we obtain $\mathbb{E}_{\lambda_\gamma} F(H) = \mathbb{E}_{\lambda_\gamma} F(z^{-1}H)$ for every such F. By the same lemma, the compact quotient of $\mathrm{SU}(2)^3$ by simultaneous conjugation is homeomorphic to the image of the seven traces. The law of the conjugacy class of H under λ_γ, a Borel probability on this compact metric space, is therefore invariant under the continuous map induced by multiplication by z^{-1}. Indeed, continuous functions determine Borel probabilities on a metric space. For a closed set C, the continuous functions $\max(0, 1 - j\,\mathrm{dist}(\cdot, C))$ decrease to $\mathbf{1}_C$, so the two probabilities agree on closed sets, and hence on all Borel sets by the monotone class theorem. The identity then extends to bounded Borel functions on

the quotient. Since $\mathcal{V}$ is invariant, the logarithm is conjugation covariant on it, and φ is invariant, the observable $\mathcal{I}^z_{\gamma,\varphi}$ is a bounded Borel function on the quotient. This proves the identity for the continuum measure, even if φ is not continuous.

Applying the identity to each numerator and denominator in Theorems 36.7 and 36.10, and to the squares of the observables for the variances, we obtain the remaining assertions. Since all eight expectations are equal, so are the constants. □

Joint asymptotics at finitely many times

We now observe the holonomies at finitely many flow times. The observables are invariant under an independent conjugation at each time; no relation between the gauge frames at different times is used or asserted.

Definition 36.13. Fix $\ell \geq 1$, positive times $t_j = \theta_j L^2$ for $1 \leq j \leq \ell$, and the same three based coordinate cycles at each time, before varying γ. Choose the parameters, the side n, and the margins as in Definition 36.1, so that the finitely many lower bounds required at each of the times t_j hold. Write $H^{(j)}$ for the triple of cycle holonomies at time t_j. Let $\mathcal{V}$ be a neighborhood of (I, I, I) as in Definition 36.1, invariant under simultaneous conjugation and small enough for all listed times. For $\Phi \in C_c((\mathbb{R}^9)^\ell; \mathbb{R})$ define

$$\mathcal{J}_{\gamma,\Phi}(H^{(1)}, \dots, H^{(\ell)}) = \begin{cases} \Phi\big(\operatorname{Log} H^{(1)}/r_\gamma, \dots, \operatorname{Log} H^{(\ell)}/r_\gamma\big), & H^{(j)} \in \mathcal{V} \text{ for every } j, \\ 0, & \text{otherwise.} \end{cases}$$

The class of tests consists of the functions Φ that are invariant under independent conjugations at the different times:

$$\Phi\big(\operatorname{Ad}(k_1)Y^{(1)}, \dots, \operatorname{Ad}(k_\ell)Y^{(\ell)}\big) = \Phi\big(Y^{(1)}, \dots, Y^{(\ell)}\big) \qquad \text{for all } k_1, \dots, k_\ell \in \mathrm{SU}(2),$$

where each $\operatorname{Ad}(k_j)$ acts simultaneously on the three components of $Y^{(j)}$. Put $\Phi_\Delta(Y) = \Phi(Y, \dots, Y)$ and $m_\Delta(\Phi) = \int \Phi_\Delta \, dm_Q$. We write $\mathcal{H}^K_t$ and $\mathcal{H}^K_{0,t}(V)$ for the triples of Definition 36.1 observed at time t.

The following lemma localizes the transverse coordinates on the event that the flowed zero-fluctuation holonomies at the first time are in a window of size r_γ.

Lemma 36.14. *Use the stopped measure $\widehat{\nu}$, the coordinates $V(X, s)$, and the zero-fluctuation holonomies at the first time t_1 of Definition 36.13. Set*

$$E_R = \big\{\mathcal{H}^K_{0,t_1} \in \mathcal{V},\ |\operatorname{Log} \mathcal{H}^K_{0,t_1}| \leq R r_\gamma\big\}, \qquad D = d_{\mathrm{st}}, \qquad g^2 = \gamma/n.$$

There is a fixed neighborhood $\mathcal{U}$ of the trivial based orbit, contained in the central coordinates, such that, for every fixed $R < \infty$, all sufficiently small γ, and every K,

$$\widehat{\nu}(E_R \setminus \mathcal{U}) \leq C g^{-(D+4)} e^{-c/g^2}, \qquad \mathbb{E}_{\widehat{\nu}}\big[\mathbf{1}_{E_R \cap \mathcal{U}} |s|^a\big] \leq C_{R,a} r_\gamma g^a \quad (a = 0, 1, 2).$$

Further, $\widehat{\nu}(\mathcal{U} \cap \{|s| > r_\gamma\}) \leq C g^{-4} e^{-c r_\gamma^2/g^2}$.

Proof. We choose $\mathcal{U}$ with closure strictly inside the chart of Theorem 33.8 and inside the domains of the deterministic results at all listed times. By the localization statement of Theorem 36.3, applied with θ_1 in place of θ, there exists a fixed $\delta > 0$ such that a coarse configuration within distance δ of $\mathcal{F}_n$ whose holonomies at time t_1 have cycle radius at most δ lies in $\mathcal{U}$. For $Rr_\gamma < \delta$, every point of $E_R \setminus \mathcal{U}$ therefore lies outside the fixed neighborhood $\{d(V, \mathcal{F}_n) \le \delta\}$. There $E_0 \ge c_{n,\delta} > 0$, by compactness of the configuration space at side n and $E_0^{-1}(0) = \mathcal{F}_n$, which follows from the classification of flat configurations in Lemma 14.9. The first estimate follows as in (36.19). We use properties (P1) and (P3) in Section 33.2, namely the lower bound $E_{JK,\mathrm{sat}} \ge \kappa E_0$ on D_r and the bound on the centered effective interaction, together with the normalization of H_n and the lower bound on the normalization constant in Theorem 33.10.

On $\mathcal{U}$, Theorem 36.3 at time t_1 gives $|\operatorname{Log} \mathcal{H}^K_{0,t_1}| \ge (3/4)|X| - C|s|$, which implies

$$|X| \le C(Rr_\gamma + |s|) \qquad \text{on } E_R \cap \mathcal{U}.$$

The density factor $e^{-\overline{R}_{K,\gamma}} J_n$ is bounded above, and $F_K(X,s) \ge f_K(X) + c|s|^2 \ge c|s|^2$ by Theorem 33.8. For fixed s, the possible values of X form a set of volume at most $C_R(r_\gamma + |s|)^9$. Substituting $s = gz$, we find

$$\begin{aligned}\mathbb{E}_{\widehat{v}}\big[\mathbf{1}_{E_R \cap \mathcal{U}} |s|^a\big] &\le \frac{C_R}{\widehat{Z}} \int_{\mathbb{R}^D} |s|^a (r_\gamma + |s|)^9 e^{-c|s|^2/g^2}\, ds \\ &= \frac{C_R g^{D+a} r_\gamma^9}{\widehat{Z}} \int_{\mathbb{R}^D} |z|^a \Big(1 + \frac{g}{r_\gamma}|z|\Big)^9 e^{-c|z|^2}\, dz.\end{aligned}$$

Since $g/r_\gamma = r_\gamma/\sqrt{n} \le 1$, the Gaussian integral is bounded in the fixed dimension D. Since $\widehat{Z} \ge c g^{D+4}$ and $r_\gamma^9 g^{-4} = n^2 r_\gamma$, the right side is at most $C_{R,a} r_\gamma g^a$. The conjugation at the basepoint has not been divided out: the nine-dimensional volume in X and the Haar density are kept.

For the last estimate there is no restriction on the output, and the volume in X is bounded by a fixed constant. We split the Gaussian factor into two factors, bound one of them on $\{|s| > r_\gamma\}$ by $e^{-cr_\gamma^2/(2g^2)}$, and integrate the other over $\mathbb{R}^D$. After division by $\widehat{Z} \ge c g^{D+4}$, we obtain the bound $C g^{-4} e^{-c' r_\gamma^2/g^2}$, and renaming c' proves the claim. Since $g = r_\gamma^2/\sqrt{n}$, the first and last bounds are smaller than every fixed power of r_γ. □

Theorem 36.15. *Use Definition 36.13, and fix a radial cutoff χ. For every continuous compactly supported test Φ in the class of Definition 36.13,*

$$\lim_{\gamma \downarrow 0} \frac{\mathbb{E}_{\lambda_\gamma} \mathcal{J}_{\gamma,\Phi}}{\mathbb{E}_{\lambda_\gamma} \mathcal{I}_{\gamma,\chi(|\cdot|)}(H^{(1)})} = \frac{\int_{\mathbb{R}^9} \Phi(Y, \dots, Y) e^{-Q(Y)}\, dY}{\int_{\mathbb{R}^9} \chi(|Y|) e^{-Q(Y)}\, dY},$$

and the denominator is at least $c_\chi r_\gamma$ for small γ. If $\Phi \ge 0$ and $m_\Delta(\Phi) > 0$, the numerator is bounded above and below by positive multiples of r_γ; if $m_\Delta(\Phi) = 0$, the numerator is $o(r_\gamma)$.

More precisely, with the factor $\kappa_{K,\gamma}$ of Theorem 36.6,

$$\mathbb{E}_{\mu_{nB^K,\gamma}}\mathcal{J}_{\gamma,\Phi}(\mathcal{H}^K_{t_1},\dots,\mathcal{H}^K_{t_\ell}) = r_\gamma\kappa_{K,\gamma}\{m_\Delta(\Phi)+\delta^\Phi_{K,\gamma}\},\qquad \sup_K|\delta^\Phi_{K,\gamma}|\longrightarrow 0\quad(\gamma\downarrow 0),$$

and the expectation of $\mathcal{J}_{\gamma,\Phi}(\mathcal{H}^K_{0,t_1},\dots,\mathcal{H}^K_{0,t_\ell})$ under $\widehat{\nu}$ has the same expansion with the same factor. For every $R<\infty$ there exist $C_{R,\chi,\boldsymbol{t}}$ and $\gamma_{R,\chi,\boldsymbol{t}}>0$ such that, for every globally Lipschitz test Φ in the class with $\operatorname{supp}\Phi\subset(B_R)^\ell$ *and $0<\gamma\le\gamma_{R,\chi,\boldsymbol{t}}$, the difference between the ratio above (for λ_γ, or for $\mu_{nB^K,\gamma}$ at any finite K) and $m_\Delta(\Phi)/m(\chi(|\cdot|))$ is at most $C_{R,\chi,\boldsymbol{t}}(\|\Phi\|_\infty+\operatorname{Lip}\Phi)\gamma^{1/4}$. Here* Lip *refers to the metric of $\|\cdot\|_{\max}$, and $\boldsymbol{t}=(t_1,\dots,t_\ell)$.*

A nonnegative test that is not identically zero but vanishes near the diagonal has $m_\Delta(\Phi)=0$, and its numerator is $o(r_\gamma)$: to leading order, the rescaled logarithms at the different times coincide. The diagonal is described through tests that are invariant under independent conjugations at the different times. Uniform statements on a time interval are proved in Theorem 36.18. The constants depend additionally on the list of times, on ℓ, R, and χ.

Proof. Step 1 reduces the joint observable of the zero-fluctuation holonomies to the single-time observable of Φ_Δ, Step 2 compares with the holonomies of the configuration, and Steps 3–5 treat Lipschitz tests, continuous tests, and the continuum measure. All estimates use the same coarse configuration V and the same reconstruction.

Step 1: the zero-fluctuation holonomies near the diagonal. For each listed time we apply Theorem 35.9 with $m=0$. By its bound in $C^{1,1}$ at fixed time and its identity on flat configurations, we have, on a common smaller central neighborhood,

$$Z_j(X,s)=\operatorname{Log}\mathcal{H}^K_{0,t_j}(V(X,s))=X+O_{\boldsymbol{t}}(|X|^2+|s|),\qquad \|D_XZ_j-I\|\le C_{\boldsymbol{t}}(|X|+|s|).\tag{36.36}$$

Indeed, each of the nine coordinate directions in X consists of commuting triples. The identity on flat configurations therefore gives $Z_j(ue_a,0)=ue_a$, and hence $D_XZ_j(0,0)=I$. Integrating the Lipschitz bound on the derivative along $v\mapsto(vX,0)$, and then using the bounded derivative in s, we obtain (36.36). This is the statement of Theorem 36.3 at each listed time. We intersect finitely many domains and take the maximum of finitely many constants.

Let Φ be globally Lipschitz with support in $(B_R)^\ell$. We compare $\mathcal{J}_{\gamma,\Phi}(\mathcal{H}^K_{0,t_1},\dots,\mathcal{H}^K_{0,t_\ell})$ with $\mathcal{I}_{\gamma,\Phi_\Delta}(\mathcal{H}^K_{0,t_1})$. If either is nonzero, then the event E_R of Lemma 36.14 holds. Outside the fixed neighborhood $\mathcal{U}$ of that lemma its probability is smaller than every power of r_γ, and inside $\mathcal{U}$ we discard $\{|s|>r_\gamma\}$, again at a cost smaller than every power of r_γ. On the remaining set, the lower bound for Z_1 implies $|X|\le C_Rr_\gamma$. By (36.36), all outputs lie in $\mathcal{V}$ for small γ, and

$$\max_j\frac{|Z_j-Z_1|}{r_\gamma}\le C_R\Big(r_\gamma+\frac{|s|}{r_\gamma}\Big).$$

On this set, both observables are given by their formulas in coordinates, $\Phi(Z_1/r_\gamma,\dots,Z_\ell/r_\gamma)$ and $\Phi(Z_1/r_\gamma,\dots,Z_1/r_\gamma)$, including when one of them vanishes. Lemma 36.14 gives, for any fixed $A \geq 2$,

$$\begin{aligned}
&\Big|\mathbb{E}_{\widehat{\nu}}\mathcal{J}_{\gamma,\Phi}(\mathcal{H}^K_{0,t_1},\dots,\mathcal{H}^K_{0,t_\ell}) - \mathbb{E}_{\widehat{\nu}}\mathcal{I}_{\gamma,\Phi_\Delta}(\mathcal{H}^K_{0,t_1})\Big| \\
&\qquad \leq C_R(\operatorname{Lip}\Phi)\Big\{r_\gamma\widehat{\nu}(E_R\cap\mathcal{U}) + r_\gamma^{-1}\mathbb{E}_{\widehat{\nu}}\big[|s|\mathbf{1}_{E_R\cap\mathcal{U}}\big]\Big\} + O_A\big(\|\Phi\|_\infty r_\gamma^A\big) \\
&\qquad \leq C_R\|\Phi\|_{\mathrm{BL}} r_\gamma^2,
\end{aligned} \tag{36.37}$$

where in the last step we used $g = r_\gamma^2/\sqrt{n}$. The diagonal test Φ_Δ is globally Lipschitz, supported in B_R, and invariant under simultaneous conjugation. Theorem 36.6 at time t_1 therefore implies that

$$\mathbb{E}_{\widehat{\nu}}\mathcal{J}_{\gamma,\Phi}(\mathcal{H}^K_{0,t_1},\dots,\mathcal{H}^K_{0,t_\ell}) = r_\gamma\kappa_{K,\gamma}m_\Delta(\Phi) + O_R\big(\|\Phi\|_{\mathrm{BL}}r_\gamma^2\big). \tag{36.38}$$

The factor is the same $\kappa_{K,\gamma}$ as at a single time, and no factor depending on the times appears.

Step 2: comparison at all listed times. Let $[\tau,T]$ be an interval containing all listed times, and let

$$d = \min\Big(1,\ \sup_{\tau\leq t\leq T}\max_i \|\mathcal{H}^K_{t,i} - \mathcal{H}^K_{0,t,i}(v)\|_{\mathrm{op}}\Big).$$

By Theorem 34.11 with $p = 1,2$, we have $\mathbb{E}_{\mathbb{Q}^K_v} d \leq Cr_\gamma^2$ and $\mathbb{E}_{\mathbb{Q}^K_v} d^2 \leq Cr_\gamma^4$ for every coarse configuration v and every K, where $\mathbb{Q}^K_v$ is the conditional law of Lemma 36.9. On $\{d \leq r_\gamma\}$, if either joint observable is nonzero, then all flowed holonomies of the configuration and of the zero-fluctuation reconstruction at the listed times lie in a fixed compact subset of the logarithmic chart, and their rescaled logarithms differ by at most Cd/r_γ in the metric of $\|\cdot\|_{\max}$. In this case, the zero-fluctuation holonomies at time t_1 also lie in the enlarged window $E_{R'}$ of Lemma 36.14, which is determined by v and has probability $O_R(r_\gamma)$ by Theorem 36.6. The argument of Lemma 36.9, with the metric of $\|\cdot\|_{\max}$, gives

$$\Big|\mathbb{E}_\nu\mathcal{J}_{\gamma,\Phi}(\mathcal{H}^K_{t_1},\dots,\mathcal{H}^K_{t_\ell}) - \mathbb{E}_{\widehat{\nu}}\mathcal{J}_{\gamma,\Phi}(\mathcal{H}^K_{0,t_1},\dots,\mathcal{H}^K_{0,t_\ell})\Big| \leq C_{R,\boldsymbol{t}}\|\Phi\|_{\mathrm{BL}}r_\gamma^2. \tag{36.39}$$

The same argument at the time t_1 alone, applied to a Lipschitz function equal to one on B_{R+1}, shows that the event that $\mathcal{H}^K_{t_1}$ lies in $\mathcal{V}$ and its rescaled logarithm lies in B_{R+1} has ν-probability $O_R(r_\gamma)$.

Step 3: Lipschitz tests at finite cutoff. We remove the conditioning with Corollary 23.11 at $q = 1$, which costs at most $2\|\Phi\|_\infty C_{n,1}\gamma = 2C_{n,1}\|\Phi\|_\infty r_\gamma^4$. Combining this with (36.38) and (36.39), we obtain

$$\Big|\mathbb{E}_{\mu_{nB^K,\gamma}}\mathcal{J}_{\gamma,\Phi}(\mathcal{H}^K_{t_1},\dots,\mathcal{H}^K_{t_\ell}) - r_\gamma\kappa_{K,\gamma}m_\Delta(\Phi)\Big| \leq C_{R,\boldsymbol{t}}\|\Phi\|_{\mathrm{BL}}r_\gamma^2. \tag{36.40}$$

For the denominator, (36.35) at time t_1 holds with the same factor $\kappa_{K,\gamma}$, and the denominator is at least $c_\chi r_\gamma$. When we subtract $m_\Delta(\Phi)/m(\chi(|\cdot|))$ times the denominator, the factor $\kappa_{K,\gamma}$ cancels at finite K. Dividing by $c_\chi r_\gamma$, we obtain the rate $\gamma^{1/4} = r_\gamma$ for the ratio at finite cutoff, with one upper bound on γ for the whole class of tests supported in $(B_R)^\ell$.

Step 4: continuous tests. Let Φ be continuous, compactly supported, and in the class, with support in $(B_R)^\ell$. There exist smooth compactly supported functions Φ_η, $\eta > 0$, with support in $(B_{R+1})^\ell$ and $\|\Phi_\eta - \Phi\|_\infty \to 0$. For example, we may convolve Φ with the product of ℓ copies of a nonnegative radial smooth approximate identity on $\mathbb{R}^9$ of total mass one, and use the uniform continuity of Φ. Radial convolution preserves the invariance under independent conjugations, as we see by changing each integration variable by the orthogonal map $\mathrm{Ad}(k_j)$. Each Φ_η is globally Lipschitz. The difference of the joint observables of Φ_η and Φ is nonzero only if the first output lies in a fixed enlarged compact window, which has probability $O_R(r_\gamma)$, both for the holonomies of the configuration under ν (by Step 2) and for the zero-fluctuation holonomies under $\widehat{\nu}$ (by Theorem 36.6). The corresponding expectations therefore differ by at most $C_R r_\gamma \|\Phi_\eta - \Phi\|_\infty$. For the Wilson measure, we add at most $2C_{n,a}\gamma^a\|\Phi_\eta - \Phi\|_\infty$, with any fixed $a > 1/4$, from Corollary 23.11. Further,

$$|m_\Delta(\Phi_\eta) - m_\Delta(\Phi)| \le m(\mathbf{1}_{B_{R+1}})\|\Phi_\eta - \Phi\|_\infty.$$

At fixed η we apply (36.40) and (36.38) to Φ_η and let $\gamma \downarrow 0$ uniformly in K; then we let $\eta \downarrow 0$. Since $c \le \kappa_{K,\gamma} \le C$, this proves $\sup_K |\delta^\Phi_{K,\gamma}| \to 0$, both for the Wilson measure and for the zero-fluctuation expectation. For continuous tests we do not obtain a rate.

Step 5: the continuum measure. At fixed small γ, the joint observable is a bounded continuous function on $(\mathrm{SU}(2)^3)^\ell$, since its support lies strictly inside the logarithmic charts. By the invariance under independent conjugations, it factors through the product of the ℓ maps $\mathfrak{p}$ of seven traces of Lemma 5.6: two points with the same vector of traces at every time differ by one conjugation at each time. The factored function f is continuous on the compact image C of this product map, since every convergent sequence of trace vectors has convergent subsequences of representatives, and all possible limits give the same value. On C, the functions $\inf_{u\in C}\{f(u) + k|v - u|\}$, truncated to the range of f, are bounded Lipschitz functions on the ambient Euclidean space that converge uniformly to f on C as $k \to \infty$. This follows from the uniform continuity of f, by considering separately the points u with $|v - u|$ small and large. Joint convergence in law of the traces therefore suffices for these observables. The seven words at each time are concatenations of the three based cycles at that time, and the whole finite vector of their traces is covered by Theorem 29.25, with the comparison side justified by Corollary 29.26. Letting $K \to \infty$ at fixed γ in the lower bound on the denominator and in the combination in which $\kappa_{K,\gamma}$ cancels proves the ratio limit for continuous tests and the rate for Lipschitz tests under

λ_γ. The expansions and $c \le \kappa_{K,\gamma} \le C$ imply that the numerator is comparable with r_γ when $m_\Delta(\Phi) > 0$ and $\Phi \ge 0$, and that it is $o(r_\gamma)$ when $m_\Delta(\Phi) = 0$. These bounds are uniform in K and pass to the limit. □

36.8 Holonomy paths on a time interval

We now observe the holonomies on a whole compact time interval $[\tau, T] \subset (0, \infty)$. The observable is the path of rescaled holonomy triples modulo simultaneous conjugation. After weighting with a compactly supported cutoff at the initial time, we show that this path converges to a constant path whose value has density proportional to the cutoff times e^{-Q}. The first ingredient is a version of Theorem 36.3 that is uniform in time.

Lemma 36.16. *Fix the data of Definition 36.1 and an interval $0 < \tau < T < \infty$ before varying γ, choosing the side n and the margins for the whole interval. There exist a central coordinate neighborhood $\mathcal{U}$ and a neighborhood of the identity in $\mathcal{V}$ such that*

$$Z_{K,t}(X, s) = \operatorname{Log} \mathcal{H}^K_{0,t}(V(X, s))$$

is defined on $\mathcal{U}$ for every K and $t \in [\tau, T]$, is continuous in t, and satisfies

$$\sup_{K,t} \|Z_{K,t}\|_{C^{1,1}(\mathcal{U})} \le C_{\tau,T}, \qquad \sup_t |Z_{K,t}(X, s) - X| \le C_{\tau,T}(|X|^2 + |s|),$$

$$\sup_t \|D_X Z_{K,t}(X, s) - I\| \le C_{\tau,T}(|X| + |s|).$$

For every flat coarse configuration, the flowed zero-fluctuation holonomy triple equals the holonomy triple of the coarse configuration, for every K and t. The neighborhoods and constants do not depend on K, γ, or the number of preceding averaging steps.

Proof. We work in the smooth chart $V(X, s)$ of the based quotient, not with a Borel selection of representatives; the parameters (X, s) have a fixed dimension at the side n. On a neighborhood of the trivial flat configuration, the zero-fluctuation reconstructions stay within the input and image bounds of the reconstruction maps of Theorem 15.12. Indeed, they vanish at zero input, and the uniform bounds on the coefficients together with the contraction condition $a_{\mathrm{map}}\sqrt{B} \le 32/49 < 1$ of Definition 36.1 give one smaller neighborhood, independent of the number of steps. More precisely, items (1) and (3) of Lemma 34.4 bound the linear and quadratic flow data $\mathcal{E}_K(u)$ of the zero-fluctuation reconstruction, in the weighted norms X^a_α and Y^a_α of Definition 4.8, by a constant R on a fixed complex domain of inputs. Here $a = L/(nB^K)$ is the finest mesh, and α is the fixed regularity exponent of Definition 34.1; the bound is uniform in K with this mesh. We compose with the analytic map $u = (X, s) \mapsto V(X, s)$ of finitely many variables and shrink the domain once. Let $U_0 \Subset U_1$ be real domains whose complex neighborhoods of

radius $\delta > 0$ lie in this domain. The Cauchy integral formula on one coordinate circle, or on two circles for mixed derivatives, gives

$$\sup_{K,\,u\in U_1}\sum_{j=0}^{2}\|D_u^j\mathcal{E}_K(u)\|_{\mathrm{fl}} \le C_{n,\delta}R\bigl(1+\delta^{-1}+\delta^{-2}\bigr),$$

where $\|\cdot\|_{\mathrm{fl}}$ is the flow-data norm at the finest mesh a, which we suppress from the notation. It is the sum of the two weighted norms, which include the first differences of both components. This bound is deterministic and does not depend on the coupling.

We apply Theorem 25.13 on $U_0 \subset U_1$, with waiting time $t_* = \tau$, horizon T, and damping gauge transformations started at the identity in the common gauge frame at the basepoint. Its hypotheses are the displayed bound on derivatives and the margins of the based charts. It yields bounds, uniform in K, on the first and second derivatives in the parameters of the flowed cycle holonomies, simultaneously for all $t \in [\tau, T]$, including the finitely many remaining meshes. Continuity in t follows from the smoothness of the flow on a finite lattice. At $u = 0$ every output is the identity. By the uniform bound on the first derivatives, the outputs on a smaller central neighborhood lie in one compact subset of the logarithmic chart, simultaneously for all K and t. Since Log has bounded first and second derivatives there, we obtain the bound in $C^{1,1}$.

By Lemma 14.9, the zero-fluctuation refinements of a flat configuration are flat and have the same based cycle holonomies, and the Wilson flow is stationary on flat configurations. The flowed holonomies therefore equal the coarse holonomies at every time, in the given gauge frame. For $s = 0$ and X in one of the nine coordinate directions, the configuration consists of commuting links, and the identity on flat configurations gives $Z_{K,t}(ue_a, 0) = ue_a$. Since these directions span $\mathbb{R}^9$, we have $Z_{K,t}(0,0) = 0$ and $D_X Z_{K,t}(0,0) = I$ for all K and t. Integrating the uniform Lipschitz bound on the derivative along $v \mapsto (vX, 0)$ gives the remainder $C|X|^2$ and the error $C|X|$ for the derivative. The bounded derivative in s and the Lipschitz bound on the first derivative add $C|s|$ to these two errors. All choices were made before the coupling and are uniform on the interval. □

Definition 36.17. Let

$$\mathfrak{C} = \mathfrak{su}(2)^3/\operatorname{Ad}\mathrm{SU}(2), \qquad \rho([Y],[Y']) = \min_{k\in\mathrm{SU}(2)}|Y - \operatorname{Ad}(k)Y'|,$$
$$\mathscr{P} = C([\tau,T];\mathfrak{C}), \qquad \rho_\infty(z,z') = \sup_{\tau\le t\le T}\rho(z(t),z'(t)).$$

Fix a smooth map $\eta : \mathrm{SU}(2)^3 \to \mathfrak{su}(2)^3$, equivariant under simultaneous conjugation, that agrees with the componentwise logarithm on a fixed smaller neighborhood of the

identity. For the triple $H(t)$ of cycle holonomies of a trajectory, defined up to simultaneous conjugation, set $Z_\gamma(t) = [\eta(H(t))/r_\gamma]$. For a radial cutoff χ let

$$D_\gamma = \mathbb{E}_{\lambda_\gamma} \mathcal{I}_{\gamma,\chi(|\cdot|)}(H(\tau)), \qquad \Pi_\gamma(F) = \frac{\mathbb{E}_{\lambda_\gamma}\big[\mathcal{I}_{\gamma,\chi(|\cdot|)}(H(\tau))F(Z_\gamma)\big]}{D_\gamma}.$$

For small γ, $D_\gamma > 0$ by Theorem 36.10, and Π_γ is a probability on $\mathscr{P}$. Define $\Pi_{K,\gamma}$ by the same formula under the Wilson measure $\mu_{nB^K,\gamma}$, with the flowed lattice holonomies and with its own denominator.

Only the conjugacy class of $H(t)$ is needed to define Z_γ; we never choose representatives depending on t.

Theorem 36.18. *Fix L, an interval $0 < \tau < T < \infty$, the parameters, a sufficiently large side n on the sequence, and the central margins for that interval, all before varying γ, and use Definition 36.17. Let $b_\chi = m(\chi(|\cdot|))$, and define the probability*

$$\Pi_0 = \big(Y \mapsto (t \mapsto [Y])\big)_{\#}\Big(\frac{\chi(|Y|)e^{-Q(Y)}\,d^9Y}{b_\chi}\Big)$$

on $\mathscr{P}$. There exist $C_{\tau,T,\chi,\eta}$ and $\gamma_{\tau,T,\chi,\eta} > 0$ such that, for every bounded function $F : \mathscr{P} \to \mathbb{R}$ that is globally Lipschitz for ρ_∞, and every $0 < \gamma \le \gamma_{\tau,T,\chi,\eta}$,

$$|\Pi_\gamma(F) - \Pi_0(F)| \le C_{\tau,T,\chi,\eta}\big(\|F\|_\infty + \operatorname{Lip} F\big)\gamma^{1/4}.$$

The same bound holds for $\Pi_{K,\gamma}$, uniformly in K, and every denominator is at least $c_\chi r_\gamma$. At each fixed small γ, $\Pi_{K,\gamma} \to \Pi_\gamma$ weakly as $K \to \infty$. In particular $\Pi_\gamma \to \Pi_0$ weakly on $(\mathscr{P}, \rho_\infty)$ as $\gamma \downarrow 0$, after the continuum limit, and the limit does not depend on the choice of η.

Proof. The core of the proof is Steps 2–3, which reduce the weighted path to the single-time test $\varphi_F(Y) = \chi(|Y|)F(c_{[Y]})$ defined below.

Step 1: quotients and paths. The minimum defining ρ is attained because $\mathrm{SU}(2)$ is compact, and it vanishes exactly when the two orbits coincide. The symmetry of ρ follows from the invariance of the Euclidean norm under the orthogonal maps $\mathrm{Ad}(k)$, and composing minimizers gives the triangle inequality. The quotient map is 1-Lipschitz. Since $\rho([Y],[0]) = |Y|$, closed bounded balls of $\mathfrak{C}$ are continuous images of compact Euclidean balls. They are therefore compact, and $\mathfrak{C}$ is complete. The classes of vectors with rational coordinates are dense, and $\mathfrak{C}$ is separable. Since uniform limits of continuous paths are continuous, $\mathscr{P}$ is complete. For separability, let $\varepsilon > 0$. Given a path, by uniform continuity there exist a rational subdivision of $[\tau, T]$ on whose intervals the path oscillates by at most ε, and balls of radius ε, centered in a fixed countable dense set, containing its values at the subdivision points. We consider the classes of paths determined by

a rational subdivision and a finite list of such balls, with oscillation at most ε on each interval. There are countably many classes, each of diameter at most 4ε, and we choose one path in each nonempty class. For $\varepsilon = 1/j$, $j \geq 1$, the chosen paths form a countable dense set, and $\mathscr{P}$ is Polish.

To see that a map η exists, we multiply the componentwise logarithm by a smooth cutoff, invariant under conjugation, supported strictly inside the logarithmic chart, and equal to one on a smaller neighborhood, and we extend the product by zero. The result is smooth and equivariant, and its global Lipschitz constant is finite by compactness of $\mathrm{SU}(2)^3$, for the maximum of the operator norms of the three components. By Lemma 5.6, the map $\mathfrak{p}$ of seven traces identifies the quotient of $\mathrm{SU}(2)^3$ by simultaneous conjugation homeomorphically with $C = \mathfrak{p}(\mathrm{SU}(2)^3)$. The map

$$f_\eta : C \to \mathfrak{C}, \qquad f_\eta(\mathfrak{p}(H)) = [\eta(H)],$$

is therefore well defined, by the equivariance of η, and continuous. Composing with this uniformly continuous map at each time carries a continuous path of traces to a continuous path in $\mathfrak{C}$, continuously for the uniform metrics, and scaling by $1/r_\gamma$ is continuous at fixed γ. This defines Z_γ under λ_γ.

Step 2: comparison with the zero-fluctuation path. We abbreviate $I(H) = \mathcal{I}_{\gamma,\chi(|\cdot|)}(H(\tau))$, and we write Z and Z^0 for the paths of the flowed holonomies of the configuration and of the zero-fluctuation reconstruction. Let $d = d_{K,[\tau,T]}$ be the quantity of Theorem 34.11, that is, the minimum of 1 and the supremum over $t \in [\tau, T]$ of $\max_i \|\mathcal{H}^K_{t,i} - \mathcal{H}^K_{0,t,i}(v)\|_{\mathrm{op}}$. Since η is globally Lipschitz and the quotient map is 1-Lipschitz,

$$\rho_\infty(Z, Z^0) \leq C_\eta \frac{d}{r_\gamma} \qquad \text{on } \{d \leq r_\gamma\},\ r_\gamma < 1.$$

On this event, if either $I(\mathcal{H}^K)$ or $I(\mathcal{H}^K_0)$ is nonzero, the zero-fluctuation holonomies at time τ lie in an enlarged window E_R as in Lemma 36.14, and

$$|I(\mathcal{H}^K) - I(\mathcal{H}^K_0)| \leq C_\chi \frac{d}{r_\gamma}.$$

These two assertions use the logarithm only at time τ, in its fixed compact subchart; at the other times we use η. Writing the difference of products as $(I(\mathcal{H}^K) - I(\mathcal{H}^K_0))F(Z) + I(\mathcal{H}^K_0)(F(Z) - F(Z^0))$, we find, on the same event,

$$|I(\mathcal{H}^K)F(Z) - I(\mathcal{H}^K_0)F(Z^0)| \leq C_{\chi,\eta}\big(\|F\|_\infty + \operatorname{Lip} F\big)\frac{d}{r_\gamma}\mathbf{1}_{E_R}.$$

Integrating with the disintegration of Lemma 15.10, we have $\mathbb{E}_\nu[d\mathbf{1}_{E_R}] \leq C r_\gamma^2 \widehat{\nu}(E_R) \leq C_R r_\gamma^3$, exactly as in the proof of Lemma 36.9. On $\{d > r_\gamma\}$ we use the bound $2\|\chi\|_\infty\|F\|_\infty$ and $\nu(d > r_\gamma) \leq C r_\gamma^2$. We conclude that

$$\Big|\mathbb{E}_\nu I(\mathcal{H}^K)F(Z) - \mathbb{E}_{\widehat{\nu}} I(\mathcal{H}^K_0)F(Z^0)\Big| \leq C_{\chi,\eta}\|F\|_{\mathrm{BL}} r_\gamma^2. \tag{36.41}$$

Step 3: the weighted zero-fluctuation path is nearly constant. We use Lemma 36.14 with $t_1 = \tau$, choosing its neighborhood $\mathcal{U}$ with closure in the domain of Lemma 36.16; the localization argument in the proof of that lemma allows any such fixed reduction. Outside $\mathcal{U}$ the contribution of the window at time τ is smaller than every power of r_γ, and so is the contribution of $\{|s| > r_\gamma\}$. On the remaining part of the weighted set, the lower bound on the output at time τ implies $|X| \le C_\chi r_\gamma$. By Lemma 36.16, for small γ every output lies in the region where $\eta = \mathrm{Log}$, and

$$\rho_\infty\big(Z^0, c_{[Z_{K,\tau}(X,s)/r_\gamma]}\big) \le \sup_{\tau \le t \le T} \frac{|Z_{K,t} - Z_{K,\tau}|}{r_\gamma} \le C_\chi\Big(r_\gamma + \frac{|s|}{r_\gamma}\Big),$$

where $c_{[Y]}$ denotes the constant path with value $[Y]$. The localized moments give $\widehat{\nu}(E_R) \le C_R r_\gamma$ and $\mathbb{E}_{\widehat{\nu}}[|s|\mathbf{1}_{E_R \cap \mathcal{U}}] \le C_R r_\gamma g$, with $g = r_\gamma^2/\sqrt{n}$. Since $I(\mathcal{H}_0^K)F(c_{[Z_{K,\tau}/r_\gamma]}) = \mathcal{I}_{\gamma,\varphi_F}(\mathcal{H}_{0,\tau}^K)$ on this set, we obtain

$$\Big|\mathbb{E}_{\widehat{\nu}} I(\mathcal{H}_0^K)F(Z^0) - \mathbb{E}_{\widehat{\nu}}\mathcal{I}_{\gamma,\varphi_F}(\mathcal{H}_{0,\tau}^K)\Big| \le C_\chi \|F\|_{\mathrm{BL}} r_\gamma^2, \tag{36.42}$$

where $\varphi_F(Y) = \chi(|Y|)F(c_{[Y]})$. This test is invariant under simultaneous conjugation, supported in the fixed ball containing the support of $\chi(|\cdot|)$, and globally Lipschitz, with

$$\|\varphi_F\|_\infty \le \|\chi\|_\infty \|F\|_\infty, \qquad \mathrm{Lip}\,\varphi_F \le \mathrm{Lip}(\chi(|\cdot|))\|F\|_\infty + \|\chi\|_\infty \mathrm{Lip}\,F,$$

since the quotient map and the map $[Y] \mapsto c_{[Y]}$ are 1-Lipschitz. We apply Theorem 36.6 to φ_F at time τ. Combining (36.41) and (36.42), and removing the conditioning with Corollary 23.11 at $q = 1$, we obtain

$$A_K(F) = \mathbb{E}_{\mu_{nB^K,\gamma}} I(\mathcal{H}^K)F(Z) = r_\gamma \kappa_{K,\gamma} m(\varphi_F) + O\big(\|F\|_{\mathrm{BL}} r_\gamma^2\big). \tag{36.43}$$

Here $A_K(F)$, notation local to this proof, is the numerator of $\Pi_{K,\gamma}(F)$. The same factor appears in $A_K(1)$, with leading coefficient $b_\chi > 0$, which implies $A_K(1) \ge c_\chi r_\gamma$. Since $m(\varphi_F) = b_\chi \Pi_0(F)$, subtracting $\Pi_0(F)A_K(1)$ from $A_K(F)$ cancels the leading terms. Dividing by $A_K(1)$ gives the bound for $\Pi_{K,\gamma} = A_K(\cdot)/A_K(1)$, uniformly in K.

Step 4: the continuum limit in the uniform topology. At fixed γ we apply Theorem 30.4 to the seven loops, concatenations of the three based coordinate cycles, that define $\mathfrak{p}$. Each loop has a single lattice approximation independent of time, of uniformly bounded length. The comparison side is covered by Corollary 29.26; at fixed coupling only finitely many terms of the sequence of sides are dropped. The paths of traces converge jointly in law in $C([\tau, T]; \mathbb{R}^7)$. All their values lie in the compact set C, and $C([\tau, T]; C)$ is a closed subset. Applying the continuous map of paths induced by f_η, followed by scaling, we obtain convergence in law of the lattice paths Z to Z_γ, jointly with the vector of traces at time τ. For small fixed γ, $I(H(\tau))$ is a continuous invariant function of the triple at time

τ, and by Lemma 5.6 it is a continuous function of its seven traces. For every bounded continuous F on $\mathscr{P}$, the product $I(H(\tau))F(Z_\gamma)$ is then a bounded continuous function on the space of trace paths with values in C. By the continuous mapping theorem on this closed subspace, which carries all the measures involved, $A_K(F)$ converges to the numerator of $\Pi_\gamma(F)$, and $A_K(1)$ converges to D_γ. Dividing by the positive limit of the denominators proves $\Pi_{K,\gamma} \to \Pi_\gamma$ weakly, and the bound of Step 3 passes to the limit.

Step 5: weak convergence. The bound for bounded Lipschitz functions implies weak convergence on $\mathscr{P}$. Indeed, for a closed set $A \subset \mathscr{P}$, the functions $f_j(z) = (1 - j\,\mathrm{dist}(z, A))_+$, $j \geq 1$, are bounded and Lipschitz, and $\Pi_\gamma(f_j) \to \Pi_0(f_j)$ for each fixed j. This implies $\limsup_{\gamma\downarrow 0} \Pi_\gamma(A) \leq \Pi_0(f_j)$, and letting $j \to \infty$, by monotone convergence, $\limsup_{\gamma\downarrow 0} \Pi_\gamma(A) \leq \Pi_0(A)$. By the portmanteau theorem, $\Pi_\gamma \to \Pi_0$ weakly. The same argument applies to any sequence of finite cutoffs with $\gamma \downarrow 0$, since the bound is uniform in K. The argument works for each such η and gives the same Π_0; the limit therefore does not depend on η. □

36.9 Dilation statistics of comparison measures

To show that the value zero in Theorem 36.7 reflects the structure of λ_γ near a central triple, we compute the dilation statistic for the comparison probabilities of Definition 4.13, observed at the same cycles and the same flow time. For $k \in \{1, 2, 3, 5\}$ we write P_k for the probability of item (k) of Definition 4.13. Here P_1 is the Abelian Maxwell measure with Haar cycle holonomies, P_2 the Gaussian holonomies with independent Haar factors, P_3 the Gaussian holonomies with Gaussian constant modes, and P_5 the mixture of normalized conditional normal Gaussian measures over the cone of commuting triples. For P_5 we use the observables $\mathcal{I}^{\mathrm{coord}}$ of Definition 36.1. The local mass scales differ. A compact window has probability of order r_γ^3 under P_1, r_γ^9 under P_2, and r_γ^5 under P_5, while under P_3 the rescaled logarithm tends to zero. For λ_γ the scale is r_γ.

Recall that $\mathcal{M} = \{(\vartheta_1 u, \vartheta_2 u, \vartheta_3 u) : \boldsymbol{\vartheta} \in \mathbb{R}^3,\ u \in S^2\}$ is the cone of commuting triples, that $\mathcal{N}_y = \{b : b_i \perp u,\ \sum_i \vartheta_i b_i = 0\}$ is the normal space at $y = (\vartheta_i u)_i \neq 0$, and that Σ_θ is the normal covariance of Theorem 33.11.

Theorem 36.19. *Let χ be a radial cutoff with $\chi(0) > 0$. Under each of P_1, P_2, P_3, with the hypotheses of Definition 4.13 and Lemma 35.17, the denominator of the dilation statistic is positive for all sufficiently small γ, and*

$$\lim_{\gamma\downarrow 0} \mathcal{S}_{\gamma,P_1}(\chi) = -6, \qquad \lim_{\gamma\downarrow 0} \mathcal{S}_{\gamma,P_2}(\chi) = 4\,\frac{\int_{\mathbb{R}^9} Q(Y)\chi(|Y|)\,dY}{\int_{\mathbb{R}^9} \chi(|Y|)\,dY} > 0, \qquad \lim_{\gamma\downarrow 0} \mathcal{S}_{\gamma,P_3}(\chi) = -9.$$

For P_3 the hypotheses are that the field is a centered Gaussian field with covariance γC for a fixed covariance C, smoothed by a fixed linear operator, and that the smoothed field divided by $\sqrt{\gamma}$ has

a centered separable realization with continuous paths, a measurable and almost surely bounded supremum, and finite supremum variance, as specified there.

For P_5, let the prior be a fixed probability $\alpha(y)\,d\mathrm{vol}_{\mathcal{M}}(y)$ on a small neighborhood of the tip of $\mathcal{M}$, with α continuous at the tip and $\alpha(0) > 0$. Conditionally on $y \neq 0$, let b be the normalized Gaussian $N(0, \gamma\Sigma(y))$ on $\mathcal{N}_y$, and put $X = y + b$. Assume that Σ is measurable and positive definite, with

$$c|y|^{-2}I \le \Sigma(y) \le C|y|^{-2}I, \qquad |y|^2\Sigma(y) \longrightarrow I_{\mathcal{N}_y} \quad (|y| \downarrow 0),$$

uniformly in the angular directions. The covariance $\Sigma = \Sigma_\theta$ has these properties; in fact $\Sigma_\theta(y) = |y|^{-2}I + O(1)$ uniformly for small $|y|$. Then, for every continuous compactly supported φ,

$$r_\gamma^{-5}\mathbb{E}_{P_5}\varphi(X/r_\gamma) \longrightarrow \alpha(0)\int \varphi(y+b)\,d\mu_{13}(y,b),$$

where

$$d\mu_{13}(y,b) = (2\pi)^{-2}|y|^4 e^{-|y|^2|b|^2/2}\,d\mathrm{vol}_{\mathcal{M}}(y)\,db.$$

The weighted normal-bundle measure μ_{13} is locally finite, and y and b are bounded on compact sets of outputs $y + b$ because $y \perp b$. The denominator of $\mathcal{S}_{\gamma,P_5}(\chi)$ is positive for all sufficiently small γ. Writing $\langle\cdot\rangle_{\chi,\mu_{13}}$ for the integral against μ_{13} divided by $\int \chi(|y+b|)\,d\mu_{13}$,

$$\lim_{\gamma\downarrow 0}\mathcal{S}_{\gamma,P_5}(\chi) = 4 + 2\Big\langle \sum_{i<j}|b_i \times b_j|^2\Big\rangle_{\chi,\mu_{13}} > 4.$$

The constants in these comparisons may depend on the fixed priors, the bounds on the covariances, the smoothing, and the test, but not on γ.

The factor $|y|^4$ in μ_{13} comes from the normalization of the four-dimensional conditional Gaussian. The weighted volume element $(2\pi)^{-2}|y|^4\,d\mathrm{vol}_{\mathcal{M}}(y)\,db$ is homogeneous of degree $13 = 5 + 4 + 4$ under dilations: five from the volume of the cone, four from the normal fibers, and four from the factor $|y|^4$. The remaining factor of μ_{13} is e^{-Q_2}, where $Q_2(y,b) = |y|^2|b|^2/2$ is homogeneous of degree four. The degree 13, compared with the degree 9 of Lebesgue measure on $\mathbb{R}^9$, produces the constant 4. Without the normalization of the conditional Gaussians, both the mixture and the value would change. The conclusions concern only these specified priors and covariances.

Proof. We write $\epsilon = r_\gamma$. Each numerator is the observable of the bounded compactly supported function W_χ.

The Abelian Maxwell measure with Haar cycle holonomies. We condition on the smoothed Abelian field and on the color direction $u \in S^2$ of the embedded subgroup. The circulations of the field translate the three independent uniformly distributed phases in $(\mathbb{R}/4\pi\mathbb{Z})^3$, and conditionally the cycle phases are still independent and uniformly

distributed. In a small neighborhood of the identity their logarithms have the form (x_1u, x_2u, x_3u), with density $(4\pi)^{-3}d^3x$. For radial tests, a further common conjugation does not change the integrals. The triple commutes, and $Q = 0$ on it. Once the compact support lies in the logarithmic chart, the denominator is exactly

$$(4\pi)^{-3}\epsilon^3 \int_{\mathbb{R}^3} \chi(|x|)\, dx > 0.$$

The divergence of $x\chi(|x|)$ on $\mathbb{R}^3$ has integral zero, which gives $\int |x|\chi'(|x|)\, dx = -3\int \chi(|x|)\, dx$. The dilation statistic therefore equals $-9 + 3 = -6$ for every sufficiently small γ.

Gaussian holonomies with independent Haar factors. By Lemma 35.17, the triple has the law of three independent Haar distributed matrices for every γ. We write $H = \cos(|x|/2)I + 2\sin(|x|/2)(x/|x|)^a\tau_a$. The Haar probability is the normalized volume of S^3, and its polar factor $\sin^2(|x|/2)\, d(|x|/2)/(2\pi^2)$ gives $dH(e^x) = (16\pi^2)^{-1}\operatorname{sinc}^2(|x|/2)\, d^3x$, as in (4.2). For every bounded test ψ supported in $\{|Y| \le R\}$, we obtain

$$\mathbb{E}_{P_2}\mathcal{I}_{\gamma,\psi} = \epsilon^9(16\pi^2)^{-3}\Big\{\int \psi(Y)\, dY + O_R\big(\|\psi\|_\infty \epsilon^2\big)\Big\}.$$

The denominator has a positive limiting coefficient. In $\mathbb{R}^9$ the divergence of $Y\chi(|Y|)$ has integral zero, that is, $\int (9\chi(|Y|) + |Y|\chi'(|Y|))\, dY = 0$. The limit of the statistic is therefore $4\int Q\chi / \int \chi$. To see that it is strictly positive, take a radius at which $\chi > 0$ and, at that radius, a triple with two nonzero orthogonal components. Then $Q > 0$ there, and a neighborhood of this point has positive measure, $\chi > 0$, and $Q > 0$.

Gaussian holonomies with Gaussian constant modes. At the observation time $t = \theta L^2$, let $G_i(x) = (\mathsf{S}_t a)_i(x)/\sqrt{\gamma}$ be the smoothed field divided by $\sqrt{\gamma}$, and consider the real process

$$Z_{x,i,v} = \langle v, G_i(x)\rangle, \qquad (x, i, v) \in \mathcal{T} = \mathbb{T}^3_L \times \{1, 2, 3\} \times S^2.$$

The index set $\mathcal{T}$ is nonempty, compact, and metrizable, and the process is centered Gaussian since the smoothing is fixed and linear. By the hypotheses of Definition 4.13 and Lemma 35.17, there exists a separable realization with almost surely continuous paths on $\mathcal{T}$, and $\sigma_*^2 = \sup_{x,i,v} \mathbb{E}Z^2_{x,i,v} < \infty$. These are the hypotheses of Lemma 35.16, which allows degenerate covariances; that lemma is the Borell–TIS inequality in the formulation of Adler and Taylor [3, Theorem 2.1.1]. It provides a measurable, almost surely finite, and integrable supremum

$$Z_* = \sup_{\mathcal{T}} Z_{x,i,v} = \max_i \sup_x |G_i(x)|, \qquad m_* = \mathbb{E}Z_* < \infty,$$

where the equality follows by taking the supremum over all unit vectors v. The law of G, and hence m_* and σ_*^2, do not depend on γ, since the field has covariance γC and the covariance and the smoothing are fixed. When $\sigma_*^2 > 0$, the same lemma implies that

$$\mathbb{P}\{Z_* - m_* \geq u\} \leq e^{-u^2/(2\sigma_*^2)} \qquad (u > 0). \tag{36.44}$$

The group distance of the transport along a path from the identity is at most the integral of the norm of its generator. This follows by partitioning the path, using the triangle inequality for the bi-invariant metric, and passing to the limit in the transport equation. Since each coordinate cycle has length L, we obtain

$$\Big(\sum_i \rho_G(H_i)^2\Big)^{1/2} \leq \sqrt{3}L\sqrt{\gamma}Z_*.$$

Since Z_* is almost surely finite and its law does not depend on γ, all three holonomies lie in the logarithmic chart with probability tending to one. There the rescaled logarithm has norm at most $\sqrt{3}L\epsilon Z_*$, which tends to zero in probability. Quantitatively, fix $\delta > 0$ and suppose that $\sigma_*^2 > 0$. For small γ we have $\sqrt{3}L\epsilon m_* \leq \delta/2$, and the ball of radius $\delta\epsilon$ about the identity, for the product of the group distances, lies in $\mathcal{V}$. By the transport bound and (36.44), we have

$$\begin{aligned}\mathbb{P}\big\{H \notin \mathcal{V} \text{ or } (H \in \mathcal{V},\ |\operatorname{Log} H|/\epsilon > \delta)\big\} &\leq \exp\Big\{-\frac{(\delta/(\sqrt{3}L\epsilon) - m_*)^2}{2\sigma_*^2}\Big\} \\ &\leq \exp\Big\{-\frac{\delta^2}{24L^2\sigma_*^2\sqrt{\gamma}}\Big\},\end{aligned} \tag{36.45}$$

with constants depending only on δ, L, the covariance, and the smoothing. If $\sigma_*^2 = 0$, Lemma 35.16 shows that the continuous process vanishes almost surely, and then $G = 0$ and $H = (I, I, I)$ almost surely. Since the two tests are bounded and continuous at zero, we obtain

$$\mathbb{E}_{P_3}\mathcal{I}_{\gamma,\chi(|\cdot|)} \longrightarrow \chi(0) > 0, \qquad \mathbb{E}_{P_3}\mathcal{I}_{\gamma,W_\chi} \longrightarrow W_\chi(0) = -9\chi(0);$$

to see this, we split each expectation according to whether the rescaled logarithm has norm at most δ, use continuity at zero on this event, and bound the expectation on its complement by twice the supremum of the test times its probability. This gives the value -9 without any statement about densities of the nonlinear cycle logarithms.

The mixture over the cone of commuting triples. Here P_5 is the law of the vector $X = y + b \in \mathbb{R}^9$, and the statistic uses $\mathcal{I}^{\mathrm{coord}}$. Fix $\zeta > 0$ with $\{|X| < \zeta\} \subset \operatorname{Log}\mathcal{V}$. For a bounded test ψ supported in $\{|Y| \leq R\}$ and $R\epsilon < \zeta$, we have the identity on all of $\mathbb{R}^9$

$$\mathcal{I}^{\mathrm{coord}}_{\gamma,\psi}(X) = \psi(X/\epsilon). \tag{36.46}$$

Indeed, if the right side is nonzero, then $|X| \le R\epsilon < \zeta$ and the indicator equals one; if it is zero, both sides vanish. This applies to $\psi = \chi(|\cdot|)$ and $\psi = W_\chi$ simultaneously, with one bound on the supports. The observables therefore agree with the expectations computed below, even though the conditional Gaussians have unbounded support.

We record the geometry and the normalization. Away from the tip, we write $y_i = \vartheta_i u$ and $s = |\boldsymbol{\vartheta}| = |y| > 0$; in this proof and in Remark 36.20, s denotes this radius, not a transverse coordinate. For variations of $\boldsymbol{\vartheta}$ and u, the induced metric is $|d\boldsymbol{\vartheta}|^2 + s^2|du|^2$, since $u \cdot du = 0$, and the parametrization is two-to-one under the simultaneous change of sign. The volume of the cone is therefore

$$d\mathrm{vol}_{\mathcal{M}}(y) = \tfrac{1}{2} s^4 \, ds \, d\omega \, du, \qquad \omega = \boldsymbol{\vartheta}/s \in S^2, \quad u \in S^2, \tag{36.47}$$

which is homogeneous of degree five and gives zero volume to the tip. The normal space $\mathcal{N}_y$ has dimension four, and $\langle y, b\rangle = \sum_i \vartheta_i \, u \cdot b_i = 0$, which gives

$$|y + b|^2 = |y|^2 + |b|^2. \tag{36.48}$$

The computation proving (36.14), applied with $a = \boldsymbol{\vartheta}/s$, gives

$$Q(y + b) = Q_2(y, b) + \frac{1}{2} \sum_{i<j} |b_i \times b_j|^2, \qquad Q_2(y, b) = \frac{1}{2} |y|^2 |b|^2. \tag{36.49}$$

These are identities on the normal bundle; they do not require uniqueness of the decomposition $X = y + b$.

The conditional density in the fiber $\mathcal{N}_{y_0}$ is

$$(2\pi\gamma)^{-2} \det \Sigma(y_0)^{-1/2} \exp\{ -b_0^{\mathsf{T}} \Sigma(y_0)^{-1} b_0 / (2\gamma) \} \, db_0.$$

We set $y_0 = \epsilon y$, $b_0 = \epsilon b$, and $C_\epsilon(y) = \epsilon^2 \Sigma(\epsilon y)$, using that the normal spaces are constant along rays. Then $d\mathrm{vol}(y_0) = \epsilon^5 \, d\mathrm{vol}(y)$ and $db_0 = \epsilon^4 db$, and since $\gamma = \epsilon^4$ we obtain the exact formula

$$\epsilon^{-5} \mathbb{E}_{P_5} \varphi(X/\epsilon) = \int \varphi(y + b) \, \alpha(\epsilon y) (2\pi)^{-2} \det C_\epsilon(y)^{-1/2} e^{-b^{\mathsf{T}} C_\epsilon(y)^{-1} b/2} \, d\mathrm{vol}_{\mathcal{M}}(y) \, db, \tag{36.50}$$

where the prior is set to zero outside its neighborhood; on a compact set of outputs, this neighborhood eventually contains every ϵy that occurs. By the assumptions on the covariance, we have, uniformly in the angular directions and for $y \neq 0$,

$$C_\epsilon(y) \longrightarrow |y|^{-2} I, \qquad c|y|^{-2} I \le C_\epsilon(y) \le C|y|^{-2} I.$$

Hence the Gaussian density in (36.50) tends to $|y|^4 e^{-Q_2(y,b)}$ and is bounded by $C|y|^4$. If φ is supported in the ball of radius R, then (36.48) bounds both $|y|$ and $|b|$ by R. The continuity of α at the tip bounds $\alpha(\epsilon y)$ there and gives the limit $\alpha(0)$. The dominating

integral is finite, since by (36.47) its radial factor near zero is $s^8\,ds$, and each fiber is restricted to a bounded ball in four dimensions. In finitely many angular trivializations of the normal bundle, or with the intrinsic Gaussian density on each fiber, the dominated convergence theorem applies. Then (36.50) gives the claimed limit with the normalization $(2\pi)^{-2}$ of μ_{13}.

For $\Sigma = \Sigma_\theta$, the explicit formula (4.12) gives $\Sigma_\theta(y) = |y|^{-2}I + O_\theta(1)$ uniformly in the angular directions: the term $m = 0$ of each d_i equals $e^{-2\theta|\boldsymbol{\vartheta}|^2}|\boldsymbol{\vartheta}|^{-2}$, since $R_i(0,\boldsymbol{\vartheta}) = 1$, and the sum of the terms with $m \neq 0$ is bounded for small $|\boldsymbol{\vartheta}|$, since then $\lambda_m \geq c|m|^2$ and $|R_i| \leq 1$. After a fixed reduction of the neighborhood carrying the prior, this implies both bounds on the covariance and the relative limit, and Theorem 33.11 shows that Σ_θ is positive definite and measurable there.

By the same domination and (36.48), μ_{13} is locally finite as a measure of the output $y + b$. Its integral against $\chi(|y+b|)$ is finite and strictly positive, for instance by considering an open set of the bundle with $|y| > 0$ and output radius in an interval on which $\chi > 0$. By (36.46), the denominator of the statistic satisfies

$$\mathbb{E}_{P_5}\mathcal{I}^{\mathrm{coord}}_{\gamma,\chi(|\cdot|)}(X) \sim \epsilon^5\alpha(0)\int \chi(|y+b|)\,d\mu_{13} > 0.$$

Under the dilation $(y,b) \mapsto (\lambda y, \lambda b)$, the measure $d\mathrm{vol}_{\mathcal{M}}\,db$ is homogeneous of degree $5+4=9$, the factor $|y|^4$ of degree four, and Q_2 of degree four. Changing variables in the compactly supported integral of $\chi(\lambda|y+b|)$ and differentiating at $\lambda = 1$, we obtain

$$\int \big\{(4Q_2 - 13)\chi(\rho) - \rho\chi'(\rho)\big\}\,d\mu_{13} = 0, \qquad \rho = |y+b|. \tag{36.51}$$

The differentiation is justified on a common compact set of outputs by (36.48), with the integrable radial bound $Cs^8\,ds$. This change of variables includes the tip of the cone and needs no boundary term there. We apply the limit of the rescaled expectations to W_χ and $\chi(|\cdot|)$, using (36.46), and divide by the positive limit of the denominators. Combining (36.49) and (36.51), we find

$$\lim_{\gamma\downarrow 0}\mathcal{S}_{\gamma,P_5}(\chi) = 4 + 2\,\frac{\int \sum_{i<j}|b_i \times b_j|^2\chi(\rho)\,d\mu_{13}}{\int \chi(\rho)\,d\mu_{13}}.$$

The second term is strictly positive. To see this, take $\boldsymbol{\vartheta}$ in the third coordinate direction, a fixed color direction u, linearly independent $b_1, b_2 \in u^\perp$, and $b_3 = 0$. Then $b \in \mathcal{N}_y$ and $b_1 \times b_2 \neq 0$. Scaling y and b together, we place the output radius in an interval on which $\chi > 0$. A neighborhood of this point in the bundle has positive measure, and on it $\chi > 0$ and the polynomial $\sum_{i<j}|b_i \times b_j|^2$ is positive. This proves the strict inequality. □

Remark 36.20. With the normalization of μ_{13} in Theorem 36.19,

$$\mu_{13}\{|y+b| \leq \rho\} = \frac{8\pi^2}{1287}\rho^{13}\big[1 + O(\rho^4)\big] \qquad (\rho \downarrow 0).$$

Indeed, on the ball $\{|y+b| \le \rho\}$ we have $0 \le Q_2 \le \rho^4/8$ by (36.48), and $e^{-Q_2} = 1 + O(\rho^4)$ uniformly there. The angular integral in (36.47) is $(4\pi)^2/2 = 8\pi^2$, and the ball of radius $(\rho^2 - s^2)^{1/2}$ in the four-dimensional fiber has volume $(\pi^2/2)(\rho^2 - s^2)^2$. Hence

$$\begin{aligned}\mu_{13}\{|y+b| \le \rho\} &= \pi^2 \int_0^\rho s^8 (\rho^2 - s^2)^2 \, ds \, \big[1 + O(\rho^4)\big] \\ &= \pi^2 \rho^{13} \Big(\frac{1}{9} - \frac{2}{11} + \frac{1}{13}\Big) \big[1 + O(\rho^4)\big] = \frac{8\pi^2}{1287} \rho^{13} \big[1 + O(\rho^4)\big].\end{aligned}$$

This formula is not used elsewhere.

36.10 The main result on central holonomies

We conclude by deducing Theorem 2.11 from the results of this section.

Proof of Theorem 2.11. Fix $L > 0$, an odd integer $M \ge 3$, an integer n divisible by four, and $\theta > 0$. By Theorem 2.3 (part 5), proved in Theorem 29.28, the measure $\lambda_\gamma = \lambda_{L,\gamma,[n]_M}$ depends only on L, γ, and the class $[n]_M$. We choose J and the remaining parameters as in Corollary 29.26 and Definition 34.1, so that $a_{\mathrm{map}}\sqrt{B} \le 32/49$, and take $n_* = n$ and a comparison side nB^a satisfying the lower bounds of Definition 36.1. Then λ_γ is the continuum measure of the sequence $(nB^K)_{K \ge 0}$, and the results of this section apply with this comparison side in place of n; all choices depend only on L, M, n, and θ. The observable $\mathcal{I}_{\gamma,\varphi}$ of Theorem 2.11 is the observable of Definition 36.1, with the extension by zero outside the fixed neighborhood $\mathcal{V}$ of the identity. With $\rho = |X|/r_\gamma$, the statistic of part (3) of Theorem 2.11 is the dilation statistic $\mathcal{S}_{\gamma,\lambda_\gamma}(\chi)$.

Part (1) of Theorem 2.11 is the ratio limit and the two-sided bound of Theorem 36.7. Parts (2) and (3) are the rates of Theorem 36.10, for invariant Lipschitz tests supported in the ball of radius R and for the dilation statistic. Part (4) follows from Theorem 36.12, with $\mathcal{V}$ chosen invariant under simultaneous conjugation: at each fixed γ the expectations near the eight central triples are equal, and hence parts (1)–(3) hold near each of them with the same constants. In all these results, the continuum limit is taken first, at fixed γ, and then $\gamma \to 0$. The constants depend on L, M, n, θ, and the test functions, but not on γ. The further statements after Theorem 2.11 are Theorems 36.15, 36.18, and 36.19. □
